$$\|g\|^2 := \int_0^\infty \frac{1}{f^2(r)}\Big(|g_1(r)|^2 + |g_2(r)|^2\Big)dr. \tag{8}$$

Recall that we want to consider $f^2(r)$ having singularity at zero that is milder than the RWN spacetime has. For this purpose, we make the following assumptions on $m(r)$:

- $m(r)$ is continuous for $r > 0$;
- $m(r)/r < 1/2G$;
- $m(r) \sim -C_\alpha r^{-\alpha}$ as $r \searrow 0$, where $\alpha \geq 0$ and $C_\alpha > 0$;
- $m(r) \to M > 0$ as $r \to \infty$.

Our first two assumptions on $m(r)$ are equivalent to ruling out black holes in spacetimes with the line element (4). So our spacetimes feature a charged naked singularity. By the third and fourth assumptions on $m(r)$, the naked singularity has a negative *bare mass* ($\lim_{r\downarrow 0} m(r)$), which is finite only for $\alpha = 0$, in which case $m(0) = -C_0$.

The function $\phi(r)$ is the potential of the electrostatic field generated by the nucleus, and we have $\mathcal{E}(r) = \frac{1}{2}\int_r^\infty |\phi'(s)|^2 s^2 ds$. We also assume

- $\phi(r)$ is continuously differentiable;
- $\phi(r) \sim Ze/r$ as $r \to \infty$;
- $\phi(r) \sim C''_\beta + C'_\beta r^{-\beta}$ as $r \searrow 0$, with $\beta \leq 1$.

Before we give the main theorem, we need to define the unitary operator U. Let $r(x)$ be the solution to the differential equation

$$\frac{d}{dx}r(x) = f^2(r(x)) \tag{9}$$

subject to the conditions that $r(x) \to 0^+$ as $x \to 0^+$. We now define U as

$$(Ug_i)(x) = g_i(r(x))f(r(x))^{1/2} \tag{10}$$

for (g_1, g_2) in the subspace induced by the norm (8). Let also $\widetilde{H}_k = UH_kU^{-1}$. Then, we have the following theorem. Interested readers can find the details of the proof in [3].

Theorem 2.1. *Under the stated assumptions on $m(r)$ and $\phi(r)$ the operator $\widetilde{H}_k$, and, therefore H_k, for $k \in \mathbb{Z}\backslash\{0\}$, has uncountably many self-adjoint extensions. The extensions are given by $\widetilde{H}_{k:\theta} = \widetilde{H}_k|_{D_\theta}$ where*

$$D_\theta = \Big\{(f_1, f_2) \in D(\widetilde{H}_k^*); \quad f_1(0) = -f_2(0)\tan\theta, \ -\frac{\pi}{2} \leq \theta \leq \frac{\pi}{2}\Big\}.$$

Moreover, for each θ

(a) The essential spectrum $\sigma_{ess}(\widetilde{H}_{k:\theta}) = (-\infty, -m] \cup [m, \infty)$;
(b) $\widetilde{H}_{k:\theta}$ has purely absolutely continuous spectrum in $(-\infty, -m) \cup (m, \infty)$;
(c) the singular continuous spectrum $\sigma_{sc}(\widetilde{H}_{k:\theta}) = \emptyset$.

Note that this theorem concludes that a milder singularity with strictly negative bare mass than that of RWN does not yield an essentially self-adjoint H_k. On the contrary, it appears that the self-adjointness might require a stronger singularity such as when $\beta > \frac{\alpha+3}{2}$. However, these values of α and β do not match with the asymptotics of the mass functions for the electrostatic spacetimes in (4).

It turns out that there is a way to restore the essential self-adjointness of the Dirac operator, namely by including a sufficiently large anomalous magnetic moment of the electron. This has been carried out in the naked RWN geometry in [1].

Assuming a nonzero anomalous magnetic moment, the radial partial-wave Dirac operator is given by

$$H_{\mu_a,k} := H_k + \begin{bmatrix} 0 & -\mu_a\phi'(r)f(r) \\ -\mu_a\phi'(r)f(r) & 0 \end{bmatrix}. \tag{11}$$

Regarding $H_{\mu_a,k}$, we have the following theorem:

Theorem 2.2. *Let $m(r)$ be as in the Theorem 3.1 with $\alpha \geq 0$ and $\phi(r) = C''_\beta + C'_\beta r^{-\beta} + O_1(r^{\frac{3}{2}-\beta})$ for $\beta \leq 1$, where $f \in O_k(g)$ indicates $\frac{d^j}{dr^j}f = O(\frac{d^j}{dr^j}g)$ for $j = 0, 1, ..k$. Then the operator $H_{\mu_a,k}$ is essentially self-adjoint if either $\beta > \frac{1+\alpha}{2}$, or $\beta = \frac{1+\alpha}{2}$ and $|\mu_a| \geq \frac{2+\alpha}{1+\alpha}\sqrt{2GC_\alpha}/|C'_\beta|$. On the other hand, if $\beta < \frac{1+\alpha}{2}$, then $H_{\mu_a,k}$ has multiple self-adjoint extension.*

An important consequence of this theorem is the fact that the Dirac operator in the Hoffmann spacetime is not self-adjoint unless $m(0) = 0$; in the negative bare mass case the anomalous magnetic moment cannot restore essential self-adjointness. Recall, the electric potential in the Hoffmann spacetime is given as

$$\phi(r) = Q\int_r^\infty \zeta'\Big(\frac{Q^2}{2s^4}\Big)\frac{ds}{s^2}, \ \ \zeta(\mu) = \sqrt{1+2\mu} - 1.$$

3. Point nucleus as singularity in static interior of black hole spacetime

Recall that in the RWN spacetime, the line element $f^2(r)$ in (4) arises as

$$f^2(r) = 1 - 2\frac{GM}{r} + \frac{GQ^2}{r^2} = \frac{1}{r^2}(r - r_-)(r - r_+) \tag{12}$$

where r_- and r_+ are given as in (6). We consider the operators H_k given in (7) when $0 \leq r \leq r_-$. Note that, in the extremal case, we have $r_- = r_+ = r_0$.

As in the previous section, we define $\widetilde{H}_k = UH_kU^{-1}$, where U is defined as in (10). We use (12) in the change of variable (9), with $x = 0$ when $r = 0$, which for the subextremal sector yields

$$x = r + \frac{r_+^2}{r_+ - r_-} \ln\left(1 - \frac{r}{r_+}\right) - \frac{r_-^2}{r_+ - r_-} \ln\left(1 - \frac{r}{r_-}\right); \qquad r < r_-; \tag{13}$$

in the extremal limit $r_- \nearrow r_0$ & $r_+ \searrow r_0$ this becomes

$$x = r_0 \left[\frac{1}{1 - \frac{r}{r_0}} + 2\ln\left(1 - \frac{r}{r_0}\right) - \left(1 - \frac{r}{r_0}\right)\right], \qquad r < r_0. \tag{14}$$

It is clear from (13) and (14), one has $r - r_- \sim e^{-ax}$ as $x \to \infty$ in the subextremal case, whereas $r - r_0 \sim x^{-1}$ as $x \to \infty$ in the extremal case. This difference between the asymptotics result in differences in the spectrum of the corresponding Dirac operators, see [4] for more details. We have,

Theorem 3.1. *The operator $\widetilde{H}_k$ has uncountably many self-adjoint extensions for both the subextremal and the extremal black hole sector. The extensions are given by $\widetilde{H}_{k:\theta} = \widetilde{H}_k|_{D_\theta}$ where*

$$D_\theta = \left\{(f_1, f_2) \in D(\widetilde{H}_k^*); \quad f_1(0) = -f_2(0)\tan\theta, \ -\frac{\pi}{2} \leq \theta \leq \frac{\pi}{2}\right\}.$$

Moreover for each θ,

- *(a) The essential spectrum $\sigma_{ess}(\widetilde{H}_{k:\theta}) = \mathbb{R}$ in both subextremal and the extremal case.*
- *(b) $\widetilde{H}_{k:\theta}$ has absolutely continuous spectrum in $\mathbb{R}$ in both subextremal and the extremal case. Moreover, $\widetilde{H}_{k:\theta}$ has no eigenvalue in the subextremal case.*
- *(c) The singular continuous spectrum $\sigma_{sc}(\widetilde{H}_{k:\theta}) = \emptyset$ in both subextremal and the extremal case.*

In the extremal case the only possible eigenvalue is $-\frac{Q}{r_0}$, and whether it is an eigenvalue or not is not determined in this study. However, we believe that the answer should depend on the values of Q and r_0.

Similar to our previous section, we also considered the effect of an anomalous magnetic moment. Consider (11) with $\phi(r) = Q/r$. We have

Theorem 3.2. *In both the subextremal and the extremal case, the operator $H_{\mu_a,k}$ is essentially self-adjoint iff $|\mu_a| \geq \frac{3}{2}\sqrt{G}$. Moreover, in both subextremal and extremal cases, the self-adjoint operators have $\sigma_{ess}(H_{\mu_a,k}) = \sigma_{ac}(H_{\mu_a,k}) = \mathbb{R}$, $\sigma_{sc}(H_{\mu_a,k}) = \emptyset$, and $\sigma_p(H_{\mu_a,k}) = \emptyset$.*

Relic magnetic wormholes as possible source of toroidal magnetic fields in galaxies

A. A. Kirillov* and E. P. Savelova

Department of Mathematical Modeling, Bauman Moscow State Technical University, Moscow, 105005, Russian Federation

**E-mail: kirillov@bmstu.ru*

We present the hypothesis that some of ring galaxies were formed by relic magnetic torus - shaped wormholes. In the primordial plasma before the recombination magnetic fields of wormholes trap baryons whose energy is smaller than a threshold energy. They work as the Maxwell's demons collecting baryons from the nearest (horizon size) region and thus forming clumps of baryonic matter which have the same torus-like shapes as wormhole throats. Such clumps may serve as seeds for the formation of ring galaxies and smaller objects having the ring form. Upon the recombination torus-like clumps may decay and merge. Unlike galaxies, such objects may contain less or even no dark matter in halos. However, the most stringent feature of such objects is the presence of a large - scale toroidal magnetic field. We show that there are threshold values of magnetic fields which give the upper and lower boundary values for the baryon clumps in such protogalaxies.

Keywords: Wormholes; cosmic rays; ring galaxies; galactic magnetic fields.

1. Introduction

One of challenges of modern astrophysics is to finding possible traces of relic wormholes. It is expected that relic cosmological wormholes were created from virtual wormholes on quantum stage, or during the inflationary period of evolution of the Universe. Virtual wormholes exist at Planckian scales and they represent the most natural objects to compose spacetime foam picture.[1,2] Their existence is straightforwardly predicted by lattice quantum gravity models, e.g., see Refs.[3–6] and references therein.

Spherically symmetric relic wormholes are highly instable and collapse very rapidly. To be stable they require the presence of exotic matter at throats or an essential modification of general relativity.[7,8] This means that all primordial spherical wormholes have collapsed long ago and at present they cannot probably be distinguished from black holes. However less symmetric configurations can be made stable without exotic matter or any modification of GR. First rigorous example was presented in Ref.[9] It was demonstrated that in the open Friedmann model a stable wormhole can be obtained simply by the factorization of space over a discrete subgroup of the group of motions of space. To illustrate such a factorization one may consider flat plane in which one of coordinates, say x, becomes periodic $x = R\varphi/(2\pi)$ with the angle $0 < \varphi < 2\pi$. Then the space becomes a cylinder with

the radius R. In the open model (on space of a constant negative curvature) any parallel geodesics ($\varphi = 0$ and $\varphi = 2\pi$) diverge and the distance between them changes $R(\ell)$, where ℓ is a parameter along the geodesic line. Therefore, if we move along the geodesic line from the point where the distance is the shortest R_{min}, the space opens out $R \to \infty$ and becomes unrestricted.[10] Here the wormhole configuration coincides with a cylinder on which the metric is specified to produce a constant negative curvature. The simplest 3D wormhole obtained by the factorization has also the topology of a cylinder, while its throat has the topology of the 2D- torus.[9,10] In flat space such a configuration corresponds to a wormhole whose throat has the shape of a doughnut. Such wormholes are not static but expand in agreement with the expansion rate of the Universe. It can be considered as having been frozen into space and, therefore, they are static in the co-moving coordinates. It is important that the factorization allows to get an arbitrary number of such wormholes in space.

In flat space the torus - like wormholes become dynamical objects and evolve.[9] Whether they are static, expand, or collapse, depends on surrounding matter and peculiar motions of throats. The shape of throats of such wormholes resembles a doughnut and is characterized by two radii R_w and r_w. In the limit $R_w \gg r_w$ it can be approximately described by the cylindrical (axial) configuration. It turns out that static and stationary cylindrical wormhole solutions do exist and it was found that asymptotically flat wormhole configurations do not require exotic matter violating the weak energy condition.[11,12] This shows that such objects, as doughnut - shaped wormholes, have all chances to be observed in astrophysical systems. We point out that the investigation of the evolution of doughnut-shaped wormholes in flat space is a rather complex problem.

The possibility to directly observe wormholes attracts the more increasing attention, e.g., see Refs.[13–15] At first glance the most promising are collective effects produced by a distribution of wormholes in space. However, our previous investigation have shown that observational effects of a distribution of wormholes are very well hidden under analogous effects produced by ordinary matter e.g., see Refs.[16,17] The only exclusion may be the noise (stochastic background) produced by the scattering of emitted by binaries gravitational waves on wormholes.[18]

In general a single wormhole produces much less noticeable effects (lensing, cosmic ray scattering, etc.). However, wormholes may possess non-trivial magnetic fields as vacuum solutions. In this case possible imprints of wormholes in the present picture of the Universe may be rather considerable. In particular, when such a magnetic wormhole gets close to a galaxy, it starts to work as an accelerator of charged particles[10,19] which is capable of explaining the origin of high-energy cosmic-ray particles.[20] The idea that the observed cosmic rays require magnetic fields for their creation was first suggested by Fermi.[21] In voids a relic magnetic wormhole works simply as a generator of synchrotron radiation and can be detected via the magnetic field.[22,23] The primordial magnetic fields[24] in turn may form small-scale non-linear clumps of baryonic matter[25,26] and as it was recently discussed in Ref.[27] they may

allow to solve the existing Hubble tension. In other words, magnetic wormholes should leave a clear imprint on the sky. In particular, relic magnetic wormholes may play also the key role in formation of ring type baryonic structures, analogous to the ring galaxies without involving dark matter.[28] Moreover, such wormholes may also form ring - type structures even in the present epoch which may explain the origin of the recently found unexpected class of astronomical ring-type objects.[29]

2. Vacuum magnetic fields of wormholes

Nontrivial topology of space which contains a static wormhole allows us to get additional nontrivial solutions of static vacuum Maxwell equations.[30] This means that already in the absence of real sources (charged particles, electric currents) space may possess nontrivial quasi-static magnetic and electric fields. The physical mechanism is rather clear, during the quantum period of the Universe when the wormhole forms, it may capture some portion of closed magnetic or electric lines. Such lines cannot simply leave the wormhole. Electric fields perform work and decay very rapidly in the primordial plasma. Magnetic fields do not perform work and may survive till the present days. For exact solutions which involve magnetic fields and wormholes see e.g.,[31,32]

In this section for the sake of simplicity we assume that sufficiently far from the wormhole entrances the space is flat. Generalization to the curved spacetime and consideration of magnetic fields in the Friedmann model can be found, e.g., in.[33] Consider first the simplest genus $n = 0$ wormhole. Then the space-time metric can be taken as

$$dl^2 = c^2dt^2 - h^2(r)\left(dx^2 + dy^2 + dz^2\right). \tag{1}$$

We shall use the Ellis–Bronnikov massless wormhole[34,35] when the scale function is simply $h = 1 + \frac{R^2}{r^2}$. This model of a wormhole possesses two asymptotic Euclidean spaces E_+ as $r \gg R$ and E_- as $r \ll R$. In the region $r \ll R$ the transformation $\widetilde{r} = R^2/r$ reduces the above metric to the standard Euclidean form. The Maxwell equations for magnetic field take the standard form

$$rot\mathbf{B} = div\mathbf{B} = 0, \tag{2}$$

where $B_i = \varepsilon_{ijk}F^{jk}$. These equations possess a nontrivial solution in the form

$$\mathbf{B} = -\frac{Q}{r^2h}\mathbf{n} \tag{3}$$

with an arbitrary constant value Q, where $\mathbf{n} = \mathbf{r}/r$ is the unit vector. Indeed, vacuum magnetic field can be expressed via the magnetic scalar potential $\mathbf{B} = -\nabla\phi$ which obeys the equation

$$\Delta\phi = 0. \tag{4}$$

In the spherically symmetric case this equation reduces to

$$\frac{1}{r^2h^3}\partial_r r^2 h \partial_r \phi = 0 \tag{5}$$

and has the solution as

$$\phi = \int_0^r \frac{Q}{r^2 h} dr + \phi_0. \tag{6}$$

This defines the magnetic field

$$\mathbf{B} = -\nabla\phi = -\frac{Q}{r^2 h}\nabla r = -\frac{Q}{r^2 h}\mathbf{n}. \tag{7}$$

This solution works for any spherically symmetric wormhole with an arbitrary scale function $h(r)$ in (1).

In the region E_+ ($r \gg R$) it describes the field of the magnetic charge Q homogeneously distributed over the sphere $r = R$ (Coulomb law). In the region E_- ($r \ll R$) the transformation $\widetilde{r} = R^2/r$ interchanges the inner and outer regions of the sphere $r = R$ and we get the same field with the magnetic charge $-Q$.

In the case when both entrances are in the same space this transforms to the dipole field. Let the positions of the two spheres are $\mathbf{x}_+$ and $\mathbf{x}_-$ then the field can be taken as ($h_\pm = h(r_\pm) \sim 1$ as $r_\pm = |\mathbf{x} - \mathbf{x}_\pm| \gg R$)

$$\mathbf{B}(\mathbf{x}) = \frac{Q\,(\mathbf{x} - \mathbf{x}_+)}{h_+\,|\mathbf{x} - \mathbf{x}_+|^3} - \frac{Q\,(\mathbf{x} - \mathbf{x}_-)}{h_-\,|\mathbf{x} - \mathbf{x}_-|^3}. \tag{8}$$

Consider now the genus $n = 1$ wormhole. In the flat space such a wormhole can be constructed by means of cutting two solid tori and gluing along their surfaces. In this case we have two different new kinds of solutions. First is obtained by placing an arbitrary magnetic charge density $\rho(x)$ in the internal region of one torus and the opposite density $-\rho(x)$ in the internal region of the second torus. Then we solve the system

$$rot\mathbf{B} = 0, \quad div\mathbf{B} = 4\pi\rho. \tag{9}$$

Recall that internal regions of tori correspond to fictitious points, while $\rho(x) = 0$ as x lies outside the tori. Therefore, such a system coincides exactly with (2). In this case the exact form of the magnetic field is rather complicated. However averaging over orientations of the tori we restore the spherical symmetry of the wormhole and get exactly the same solution as (8). In this sense for the sake of simplicity we may always restrict to the spherically symmetric wormholes (i.e., consider $n = 0$ wormhole as the first order approximation).

Solutions of the second kind can be obtained by placing an arbitrary current density $\mathbf{j}(x)$ within the surface of torus/throat and solving the system

$$rot\mathbf{B} = \frac{4\pi}{c}\mathbf{j}, \quad div\mathbf{B} = 0. \tag{10}$$

Again here the non-vanishing current density corresponds only to fictitious points, while in physical regions of space such a system represents the same system (2).

The system (10) corresponds to the field generated by an electric loop which produces the toroidal magnetic field. Such solutions cannot be reduced to the spherically symmetric case, since upon the averaging over orientations of the loop the field vanishes.

In conclusion of this section we point out that the new two classes of vacuum solutions reflect the topological non-triviality of space. Indeed, according to the Stocks theorem the system (2) implies $\oint \mathbf{Bdl} = 0$ for any loop which can be pulled to a point. In the case of a non-trivial topology of space there appear new classes of loops Γ_a which cannot be contracted to a point and, therefore, to fix the unique solution we have to fix additional boundary data $\oint_{\Gamma_a} \mathbf{Bdl} = C_a$. In general $C_a \neq 0$. In the case of genus $n = 0$ wormhole there is only one such a non-trivial loop which goes through the wormhole throat. In the case of genus $n = 1$ wormhole we have already two such loops, one goes through the throat (it corresponds to the system (9)) and one additional crosses the torus (the system (10)).

3. Wormhole as an accelerator

In galaxies charged particles undergo an acceleration when interacting with galactic radiation. For definiteness we shall speak of electrons. Indeed, by means of the Compton scattering photons transmit part of their momentum to electrons. Upon the scattering the momentum obtained by the electron from the incident photon is

$$\mathbf{\Delta p} = \mathbf{p}' - \mathbf{p} = \frac{h\nu}{c}\left(\mathbf{n} - \frac{\nu'}{\nu}\mathbf{n}'\right) \tag{11}$$

where $\mathbf{n}$ and $\mathbf{n}'$ are the direction of the photon before and after scattering and

$$\frac{\nu'}{\nu} = \frac{\left(1 - \frac{c}{E}\mathbf{pn}\right)}{\left(1 + \frac{h\nu}{E}\left(1 - \mathbf{nn}'\right) - \frac{c}{E}\mathbf{pn}'\right)}. \tag{12}$$

Upon averaging over possible orientations of $\mathbf{n}'$ we get for the average momentum transmitted from the incident photon

$$\mathbf{\Delta p} = \frac{1}{c}\beta_\nu(\mathbf{p}) h\nu \mathbf{n}. \tag{13}$$

Here the spectral coefficient $\beta_\nu(\mathbf{p}) = 1 - \left\langle \frac{\nu'}{\nu}\mathbf{nn}' \right\rangle$ is given by

$$\beta_\nu(\mathbf{p}) = 1 - \frac{1}{4\pi}\int \left(\frac{\nu'}{\nu}\mathbf{nn}'\right) d\Omega', \tag{14}$$

where $\frac{\nu'}{\nu}$ is determined by (12). In the case when $\mathbf{p} = p\mathbf{n}$, it reduces to the form

$$\beta_\nu = 1 + \frac{1}{2x}\left[2 - \left(1 + \frac{1}{x}\right)\ln\left(1 + 2x\right)\right],$$

where $x = \left(h\nu + cp\right)\left(E + cp\right)/m^2c^4$. Now multiplying (13) on the number density of photons with the frequency ν and on the cross section we get the spectral force

which accelerates the electron in the form

$$\mathbf{f}_\nu = \frac{\Delta \mathbf{p}}{\Delta t} = c\sigma_T N_\nu \frac{1}{c}\beta_\nu(p) h\nu \mathbf{n} = \frac{\sigma_T \beta_\nu(p)}{c}\mathbf{P}_\nu \tag{15}$$

where $\mathbf{P}_\nu$ is the spectral component of the Poynting vector $\mathbf{P}_\nu = \frac{c}{4\pi}\mathbf{E}_\nu \times \mathbf{B}_\nu$ and σ_T is the Thomson cross section. The total force is given by $\mathbf{F} = \int \mathbf{f}_\nu d\nu$.

It is important that the force is determined by the Poynting's vector $\mathbf{P}_\nu$. In a quite (quasi-stationary or steady state) galaxy both the Poynting's vector and the force have the potential character, i.e., they can be presented as $\mathbf{P}_\nu = -\nabla\Psi_\nu$. Non-stationary processes in active galactic nuclei may produce some additional acceleration, e.g., the stochastic Fermi acceleration, etc., which we do not discus here. For the quasi-stationary galaxy the Poynting's theorem gives the discontinuity equation

$$div\mathbf{P}_\nu = \ell_\nu \tag{16}$$

where $\ell_\nu(x)$ is the spectral density of sources of radiation (stars, hot gas, dust, etc.) or the radiative capability of a unite volume in the galaxy. If the topology is simple, then sufficiently far from the galaxy we get

$$\mathbf{P}_\nu = \frac{M_\nu}{4\pi r^2}\mathbf{l}, \tag{17}$$

where $\mathbf{l} = \mathbf{r}/r$, $\mathbf{r}$ is the distance from the center of the galaxy, and M_ν is the total spectral energy emitted by the galaxy in the unit time. Observations show that the intergalactic medium possesses a magnetic field.[22,23] Therefore, the electron may have a closed trajectory. It is easy to verify that the total energy obtained by the electron from the galactic radiation during the cycle is exactly zero, i.e., $\oint \mathbf{f}_\nu \mathbf{dl} \equiv 0$. This means that in the case when topology is simple, the only possible mechanism of the electron acceleration relates to high-energy non-stationary processes (jets, shock waves, supernovae explosions, active galactic nuclei, etc.).

The situation changes when the galaxy is accompanied with a wormhole. In the presence of the wormhole the Poynting's field also admits non-trivial solutions of (16). For the sake of simplicity we consider the spherically symmetric (genus $n = 0$) wormhole. For a more general wormhole the rough picture remains the same, at least from the qualitative standpoint. We point out that the genus $n \geq 1$ wormholes are more preferred from the astrophysical standpoint, since they may work as accelerators even in the case when a wormhole is not traversable (e.g., when the length of the trajectories which go through the throat are too big).

Indeed, the scattering of the radiation on the wormhole (e.g., see[16,17]) produces an additional field in the dipole form

$$\delta\mathbf{P}_\nu = \frac{\delta M_\nu}{4\pi r_-^2}\mathbf{n}_- - \frac{\delta M_\nu}{4\pi r_+^2}\mathbf{n}_+ \tag{18}$$

where $\mathbf{n}_\pm = \mathbf{r}_\pm/r_\pm$, $\mathbf{r}_\pm = \mathbf{r} - \mathbf{x}_\pm$, $\mathbf{x}_\pm$ are positions of the wormhole entrances (we assume that $r_+ \ll r_-$), $\delta M_\nu \simeq \frac{M_\nu \pi R^2}{4\pi r_+^2}$ is the portion of the spectral energy absorbed

by the closest entrance into the wormhole throat and R is the radius of the throat. If the wormhole possesses a magnetic field in the form (8), it forms a magnetic trap for the electron, while the Poynting's vector field $\delta\mathbf{P}_\nu$ in form (18) forms the accelerating force which acts exactly along the magnetic lines. On every cycle the electron will gain the energy from radiation $A = \int A_\nu d\nu > 0$, where $A_\nu = \oint \delta\mathbf{f}_\nu \mathbf{dl}$, whose exact value depends on the length of the trajectory of the electron and on all the rest parameters of the wormhole (distance to the galaxy, throat size, etc.). Some part of this energy will be spent on the synchrotron radiation of electrons and, therefore, there is a competition between the acceleration produced by the galactic radiation and loss of energy on the reradiation. The reradiation can be accounted for by adding the standard force of the radiation friction.

4. Magnetic wormholes as baryon traps

Consider a single wormhole whose throat has the shape of a torus (the genus - 1 wormhole by the classification suggested in Ref.[10]). In the presence of such a wormhole Maxwell's equations possess two additional classes of non-trivial vacuum solutions. Indeed, according to the Stocks theorem the system of vacuum Maxwell equations implies $\oint \mathbf{Bdl} = 0$ for any loop which can be pulled to a point (where $\mathbf{B}$ is the magnetic field). In the case of a non-trivial topology of space[a] there appear new classes of loops Γ_a which cannot be contracted to a point and, therefore, to fix the unique solution we have to fix additional boundary data $\oint_{\Gamma_a} \mathbf{Bdl} = \frac{4\pi}{c} I_a$ and in general $I_a \neq 0$. The constants I_a depend only on time and they can be viewed as fictitious currents[b] which intersect the loops Γ_a. In the case of genus $n = 0$ (spherical) wormhole there is only one such a non-trivial loop which goes through the wormhole throat. In the case of genus $n = 1$ wormhole (doughnut - shaped throat) we have already two such loops, one goes through the throat and one additional goes through the hole in the center of the doughnut and surrounds the throat.

The first class produces the magnetic field of a wormhole which can be described by magnetic poles placed in two different entrances into the throat. The two entrances have opposite magnetic poles. If the distance between the entrances is big enough the resulting field is very weak and when crossing such a field high-energy charged particles only slightly change the direction of propagation. The field can be strong only very close to the throat entrances. However, since charged particles can

[a]The simplest scheme to get a general genus - n wormhole can be described as follows. We take a couple of equal spheres with n handles in space, remove the internal regions (insides of the spheres), and glue along their surfaces (the so-called Hegor diagrams). If we take two simple spheres without handles the resulting space corresponds to a spherical wormhole (throat is the sphere). The sphere with a handle is the torus. A couple of toruses corresponds to the doughnut shaped wormhole, etc.
[b]We point out that the currents are fictitious, for from the point of view of the Hegor diagrams they take place in inner regions of spheres which are removed, i.e., in fictitious regions.

freely propagate along the field lines (which are roughly orthogonal to entrances), the particles captured by the field are distributed in the whole region between the entrances. Such fields have the long-range character and can be used to explain the origin of long-correlated magnetic fields in voids[22,23] and, more generally, of primordial magnetic fields.[24]

The situation changes when the wormhole possesses also the field of the second class. The second class corresponds to the field produced by a single loop of a current (the loop of the corresponding fictitious current goes inside of the surface of the doughnut). In this case the field lines of force repeat the shape of the entrance (the shape of a doughnut) which roughly corresponds to the fields observed in spiral galaxies.[36–38] It is necessary to point out that the magnetic fields in the galaxies cannot exactly repeat the shape of a doughnut. There are a number of well-known processes in galaxies which naturally lead to the generation of galactic magnetic fields[37] and the actual field does not reduce to such a simple model. It is known that the pitch angle (between the toroidal field and radial one) is usually between 4 and 17 degrees.

The most strong field is close to the entrance and particles captured by the field remain always near the entrance. In the primordial plasma before the recombination such a wormhole traps all baryons[c] propagating near it and thus forms a primeval structure of a galaxy (a protogalaxy). Such a scheme works only for wormholes which possess sufficiently strong magnetic fields, since high-energy baryons cannot be captured by the wormhole. The mean energy of baryons is determined by the temperature which depends on the redshift. The intensity of the magnetic field also depends on the redshift. While baryons are relativistic particles the threshold value of the fictitious (or equivalent) current does not depend on time.

Indeed, only particles below the threshold energy are captured by the wormhole magnetic field[10] which is given by

$$E = 3kT < E_{th} = eBR_w,$$

where e is the electron charge and R_w is the biggest radius of the doughnut - shaped throat of the wormhole. The energy of relativistic baryons behaves with the redshift as $T = T_\gamma(1+z)$, where T_γ is the present day temperature of CMB radiation. The intensity of the magnetic field can be estimated by the value in the hole of the doughnut. We take it as

$$B = \frac{\kappa I}{cR_w},$$

where $\kappa = 2\pi$ in the center of the doughnut hole, while close to the throat (surface of the doughnut), where the field reaches the maximum value, in the approximation $r_w/R_w \ll 1$ we get the estimate $\kappa \simeq 2R_w/r_w$. The field depends on the parameter I

[c]We present here estimates for baryons only, since leptons are much lighter than baryons and in the primordial plasma leptons simply follow baryons (bounded by the Coulomb potential).

(which is the fictitious or equivalent current) and the big radius R_w of the doughnut which also depends on the redshift as $R_w = R_0/(1+z)$.

The constant I behaves with the redshift as $I = I_0(1+z)$. Indeed the invariant characteristics is the number of magnetic lines captured by the throat (which go through the internal hole of the doughnut). This gives $\int_S \mathbf{Bds} = const = \Phi$, where S an arbitrary surface whose boundary contour γ (dual to Γ) lays on the surface of the throat and cannot be contracted to a point, so that all magnetic lines intersect S only once. Taking the minimal surface S we find $\Phi \sim \frac{2\pi^2}{c} R_w I$ which gives the behavior $I \sim 1/R_w \sim 1/a$, where $a = a_0/(1+z)$ is the scale factor of the Universe. We point out that the same dependence on the redshift z follows from the fact that the energy density of the magnetic field $\rho_B \sim B^2/4\pi$ decreases with the scale factor as $\rho_B \sim 1/a^4$. This gives the threshold value for the equivalent current which defines the intensity of the magnetic field as

$$I_0 > I_{th} = \frac{ce}{\kappa r_\gamma} \sim \frac{3.2}{\kappa} \times 10^{-5} A, \tag{19}$$

where $r_\gamma = \frac{e^2}{3kT_\gamma}$. It is convenient to express r_γ as follows $r_\gamma = r_p(1+z_r)$, where $r_p = \frac{e^2}{m_p c^2}$ is the classical radius of the proton and $1+z_r = \frac{m_p c^2}{3kT_\gamma} \sim 10^{12}$ is the redshift at which baryons become relativistic particles. It is curious that the threshold value I_{th} is extremely small. It does not depend on the absolute size of the wormhole (which is given by the big radius R_w) but only on the ratio of the wormhole radii $\kappa = 2R_w/r_w$. All wormholes with the present day values $I_0 > I_{th}$ strongly interact with baryons. We may say that they are frozen into baryons and, therefore, peculiar motions of baryons repeat peculiar motions of such wormholes. Wormholes with smaller magnetic fields $I_0 < I_{th}$ slightly interact with baryons and can be considered as free objects. They may participate in independent from baryons motions. As we shall see on the early stage of the evolution of the Universe, before the recombination, they cannot capture baryons and therefore do not form an enhancement in the baryon density. On latter stages upon reheating they may capture charged particles and form cosmic rays and compact sources of synchrotron radiation. The relativistic stage for baryons finishes at the redshift z_r upon which (e.g., for $z < z_r$) baryons become non-relativistic and the above consideration brakes.

At redshifts $z_r > z > z_{rec}$ baryons are non-relativistic, while upon the recombination z_{rec} baryons form neutral Hydrogen atoms and do not interact with magnetic fields of all wormholes. They again start to interact with wormholes only at the epoch of re-ionization when first stars have fired.

On the stage $z_r > z > z_{rec}$ for every particular wormhole it is possible to define the critical redshift z_0 when it captures baryons (for $z > z_0$). The critical value z_0 can be estimated as follows. The mean energy of baryons is $m_p V^2/2 = 3kT/2$ with $T = T_\gamma(1+z)$. Then the critical redshift can be found from the inequality $r_B = \frac{V}{\omega_B} = \frac{V m_p c}{eB} < r_d$, where r_B and ω_B are Larmor radius and frequency respectively for protons, while r_d denotes the width of the baryon cloud around the wormhole

throat. The width r_d should be smaller, than the proton diffusion length and it defines the critical value of the magnetic field. This gives

$$B = \frac{\kappa I}{cR_w} > \frac{m_p c}{e r_d}\sqrt{\frac{3kT}{m_p}},$$

or equivalently

$$I_0(1+z) > \frac{\alpha e}{\kappa r_p}\sqrt{\frac{3kT}{m_p}} = \alpha I_{th}(1+z_r)\sqrt{\frac{(1+z)}{(1+z_r)}},$$

where the ratio $\alpha = \frac{R_w}{r_d} \gg 1$. This defines the critical redshift z_0 at which the wormhole starts to trap baryons as

$$(1+z) > (1+z_0) = \alpha^2 \frac{I_{th}^2}{I_0^2}(1+z_r).$$

The relation between z_0 and I_0 can be rewritten as

$$I_0^2 = \frac{(1+z_r)}{(1+z_0)}\alpha^2 I_{th}^2. \tag{20}$$

When $z_0 = z_r$ we get $I_0 = \alpha I_{th}$ and if we take $\alpha = 1$, this will give the absolute threshold of the field. We point out that the value $\alpha = 1$ may have sense only for sufficiently small wormholes with the radius $R_w \lesssim 10^{-5} R_{gal}$, e.g., see estimates in the next section. At redshifts $z > z_r$ we get into the epoch where baryons are relativistic particles and wormholes with $I_0 < I_{th}$ do not bound baryons at all. There is one more critical value I_{rec} which corresponds to $z_0 = z_{rec}$.

$$I_{rec}^2 = \alpha^2 I_{th}^2 \frac{(1+z_r)}{(1+z_{rec})} \gg I_{th}^2. \tag{21}$$

All fields with $I_0 > I_{rec}$ are strong enough to capture baryons during the whole evolution $z > z_{rec}$.

5. The number of baryons in traps

The efficiency of wormhole traps can be described by the number of baryons collected. The number of baryons collected around magnetic wormholes depends on the proton diffusion length $\ell(z)$, the big radius a wormhole throat $R_w(z)$, and the radius of the baryon cloud $r_{cl}(z) \ll R_w$. For estimates one may use $r_{cl} \sim r_w$. This number can be estimated as the increase of the effective volume of the torus-shaped throat

$$\Delta N = < n_b > \left(V(R_w + \ell, r_{cl} + \ell) - V(R_w, r_{cl})\right),$$

where $< n_b >$ is the mean density of baryons and $V = 2\pi^2 R_w r_{cl}^2$ is the throat volume. We define the parameter $\delta_b = \Delta N/(V < n_b >)$ which depends on the position in space. Close to wormhole throats $\delta_b > 0$, while sufficiently far from the wormhole $\delta_b < 0$ since baryons from those regions have captured by the wormhole.

The value $< \delta_b^2 >= b$, where brackets define the averaging over the space, relates to the baryon clumping factor $b = (< n_b^2 > - < n_b >^2)/ < n_b >^2$, e.g.,[25,26]

In the case $\ell(z) \ll r_{cl}(z)$ we get

$$\delta_b(z) \sim \frac{\ell(z)}{R_w(z)} + \frac{2\ell(z)}{r_{cl}(z)} \ll 1. \tag{22}$$

In the intermediate case $r_{cl}(z) \ll \ell(z) \ll R_w(z)$ we find the estimate

$$\delta_b(z) \sim \frac{\ell^2(z)}{r_{cl}^2(z)} \left(1 + \frac{\ell(z)}{R_w(z)}\right) \gg 1. \tag{23}$$

And in the case $\ell(z) \gg R_w(z)$ the estimate has the order

$$\delta_b(z) \sim \frac{\ell^3(z)}{R_w(z) r_{cl}^2(z)} \gg 1. \tag{24}$$

On the stage $z > z_r$ protons are relativistic particles, plasma is degenerate, and the length of the proton propagation can be estimated by the value of the horizon size $\ell(z) \sim l_h = c/H(z)$. At the redshift $z = z_r$ it is extremely small and has the order $\ell(z_r) \sim (7 \div 8) \times 10^{-15} pc$. Consider a wormhole throat with the big radius $R_w(0) \sim 15 kpc$ which corresponds to a galaxy size,[41] while the radius of the baryon cloud has the order $r_{cl} \sim 0.2 R_w$. Then we find $R_w(z_r) \sim 15 \times 10^{-9} pc \gg \ell(z_r)$ and from (22) we get $\delta_b(z_r) \sim (0.5 \div 0.6) \times 10^{-5}$. Such a value is too small to form a galaxy without additional means (e.g., a dark matter clump).

At the recombination $z_{rec} = 1100$ the proton diffusion length has the co-moving value of the order $\ell(z_{rec}) \sim 0.4 \div 1 pc$, while $R_w(z_{rec}) \sim 13.6 pc$ and we still may consider $\ell(z_{rec}) \ll R_w$ and $\ell \lesssim r_{cl}$. Therefore we again may use (22) and find $\delta_b(z) \sim 0.32 \div 0.8$. Such a big value shows that the respective protogalaxy forms immediately after the recombination and it is already in the non-linear regime. We should expect that wormholes with such strong clumps of baryons depart the Hubble expansion very soon and form rather small objects. Smaller wormholes form too strong inhomogeneities before recombination and probably collapse to blackholes. We point out that this may give a new mechanism of blackhole formation with huge masses.

Galaxies are observed up to $z \simeq 11$ (e.g., the most distant GN-z11 is observed at $z = 11.09$[39]). Therefore, to be consistent with the present day size of a typical ring galaxy the wormhole radius should be at least two orders bigger $R_w(0) \lesssim 1 Mpc$, which gives already $R_w(z_{rec}) \lesssim 900 pc$ and $\delta_b(z_{rec}) \sim 4,8 \times 10^{-3}$. Such a clump departs the Hubble expansion already at $z \sim 100$ and gives a ring of the order $R \sim 10 Kpc$.

6. Conclusions

In conclusion we point out two important facts. First one is that the wormholes whose size $R(z_{rec})$ exceeds the value $\ell(z_{rec})$ more than on the factor 10^3 do not form a sufficient enhancement in the baryon number density and, therefore, cannot

form ring galaxies. They however may form ring-type structures in the future, e.g. see the recently reported findings of unexpected class of astronomical ring-type objects in.[29]

The second fact is that upon the recombination $z < z_{rec}$ the doughnut-shaped wormholes do not interact with baryons and evolve. Therefore, they may leave the ring clump formed. They either expand or collapse forming a magnetized black hole in the middle. If the wormhole collapses, it should also draw some portion of the baryon clump and form a bulge in the center of the ring. In this case it may form the ideal symmetric structure similar to the Hoag's object. Additional rotational perturbations of clumps may however lead to irregular structures. If the wormhole expands further, the center part of the ring remains to be empty. We may expect that in such a case the mean value of the magnetic field within the ring retains. We recall that different active processes in galaxies generate magnetic fields which in general have a turbulent character. Therefore, by the measuring the mean flow of the magnetic field in a ring galaxy one may at least estimate the present day value of the big radius $R = \frac{\kappa I}{cB}$ of such a wormhole and estimate its present day position. This may be used in the direct search for wormhole traces in the Universe.

At first glance the most direct indication on the possible role of relic magnetic wormholes in the formation of some ring galaxies should be the discrepancy between the observed amount of dark matter in such galaxies and the predictions of the standard theory.[40,42,43] However there exist some extensions of general relativity which are capable of reproducing dark matter effects in galaxies without dark matter particles, e.g., see[44,45] and references therein. Therefore, we think that the only rigorous indication on the presence of relic magnetic wormholes should be large-scale toroidal magnetic fields.

In this work, we explore wormhole geometries in a recently proposed modified gravity theory arising from a non-conservative gravitational theory, tentatively denoted action-dependent Lagrangian theories. The generalized gravitational field equation essentially depends on a background four-vector λ^μ, that plays the role of a coupling parameter associated with the dependence of the gravitational Lagrangian upon the action, and may generically depend on the spacetime coordinates. Considering wormhole configurations, by using "Buchdahl coordinates", we find that the four-vector is given by $\lambda_\mu = (0, 0, \lambda_\theta, 0)$, and that the spacetime geometry is severely restricted by the condition $g_{tt}g_{uu} = -1$, where u is the radial coordinate. We find a plethora of specific asymptotically flat, symmetric and asymmetric, solutions with power law choices for the function λ, by generalizing the Ellis-Bronnikov solutions and the recently proposed black bounce geometries, amongst others. We show that these compact objects possess a far richer geometrical structure than their general relativistic counterparts.

Keywords: General relativity, alternative theories of gravity; wormhole; action-dependent Lagrangian theories; energy conditions.

1. Introduction

A key ingredient in traversable wormhole geometries is the flaring-out condition,[1,2] which in General Relativity (GR) entails the violation of the null energy condition (NEC). The latter is defined as $T_{\mu\nu}k^\mu k^\nu \geq 0$, for *any* null vector k^μ,[3,4] and matter violating the NEC has been denoted as *exotic matter*. However, it has been shown that these violations may be minimized using several procedures, such as the cut-and-paste techniques in the thin-shell formalism, where the exotic matter is concentrated at the junction interface.[5–14] In fact, the problem is improved with evolving traversable wormholes, where it has been demonstrated that these time-dependent geometries may satisfy the energy conditions in arbitrary finite intervals of time,[15,16] and recently specific dynamical four-dimensional solutions were presented that satisfy the null and weak energy conditions everywhere and everywhen.[17,18] In fact, modified theories of gravity is an interesting avenue of research to explore traversable wormholes, where these compact objects possess a richer geometrical structure than their general relativistic counterparts. In this context, it has been shown that the NEC can be satisfied for normal matter threading the

wormhole throat, where it is the higher order curvature terms that sustain the wormhole.[19–27]

In this work, we will be interested in studying wormhole geometries in a recently proposed modified gravity theory arising from a non-conservative gravitational theory, tentatively denoted action-dependent Lagrangian theories.[28] The latter are obtained through an action principle for action-dependent Lagrangians by generalizing the Herglotz variational problem[29,30] for several independent variables. The novel feature when comparing with previous implementations of dissipative effects in gravity is the possible arising of such phenomena from a least action principle, so they are of a purely geometric nature. Applications to this model have also been explored, namely, in cosmology,[31] braneworld gravity,[32] cosmic string configurations,[33] the late-time cosmic accelerated expansion and large scale structure,[34] and static spherically symmetric stellar solutions,[35] amongst others.

The complete set of field equations considered in this action-dependent Lagrangian theory[28] is based on the following total Lagrangian

$$\mathcal{L} = \mathcal{L}_g + \mathcal{L}_m = (R - \lambda_\mu s^\mu) + \mathcal{L}_m, \tag{1}$$

where the Einstein-Hilbert Lagrangian is extended with the geometrical sector dealing with the additional dissipative term $\lambda_\mu s^\mu$ while $\mathcal{L}_m$ is the Lagrangian of the matter fields. In general, the background four-vector λ^μ depends on the spacetime coordinates, however it can be assumed to be constant. The field s^μ is an action-density field which disappears after the variation of the action such that the modification to the GR counterpart is given by the four-vector λ^μ only. Note that λ^μ may be considered a background four-vector, that plays the role of a coupling parameter associated with the dependence of the gravitational Lagrangian upon the action. In the majority of the works considered above it is assumed to be constant, however, in a more general scenario, one may assume it to be a coordinate-dependent four-vector.

Thus, the field equations are given by

$$G_{\mu\nu} + Z_{\mu\nu} = \kappa^2 T_{\mu\nu}, \tag{2}$$

where we have defined $\kappa^2 = 8\pi$, $G_{\mu\nu}$ is the Einstein tensor, and for notational simplicity, we have defined $Z_{\mu\nu}$ as

$$Z_{\mu\nu} = K_{\mu\nu} - \frac{1}{2} g_{\mu\nu} K. \tag{3}$$

The symmetric geometric structure $K_{\mu\nu}$ is defined as

$$K_{\mu\nu} = \lambda_\alpha \Gamma^\alpha_{\mu\nu} - \frac{1}{2}(\lambda_\mu \Gamma^\alpha_{\nu\alpha} + \lambda_\nu \Gamma^\alpha_{\mu\alpha}), \tag{4}$$

which is constructed from the particular combination of the four-vector λ_μ and the Christofell symbols

$$\Gamma^\alpha_{\mu\nu} = \frac{g^{\alpha\beta}}{2}\left(g_{\beta\mu,\nu} + g_{\beta\nu,\mu} - g_{\mu\nu,\beta}\right). \tag{5}$$

The quantity $K_{\mu\nu}$ (and its trace K) represents the geometric structure behind the dissipative nature of the theory. Note that the limit of a vanishing λ_μ restores the dissipationless feature of GR.

Thus, motivated by the existence of static spherically-symmetric compact objects analysed in,[35] we extend this analysis to the context of wormhole physics. This work is outlined in the following manner: In Sec. 2, we present the most general restrictions on static and spherically symmetric wormhole geometries imposed by the geometrical structure of the action-dependent Lagrangian theory. In Sec. 3, we consider a plethora of specific solutions of action-dependent Lagrangian induced wormhole geometries. Finally, in Sec. 4, we summarize our results and conclude.

2. General restrictions on wormhole geometries

Consider the general static and spherically symmetric metric given by

$$ds^2 = -f(u)dt^2 + g(u)du^2 + R^2(u)d\Omega^2, \tag{6}$$

where $d\Omega^2 = d\theta^2 + \sin^2\theta d\phi^2$ is the linear element of the unit sphere, and the metric functions $f(u)$, $g(u)$ and $R(u)$ are functions of the radial coordinate u. The coordinate choices used in metric (6) are often called "Buchdahl coordinates".[36–38] Note that one possesses a freedom in choosing the radial coordinate, consequently allowing one to fix the form of one of the metric functions $f(u)$, $g(u)$ or $R(u)$, which will be considered below. Here the radial coordinate lies in the range $u \in (-\infty, +\infty)$, so that two asymptotically flat regions exist, i.e., $u \to \pm\infty$, and are connected by the throat. The function $R(u)$ possesses a global positive minimum at the wormhole throat $u = u_0$, which one can set at $u_0 = 0$, without a loss of generality. Thus, the wormhole throat is defined as $R_0 = \min\{R(u)\} = R(0)$.

In order to avoid event horizons and singularities throughout the spacetime, one imposes that the metric functions $f(u)$ and $g(u)$ are positive and regular everywhere. Taking into account these restrictions, namely, the necessary conditions for the minimum of the function imposes the flaring-out conditions, which are given by

$$R_0' = 0\,, \qquad R_0'' > 0\,. \tag{7}$$

In this work, we consider an anisotropic distribution of matter threading the wormhole described by the following stress-energy tensor $T_{\mu\nu}$

$$T_{\mu\nu} = (\rho + p_t)U_\mu U_\nu + p_t\, g_{\mu\nu} + (p_r - p_t)\chi_\mu\chi_\nu\,, \tag{8}$$

where U^μ is the four-velocity, χ^μ is the unit spacelike vector in the radial direction, i.e., $\chi^\mu = g^{-1/2}(u)\delta^\mu_u$; $\rho(u)$ is the energy density, $p_r(u)$ is the radial pressure measured in the direction of χ^μ, and $p_t(u)$ is the transverse pressure measured in the orthogonal direction to χ^μ.

Now, rather than write out the full gravitational field equations (2) for the metric (6), we note that the only non-zero components of the Einstein and the stress-energy tensor are the diagonal terms, so that the non-diagonal part of the additional

tensor $Z_{\mu\nu}$, defined by Eq. (3), also provides additional information on the geometrical structure of the solutions of the theory, namely, that $Z_{\mu\nu} = 0$ for $\mu \neq \nu$. More specifically, the non-diagonal components of the symmetric tensor $Z_{\mu\nu}$ places restrictions on the form of the four-vector λ_μ.

The independent components of the tensor $Z^\mu_\nu = K^\mu_\nu - \frac{1}{2}\delta^\mu_\nu K$ are given by

$$Z^u_t = -\frac{\lambda_t[fg'R - g(f'R - 4fR')]}{4fg^2R}, \quad Z^u_u = \frac{\lambda_\theta}{R^2}\cot\theta, \tag{9}$$

$$Z^u_\theta = -\frac{\lambda_\theta(fg)'}{4fg^2} - \frac{\lambda_u}{2g}\cot\theta, \qquad Z^u_\phi = -\frac{\lambda_\phi(fg)'}{4fg^2}, \tag{10}$$

$$Z^\theta_\theta = Z^\phi_\phi = \frac{\lambda_u(Rf' + 2fR')}{2fgR}, \tag{11}$$

$$Z^\theta_\phi = \frac{\lambda_\phi}{2R^2}\cot\theta, \qquad Z^\theta_t = -\frac{\lambda_t}{2R^2}\cot\theta, \tag{12}$$

$$Z^t_t = \frac{2\lambda_u R'}{gR} + \frac{\lambda_\theta}{R^2}\cot\theta, \qquad Z^t_\phi = 0\,. \tag{13}$$

From $Z^\theta_\phi = Z^\theta_t = 0$, one readily extracts the restrictions $\lambda_\phi = \lambda_t = 0$. Taking into account the assumption of the static and spherical symmetric character of the spacetime, the field equations should only depend on the radial coordinate, so that from the diagonal Z^u_u component, one readily verifies that $\lambda_\theta \propto (\cot\theta)^{-1}$, or more specifically $\lambda_\theta = \lambda(u)/(\cot\theta)$ (one may consider the simple case $\lambda(u) = \lambda_0 = \text{const}$). Note that if one were to consider $\lambda_\theta = 0$, then the condition $Z^u_\theta = 0$ would impose that $\lambda_u = 0$, taking us trivially back to GR. Analogously, in order for Z^t_t to only depend on the radial coordinate, from $Z^u_\theta = 0$ this imposes that $\lambda_u = 0$ and consequently places a further constraint on the metric functions, namely, $(fg)' = 0$.

Thus, the additional information on the geometrical structure of the theory, which imposes that the non-diagonal components of the symmetric tensor $Z_{\mu\nu}$ vanish, imposes the following condition on the four-vector λ_μ:

$$\lambda_\mu = \left(0, 0, \frac{\lambda(u)}{\cot\theta}, 0\right), \tag{14}$$

and the additional geometric tensor Z^μ_ν takes the diagonal form $Z^\mu_\nu = (\lambda(u)/R^2)\,\mathrm{diag}(1,1,0,0)$. Furthermore, from the constraint on the metric functions $(fg)' = 0$, we can consider, without a loss of generality, the following choice:

$$g(u) = f^{-1}(u) = A(u). \tag{15}$$

3. Specific solutions of action-dependent Lagrangian induced wormhole geometries

The analysis outlined in the previous section imposes that the static and spherical symmetric configuration (6) in the theory (1), can be written as

$$ds^2 = -A(u)dt^2 + A^{-1}(u)du^2 + R^2(u)d\Omega^2, \tag{16}$$

where as before the wormhole throat is defined as $R_0 = \min\{R(u)\} = R(0)$, and in order to avoid event horizons and singularities throughout the spacetime, one imposes that the function $A(u)$ is positive and regular everywhere. These restrictions imposes the flaring-out conditions, translated by Eq. (7).

As the metric function $A(u)$ is positive and regular for $\forall u$, it is useful to analyse its derivatives at the throat $u = 0$. In particular, the sign of A_0'' determines the type of extrema of $A(u)$, i.e., it is a minimum if $A_0'' > 0$ and a maximum if $A_0'' < 0$. This implies that the maximum (minimum) of $A(u)$ corresponds to a maximum (minimum) of the gravitational potential, so that in the vicinity of a maximum (minimum) the gravitational force is repulsive (attractive). Thus, the wormhole throat possesses a repulsive or an attractive nature that depends on the sign of A_0''.

Now, taking into account the modified Einstein equation (2), the spacetime metric (16) and the stress-energy tensor (8), the gravitational field equations are finally given by:

$$8\pi\rho = -\frac{2ARR'' + AR'^2 + A'RR' - 1}{R^2} - \frac{\lambda(u)}{R^2}\,, \tag{17}$$

$$8\pi p_r = \frac{AR'^2 + A'RR' - 1}{R^2} + \frac{\lambda(u)}{R^2}\,, \tag{18}$$

$$8\pi p_t = \frac{A''R + 2AR'' + 2A'R'}{2R}\,. \tag{19}$$

Adding Eqs. (17) and (18), yields the following relation

$$R''|_{R_0} = -\frac{4\pi R}{A}(\rho + p_r)|_{R_0}\,, \tag{20}$$

and using the condition at the throat $R_0'' > 0$, one verifies that in these specific action-dependent Lagrangian theories the NEC is generically violated at the throat, i.e., $(\rho + p_r)|_{R_0} < 0$.

Taking into account the field equations (17)–(19), one has three independent equations with six unknown functions of the radial coordinate u, namely, $\rho(u)$, $p_r(u)$, $p_t(u)$, $A(u)$, $R(u)$ and $\lambda(u)$. There are several strategies that one may now follow. More specifically, one may consider specific choices for the components of the stress-energy tensor, and then solve the field equations to determine the metric functions and $\lambda(u)$; one may also take into account a plausible stress-energy tensor profile by imposing equations of state $p_r = p_r(\rho)$ and $p_t = p_t(\rho)$, and close the system by adequately choosing the energy density, or any of the metric functions. In alternative to this approach, one may use the reverse philosophy usually adopted in wormhole physics by simple choosing specific choices for the metric functions and $\lambda(u)$, and through the field equations determine the stress-energy profile responsible for sustaining the wormhole geometry. In the following section, we will adopt several strategies outlined above, and a mixture thereof, to obtain specific exact solutions of wormhole spacetimes induced by these action-dependent Lagrangian theories.

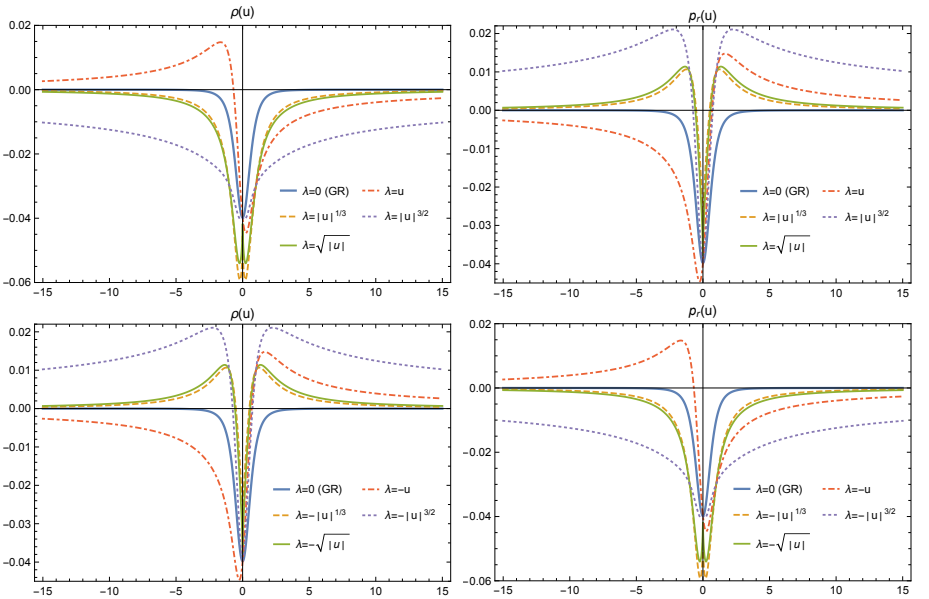

Fig. 1. The plots depict the specific case of the Ellis-Bronnikov wormhole configuration with $a = 1$, for convenience, and for different choices of the function $\lambda(u)$. Depending on the sign of $\lambda(u)$, one obtains a plethora of specific symmetric or asymmetric solutions. Note that for $\lambda(u) \sim \pm u$, one obtains asymmetric solutions, where the energy density is negative at the throat and in the positive (negative) branch of u, but becomes positive in the negative (positive) branch; the radial pressure exhibits the inverse qualitative behavior. We refer the reader to the text for more details.

3.1. *Specific wormhole solutions: Ellis-Bronnikov solution*

Using an appropriate parametrization, we can present a solution by taking into account the reverse philosophy of solving the modified field equations, as follows[39]

$$R(u) = e^{-\alpha(u)}\sqrt{u^2 + a^2}, \qquad A(u) = e^{2\alpha(u)}, \tag{21}$$

with the factor $\alpha(u)$ defined as

$$\alpha(u) = \left(\frac{m}{a}\right) \arctan\left(\frac{u}{a}\right), \tag{22}$$

where m and a are two free parameters. Thus, the spacetime metric is given by

$$ds^2 = -e^{2\alpha}dt^2 + e^{-2\alpha}\left[du^2 + (u^2 + a^2)d\Omega^2\right]. \tag{23}$$

Following the previous definition of the wormhole throat, which is situated at $u_0 = 0$, we readily obtain $R'(0) = -m/a$, so that the condition $R'(0) = 0$ imposes $m = 0$. Note that these conditions imply that the solution reduces to the well-known Ellis-Bronnikov wormhole spacetime.[40–42] This does indeed simplify the analysis below, such that $\alpha(u) = 0$, $A(u) = 1$, and

$$R''(u_0) = \frac{1}{|a|} > 0 \tag{24}$$

In addition to this, Eqs. (17)–(19) yield the following stress-energy profile:

$$\rho(u) = -\frac{\left(a^2+u^2\right)\lambda(u)+a^2}{8\pi\left(a^2+u^2\right)^2}, \tag{25}$$

$$p_r(u) = \frac{\left(a^2+u^2\right)\lambda(u)-a^2}{8\pi\left(a^2+u^2\right)^2}, \tag{26}$$

$$p_t(u) = \frac{a^2}{8\pi\left(a^2+u^2\right)^2}\,. \tag{27}$$

For the specific case of $\lambda = 0$, where the four-vector λ^μ vanishes, this solution simply reduces to the general relativistic Ellis-Bronnikov stress-energy components. However, for the general case, one still needs to impose one more condition to close the system, and in the following we consider specific choices for the function $\lambda(u)$. Equations (25)–(26) yield the following relation:

$$\rho(u) + p_r(u) = -\frac{a^2}{4\pi\left(a^2+u^2\right)^2}\,, \tag{28}$$

which states that the NEC is violated throughout the entire spacetime, and is independent of the function $\lambda(u)$.

We are only interested in asymptotically flat solutions, so that taking into account the limit of Eq. (25), one finds

$$\lim_{u\to\infty}\rho(u) \sim -\lim_{u\to\infty}\frac{\lambda(u)}{u^2}\,. \tag{29}$$

For instance, assuming a power law solution for $\lambda(u) \sim u^\alpha$, the asymptotic flatness condition imposes that $\alpha < 2$, and from the regularity of the stress-energy components we have $\alpha \geq 0$, so that the parameter lies in the range $0 \leq \alpha < 2$. One may perform a similar analysis with the radial pressure $p_r(u)$, but with a change in the sign for the limit. Note that the tangential pressure, $p_t(u)$, is independent of $\lambda(u)$, possesses a maximum value at the throat, $p_t(u=0) = (8\pi a^2)^{-1}$, and tends to zero with increasing u.

Several choices for the function $\lambda(u)$ are depicted in Fig. 1. Depending on the sign of $\lambda(u)$, one obtains a plethora of specific symmetric or asymmetric solutions. More specifically, for the case of $\lambda(u) \sim \pm u$, one obtains asymmetric solutions where the energy density is negative at the throat and in the positive (negative) branch of u, but becomes positive in the negative (positive) branch, while the radial pressure possesses the inverse qualitative behavior, as is transparent from Fig. 1. Thus, it is possible to alleviate the negative energy densities needed to thread this wormhole configurations, relative to GR. The wormhole solutions obtained with $\lambda \neq 0$ possess a richer structure that their general relativistic counterparts.

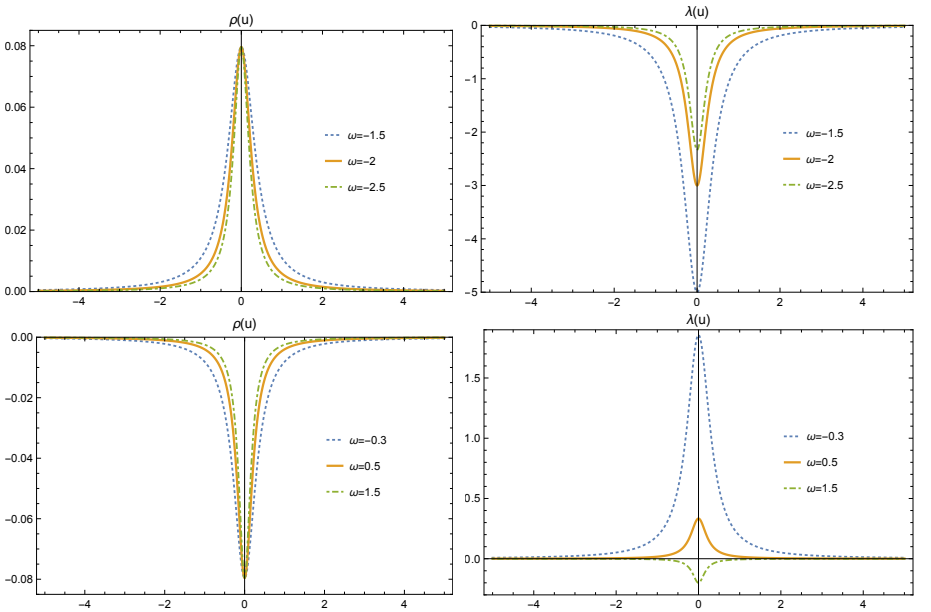

Fig. 2. Results for the specific stress-energy profile given by (30) and (31) with $a^2 = -1/(4\pi\rho_0(1+\omega))$ and $\alpha = 2$. The upper plots are for the case $\rho_0 = 1$ ($\omega < -1$), and the lower plots for $\rho_0 = -1$ ($\omega > -1$).

3.2. *Specific stress-energy profile*

We now consider the strategy of specifying the profile of the energy density and radial pressure given by:

$$\rho(u) = \rho_0 \left(\frac{a^2}{a^2+u^2}\right)^{\alpha}, \tag{30}$$

$$p_r(u) = p_0 \left(\frac{a^2}{a^2+u^2}\right)^{\alpha}, \tag{31}$$

with $\alpha > 0$, so that both components tend to zero at spatial infinity. In addition to this, we close the system by considering the specific choice for the metric function

$$R(u) = \sqrt{a^2+u^2}\,. \tag{32}$$

Note that Eqs. (30) and (31) can be written as $p_r = \omega\rho$, with $\omega = p_0/\rho_0$. Thus, this case is formally equivalent to choosing Eq. (32), one of Eqs. (30) or (31), and the equation of state $p_r(u) = \omega\rho(u)$.

The gravitational field equations (17)–(19) provide the following solutions:

$$A(u) = -4\pi a^2\rho_0(\omega+1)\left(\frac{a^2}{a^2+u^2}\right)^{\alpha-2}, \tag{33}$$

$$\lambda(u) = 1 + 4\pi\rho_0\left[2a^2\omega - (2\alpha-5)u^2(\omega+1)\right]\left(\frac{a^2}{a^2+u^2}\right)^{\alpha-1}. \tag{34}$$

As before, we impose the asymptotic flatness condition, namely,

$$\lim_{u\to\pm\infty} A(u) \to 1\,, \tag{35}$$

and taking into account that $A(u)$ should be positive and regular $\forall u$, implies the following two stringent restrictions:

$$\alpha = 2, \qquad \text{and} \qquad 4\pi a^2\rho_0(1+\omega) = -1, \tag{36}$$

where the second condition imposes:

$$\rho_0(1+\omega) < 0. \tag{37}$$

This implies two specific cases: (i) $\rho_0 > 0$ and $\omega < -1$, so that taking into account the equation of state $\omega = p_0/\rho_0$, implies a negative radial pressure at the throat; or (ii) $\rho_0 < 0$ and $\omega > -1$, so that $p_0 > 0$ for $-1 < \omega < 0$, and $p_0 < 0$ for $\omega > 0$. Specific cases are depicted in Fig. 2. Relative to the analysis at the throat, note that the wormhole conditions are satisfied, namely, $R'(u_0) = 0$ and $R''(0) = 1/|a| > 0$. In addition to this, for the imposition of the asymptotic flatness condition, namely, $\alpha = 2$, we readily obtain $A(u) = 1$, so that $A'(u_0) = A''(u_0) = 0$.

3.3. *Black bounce solutions*

Recently, a number of novel regular "black-bounce" spacetimes were explored.[43,44] These are specific geometries where the "area radius" always remains non-zero, thereby leading to a "throat" that is either timelike (corresponding to a traversable wormhole), spacelike (corresponding to a "bounce" into a future universe), or null (corresponding to a "one-way wormhole"). The regularity, the energy conditions, and the causal structure of these models were analysed in detail in Refs.[43,44] The main results are several new geometries with two or more horizons, with the possibility of an extremal case. Motivated by these novel solutions, in this subsection we shall analyse specific generalized "black-bounce" wormhole geometries induced by action-dependent Lagrangian theories.

3.3.1. *Simpson–Visser black-bounce spacetime*

In this section, we consider a specific black bounce geometry, which we denote as the Simpson-Visser solution.[13,43,44] Consider the following parameters, which were presented in Ref.[43]:

$$R(u) = \sqrt{u^2+a^2}, \qquad A(u) = 1 - \frac{2m}{\sqrt{u^2+a^2}}\,. \tag{38}$$

Note that the Schwarzschild solution is recovered, if we take the limit $a \to 0$.

This spacetime possesses several interesting properties.[43] First, for $a > 0$ the geometry is everywhere regular, which can verified as $R(u)$ is never zero, and is regular, as is $A(u)$. Now, one has several cases, for instance: (i) if $0 < a < 2m$, two horizons exist, namely, $u_\pm = \pm\sqrt{(2m)^2 - a^2}$, where u_+ is positive and u_- is

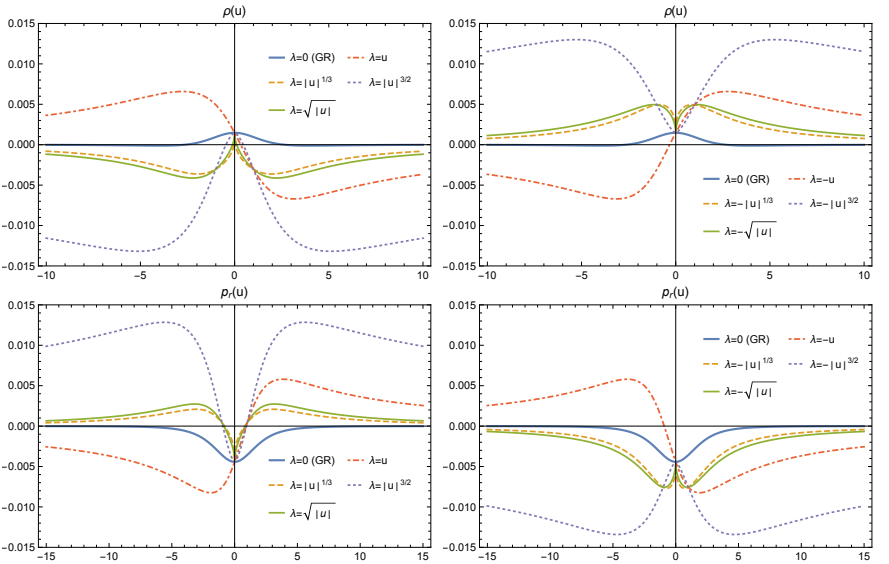

Fig. 3. The plots depict the Simpson-Visser black bounce solution, for the specific choices $m = 1$, $a = 3$. Note that one may obtain wormhole configurations with an entirely positive energy density throughout the spacetime, for negative values of the function $\lambda(u)$; and positive radial pressures in the negative branch of the u-axis. As before, it is transparent from the plots that these compact objects possess a richer geometrical structure than their general relativistic counterparts. See the text for more details.

negative. This solution corresponds to a regular black hole spacetime, where the core consists of a bounce located at $u = 0$; (ii) if $a = 2m$, a wormhole exists with a throat located at $u = 0$. This is an extremal null throat, which can only be crossed from one region to another, so that the wormhole is only one-way traversable; (iii) finally, if $a > 2m$, a two-way traversable wormhole exists, that possesses a timelike throat located at $u = 0$. Thus, only the case (c) for $a > 2m$ interests us here. We refer the reader to Refs.[43,44] for specific details.

Taking into account the choices for the metric functions (38), the field equations (17)–(19) provide the following stress-energy profile:

$$\rho(u)_{SV} = -\frac{1}{8\pi}\left[\frac{a^2\left(\sqrt{a^2+u^2}-4m\right)}{\left(a^2+u^2\right)^{5/2}} + \frac{\lambda(u)}{a^2+u^2}\right], \tag{39}$$

$$p_r(u)_{SV} = \frac{\left(a^2+u^2\right)\lambda(u) - a^2}{8\pi\left(a^2+u^2\right)^2}, \tag{40}$$

$$p_t(u)_{SV} = \frac{a^2\left(\sqrt{a^2+u^2}-m\right)}{8\pi\left(a^2+u^2\right)^{5/2}}, \tag{41}$$

respectively. The asymptotic limits of the energy density and the radial pressure

are given by:

$$\lim_{u\to\pm\infty}\rho(u)_{SV}\sim-\lim_{u\to\pm\infty}p_r(u)_{SV}\sim-\lim_{u\to\pm\infty}\frac{\lambda(u)}{a^2+u^2}. \tag{42}$$

As before, if we assume a power law for $\lambda(u)\sim u^{\alpha}$, the asymptotic flatness condition and the regularity of the stress-energy components, as before, imposes that $0\leq\alpha<2$; note that the tangential pressure $p_t(u)\to 0$ for $u\to\pm\infty$, and possesses a maximum at the wormhole throat, i.e., $p_t(u=0)=(a-m)/(8\pi a^3)$, and is positive throughout the spacetime as we are only considering the condition $a>2m$.

Several choices for the function are depicted in Fig. 3. Depending on the sign of $\lambda(u)$, one obtains a plethora of specific symmetric or asymmetric solutions. Note that these compact objects possess a richer geometrical structure than their general relativistic counterparts. It is transparent from Fig. 3 that one may obtain wormhole configurations with an entirely positive energy density throughout the spacetime, for negative values of the function $\lambda(u)$; for instance, for the latter it is also possible to obtain positive radial pressures in the negative branch of the u-axis. However, the NEC is always violated at the wormhole throat.

3.3.2. *Black bounce II*

Another black bounce spacetime that exhibits interesting properties, is given by the following specific metric functions:[44]

$$R(u)=\sqrt{u^2+a^2},\qquad A(u)=1-\frac{2mu^2}{(u^2+a^2)^{3/2}}\,. \tag{43}$$

Note that by solving for the roots of the function $A(u)=0$, we have: i) for $a<a_{\rm ext}=4m/(3\sqrt{3})$, there are four real solutions, which are symmetrical to each other, namely, $(r_+,r_C,-r_C,-r_+)$, (where u_+ corresponds to the event horizon and u_C to a Cauchy horizon); ii) for $a=a_{\rm ext}$, we have two real solutions $(u_+,-u_+)$; iii) and for $a>a_{\rm ext}$, no real value exists. We refer the reader to[44] for more details. Thus, in order to have a traversable wormhole solution, where only the case of $A(u)>0$ is satisfied, only the specific case for $a>a_{\rm ext}$ interests us here.

For this case, the gravitational field equations (17)–(19) yield the stress-energy profile, given by the following relations:

$$\rho(u)=-\frac{1}{8\pi}\left[\frac{a^2\left(a^2+u^2\right)^{3/2}-8ma^2u^2}{\left(a^2+u^2\right)^{7/2}}+\frac{\lambda(u)}{a^2+u^2}\right], \tag{44}$$

$$p_r(u)=\frac{1}{8\pi}\left[-\frac{a^2\left(a^2+u^2\right)^{3/2}+4ma^2u^2}{\left(a^2+u^2\right)^{7/2}}+\frac{\lambda(u)}{a^2+u^2}\right], \tag{45}$$

$$p_t(u)=\frac{a^2u^2\left(\sqrt{a^2+u^2}+5m\right)+a^4\left(\sqrt{a^2+u^2}-2m\right)}{8\pi\left(a^2+u^2\right)^{7/2}}, \tag{46}$$

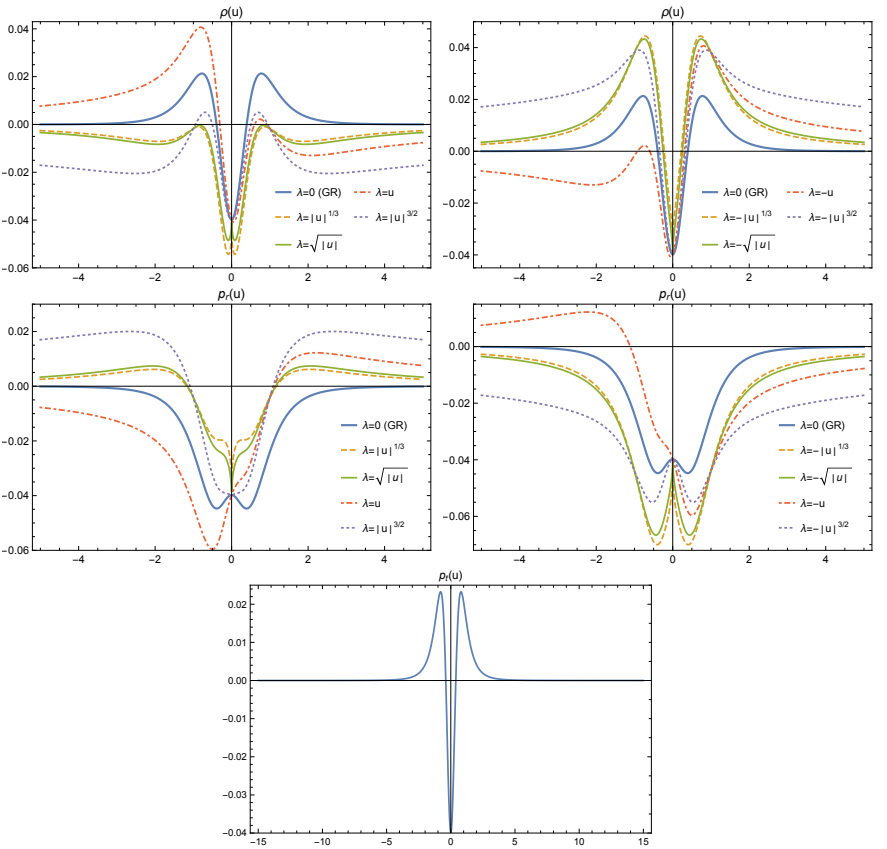

Fig. 4. The plots depict the stress-energy profile for the black bounce II solution, given by the metric function (43), where for numerical convenience we have assumed the following choices for the parameters: $m = 1, a = 1$. Recall that the parameters are restricted by the condition $a > 4m/(3\sqrt{3})$. As before these wormhole configurations possess a far richer internal structure than their general relativistic counterparts, and depending on the sign of $\lambda(u)$, specific symmetric or asymmetric solutions are obtained. However, here the tangential pressure at the wormhole throat, $p_t(u=0) = (a-2m)/(8\pi a^3)$, takes negative values for the parameter range $4m/(3\sqrt{3}) < a < 2m$, and positive values for $a > 2m$. We refer the reader to the text for more details.

respectively, which are depicted in Fig. 4 for specific choices of the model parameters.

Assume, once again, a power law for $\lambda(u) \sim u^{\alpha}$, we have that $0 \leq \alpha < 2$ by the asymptotic flatness condition and the regularity of the stress-energy components, as before. As before these wormhole geometries induced by action-dependent Lagrangian theories possesses a far richer internal structure than their general relativistic counterparts, and depending on the sign of $\lambda(u)$, specific symmetric or asymmetric solutions are obtained. We refer the reader to Fig. 4 for a qualitative behaviour of the stress-energy profile; recall that taking into account the parameter range, we consider the condition $a > 4m/(3\sqrt{3})$. Here the tangential pressure at

the wormhole throat is given by $p_t(u=0) = (a-2m)/(8\pi a^3)$, and takes negative values for $4m/(3\sqrt{3}) < a < 2m$, possessing a minimum at the throat, and positive values for $a > 2m$; note that $p_t(u) \to 0$ for $u \to \pm\infty$.

3.3.3. *Black bounce III*

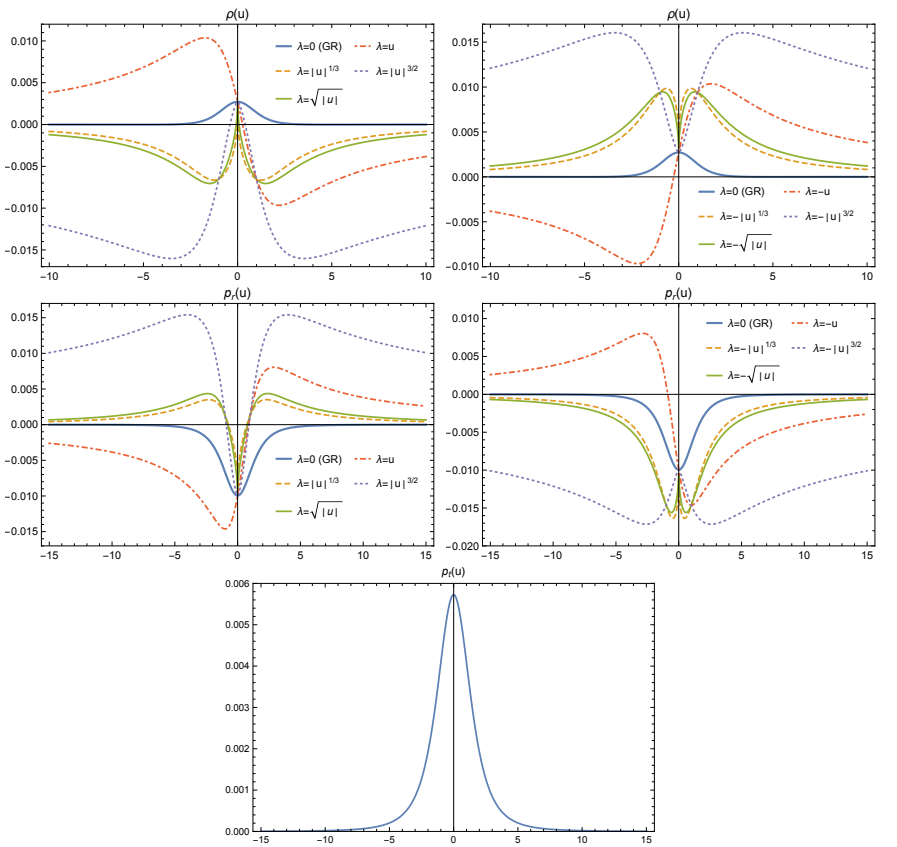

Fig. 5. The plots depict the stress-energy profile for the black bounce III solution, given by the functions (47) and (49), for the case $n = 1$, where $a > a_{\text{ext}}$, so that there are no event horizons. We have chosen the following values for the parameters: $m = 1$ and $a = 2$. Note that for these solutions, the negative energy densities are improved, and one may also obtain positive radial pressures for positive values of the function $\lambda(u)$. See the text for more details.

Finally, we consider another black bounce solution explored in,[44] that also exhibits interesting properties, given by

$$R(u) = \sqrt{u^2 + a^2}\,. \tag{47}$$

and the mass function:

$$M(u) = m\left(\frac{R(u)}{u}\right)\left(\frac{2}{\pi}\right)^n \arctan^n\left(\frac{u}{a}\right), \tag{48}$$

so that the metric function $A(u)$ is given by

$$A(u) = 1 - \frac{2M(u)}{R(u)} = 1 - \frac{2m}{u}\left(\frac{2}{\pi}\right)^n \arctan^n\left(\frac{u}{a}\right). \tag{49}$$

In the limit $(a, n) \to 0$ we regain the Schwarzschild solution. However, one can fix n and regulate the presence of horizons by adjusting a. For instance, consider $n = 1$, where the extreme case is given by $a_{\rm ext} = 4m/\pi$.[44]

The causal structure, for the specific case of $n = 1$, is given by: (i) for $a > a_{\rm ext}$, this corresponds to the traditional two-way traversable wormhole; (ii) for $a = a_{\rm ext}$, we have a one-way wormhole geometry with an extremal null throat; (iii) for $a < a_{\rm ext}$, we have one horizon located in each universe, where one may propagate through this event horizon, located at $u = u_+$ in order to reach the spacelike "bounce" hypersurface at $u = 0$, before "bouncing" into a future version of our own universe. We refer the interested reader to Ref.[44] for more details. Thus, we are only interested in the case $a > a_{\rm ext}$, for $n = 1$, where there are no event horizons.

Taking into account the metric functions (47) and (49), the gravitational field equations (17)–(19) provide the following stress-energy components:

$$\rho(u) = -\frac{1}{8\pi}\left\{\frac{a^2}{\left(a^2+u^2\right)^2}\left[1 - \frac{2m}{ua}\left(\frac{2}{\pi}\right)^n\left(\arctan\left(\frac{u}{a}\right)\right)^{n-1}\left(a\arctan\left(\frac{u}{a}\right) + nu\right)\right] + \frac{\lambda(u)}{a^2+u^2}\right\}, \tag{50}$$

$$p_r(u) = \frac{1}{8\pi}\left\{\frac{2ma}{u\left(a^2+u^2\right)^2}\left(\frac{2}{\pi}\right)^n\left(\arctan\left(\frac{u}{a}\right)\right)^{n-1}\left[a\arctan\left(\frac{u}{a}\right) - nu\right] + \frac{\left(a^2+u^2\right)\lambda(u) - a^2}{(a^2+u^2)^2}\right\}, \tag{51}$$

$$p_t(u) = \frac{a^2}{8\pi(a^2+u^2)^2}\left\{1 - \frac{m}{au^3}\left(\frac{2}{\pi}\right)^n\left(\arctan\left(\frac{u}{a}\right)\right)^{n-2} \times\left[2\left(a^3+2au^2\right)\left(\arctan\left(\frac{u}{a}\right)\right)^2 - 2nu\left(a^2+u^2\right)\arctan\left(\frac{u}{a}\right) + a(n-1)nu^2\right]\right\}. \tag{52}$$

respectively. Here, we will only consider, for simplicity, the specific case of $n = 1$ and $a > a_{\rm ext}$.

If we consider, as before, a power law for $\lambda(u) \sim u^\alpha$, the asymptotic flatness and regularity conditions impose $0 \leq \alpha < 2$. Once again, one obtains a wide variety of solutions, both symmetric and asymmetric, which are depicted in Fig. 5. The

advantage of these solutions consists essentially in that they ameliorate the negative energy densities for negative values of the function $\lambda(u)$. However, positive values of the function $\lambda(u)$ allow positive radial pressures as is transparent in Fig. 5. The tangential pressure tends to zero at spatial infinity, i.e., $p_t(u) \to 0$ for $u \to \pm\infty$, and possesses a maximum at the throat, as depicted in Fig. 5.

4. Conclusions

In this work, we have explored wormhole geometries in the recently proposed action-dependent Lagrangian theories,[28] that are obtained through an action principle for action-dependent Lagrangians by generalizing the Herglotz variational problem for several independent variables. An interesting feature of these theories as compared with previous implementations of dissipative effects in gravity is the possible arising of such phenomena from a least action principle, so they are of a purely geometric nature. It was shown that the generalized gravitational field equation essentially depends on a background four-vector λ^μ, that plays the role of a coupling parameter associated with the dependence of the gravitational Lagrangian upon the action, and may generically depend on the spacetime coordinates. In the context of wormhole configurations, we have used the "Buchdahl coordinates", and found that the four-vector is given generically by $\lambda_\mu = (0, 0, \lambda_\theta(u, \theta), 0)$. In addition to this restriction the spacetime geometry is also severely constrained by the condition $g_{tt}g_{uu} = -1$, where u is the radial coordinate.

More specifically, we have shown that the field equations (17)–(19), impose a system of three independent equations with six unknown functions of the radial coordinate u, namely, $\rho(u)$, $p_r(u)$, $p_t(u)$, $A(u)$, $R(u)$ and $\lambda(u)$. Thus, one possesses several strategies to solve the system of equations. For instance, one may consider a plausible stress-energy tensor profile by imposing equations of state $p_r = p_r(\rho)$ and $p_t = p_t(\rho)$, and close the system by adequately choosing the energy density, or a specific metric function. However, one may also adopt the reverse philosophy approach usually used in wormhole physics by simple choosing specific choices for the metric functions and $\lambda(u)$, and through the field equations determine the stress-energy profile responsible for sustaining the wormhole geometry. Here, we have found a plethora of specific asymptotically flat, symmetric and asymmetric, solutions with power law choices for the function λ, for instance, by generalizing the Ellis-Bronnikov solutions and the recently proposed black bounce geometries, amongst other solutions. We have shown that these compact objects possess a far richer geometrical structure than their general relativistic counterparts. It would be interesting to investigate time-dependent spacetimes as outlined in[17,18] in order to explore the energy conditions, and work along these lines is presently underway.

Gravitational lensing by wormholes in binary systems

S. Pietroni

E-mail: spietroni@unisa.it

We investigate binary lenses with $1/r^n$ potentials in the asymmetric case with two lenses with different indexes n and m. These kinds of potentials have been widely used in several contexts, ranging from galaxies with halos described by different power laws to lensing by wormholes or exotic matter.

Keywords: Gravitational lensing; black holes; wormholes; galaxies

1. Introduction

Space-time is curved by the presence of massive bodies and this curvature influences the motion of the bodies themselves: this leads to a geometry in constant evolution. One of the consequences is that even light, supposed to be massless, bends its trajectory while passing close to a massive body.[1]

Gravitational lensing is an important tool in astrophysics and in cosmology widely used to study both populations of compact objects (including exoplanets, black holes and other stellar remnants) , and extended objects, such as galaxies, clusters of galaxies and large-scale structures . Since most of the mysteries of our Universe do not show up in observations based on electromagnetic interactions, gravitational lensing is more and more employed to study the dark side of the Universe, including dark matter, dark energy, and any kind of exotic matter (such as wormholes) conjectured by theorists.[2]

2. Lensing by Wormholes

The metric of the Ellis wormhole falls down asymptotically as $1/r^2$ and its deflection angle goes as the inverse square of the impact parameter $1/u^2$.

Metrics falling as $1/r^n$ were investigated also by Kitamura et al.[3] who found out that the deflection angle falls down with the same exponent as the metric, $\hat{\alpha} \sim 1/u^n$ with $n > 1$, and that a demagnification of the total lensed images could appear at $\beta > \frac{2}{n+1}$ (in units of θ_E, the Einstein radius, and under a large-n approximation, β is the source position). This demagnification effect may be evidence of an Ellis wormhole and it might be used for hunting the search for exotic matter. Particular attention was posed on the study of caustics of $1/r^n$ binary lenses by Bozza and Melchiorre in Ref.[4]

The implications for the energy-momentum tensor supporting this kind of metrics falling as $1/r^n$ were investigated by Bozza and Postiglione,[5] we remind that $0 < n < 1$ may describe galactic halos, $n > 1$ would be the signature of a violation of the weak energy condition and so the existence of exotic matter, $n = 2$ correspond to the Ellis wormhole; n is the ratio between tangential and radial pressure, $n = -2p_t/p_r$.

3. The Lens Equation, Critical Curves and Caustics

In a binary system composed by two lenses (binary lenses, A and B), the lens equation can be written as follows

$$\vec{\beta} = \vec{\theta} - \frac{\vec{\theta} - \vec{\theta_A}}{|\vec{\theta} - \vec{\theta_A}|^{n+1}} - \gamma^{m+1} \frac{\vec{\theta} - \vec{\theta_B}}{|\vec{\theta} - \vec{\theta_B}|^{m+1}}, \tag{1}$$

where $\gamma = \theta_{E,B}/\theta_{E,A}$ is the "strength ratio".

The lens equation allows us to find images, given the source position and a lens configuration.

The number of images formed at a given source β depends on the source position and these regions with a different number of images are delimited by caustics.

The condition $J(z) = 0$ (the Jacobian determinant of the lens map) defines the critical curves on the lens plane; and by applying the lens map on critical points we find the corresponding points on the source plane, which form the caustics. When a source crosses a caustic, a new pair of images is created on the corresponding point in the critical curve.

4. Cases and Topology Regimes

We investigated 3 cases: the equal-strength binary with $\gamma = 1$, the unequal-strength binary with $\gamma = \sqrt{0.1}$ (the bigger lens is the standard one with fixed $n = 1$), and the reversed unequal-strength binary with $\gamma = \sqrt{0.1}$ (the standard lens is the smaller one).

For the standard binary Schwarzschild lens in the equal-strength case, we know that three topologies exist:

- close separation, for $s < s_{CI}$;
- intermediate separation, for $s_{CI} < s < s_{IW}$;
- wide separation, for $s > s_{IW}$;

and the two transitions are $s_{CI} = 1$ and $s_{IW} = 2\sqrt{2}$ in our units.

The three topologies exist for any value of m and n.

Our model contains 4 parameters: the indexes of the two potentials n, m, the separation between the two lenses s, and the ratio of the two Einstein radii γ.

5. Critical Curves and Caustics: Wide, Intermediate and Close Separations

Here we show the equal-strength case with $\gamma = 1$, the full research can be found in: *Bozza V., Pietroni S., Melchiorre C., Universe 2020, 6(8), 106*.[6]

The red curve is for the standard Schwarzschild case $n = m = 1$, we keep $n = 1$ for the first lens and we see what happens when m varies in the second lens

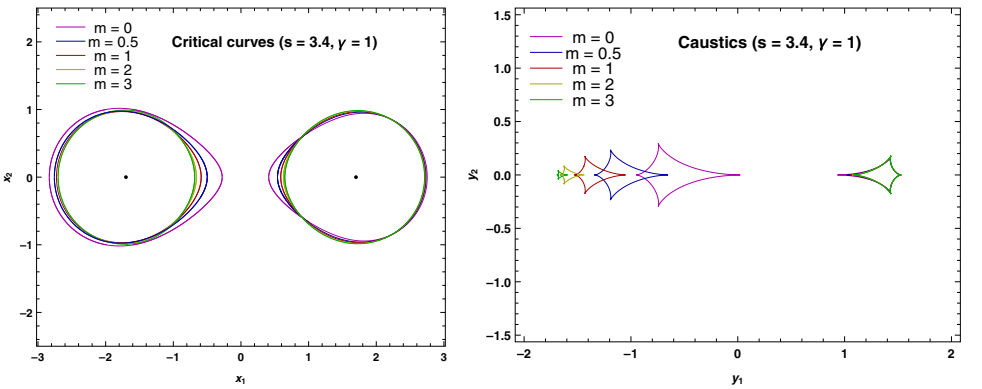

Fig. 1. Critical curves and caustics in the equal-strength binary, wide separation with fixed $n = 1$ and variable m: $m = 0$ is the singular isothermal sphere already investigated by Shin and Evans, $m = 0.5$ is the galactic halo, $m = 2$ is the Ellis wormhole and $m = 3$ is for exotic matter.

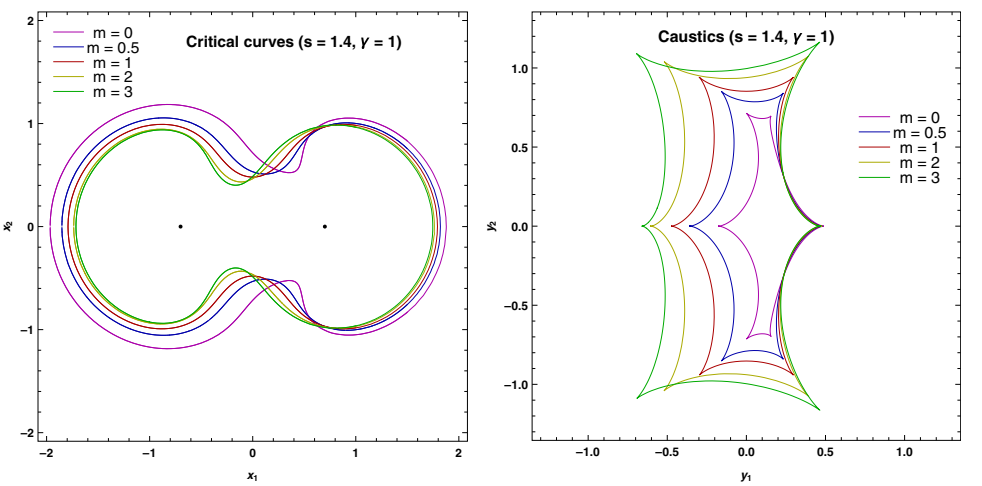

Fig. 2. Critical curves and caustics in the equal-strength binary, intermediate separation with fixed $n = 1$ and variable m. The red curve is for the standard Schwarzschild case $n = m = 1$.

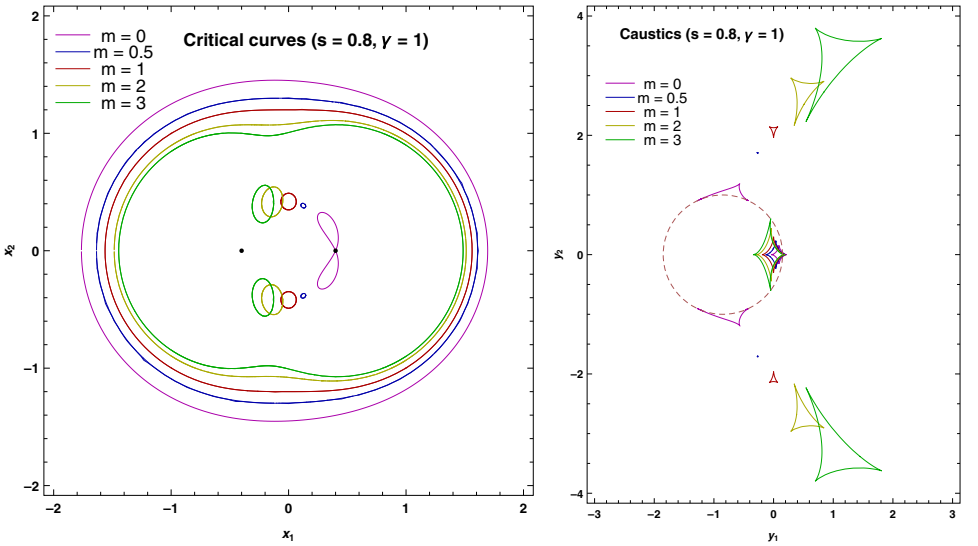

Fig. 3. Critical curves and caustics in the equal-strength binary, close separation with fixed $n = 1$ and variable m. The red curve is for the standard Schwarzschild case $n = m = 1$. Dashed magenta circle indicates the pseudocaustic for $m = 0$.

6. The Elliptic Umbilic and the Extremely Unequal-Strength Ratio Limit

In the range $0 \leq m < 1$ an *elliptic umbilic catastrophe* exists in the close separation. The value of s at which the catastrophe happens is

$$s_{euc} = \left(\frac{1-mn}{m+1}\right)^{\frac{1}{n+1}} \sqrt{1 + \frac{\gamma^2 (m+1)^{\frac{2}{n+1}}}{(n+1)^{\frac{2}{m+1}} (1-mn)^{\frac{2(m-n)}{(m+1)(n+1)}}}}. \tag{2}$$

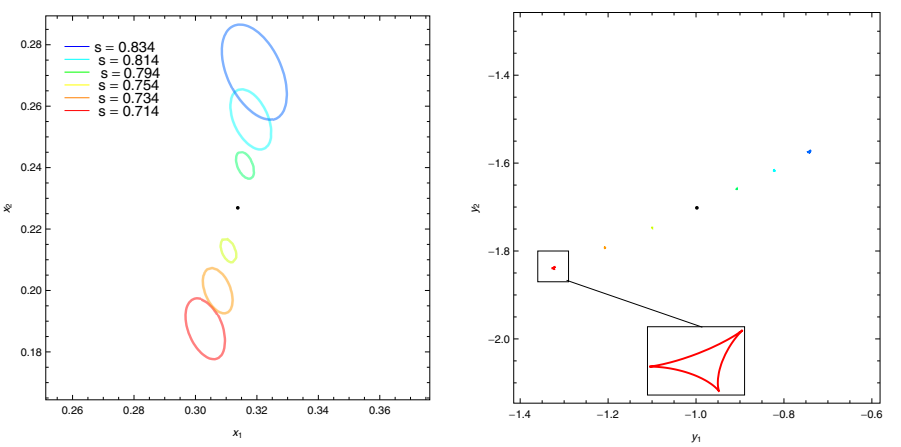

Fig. 4. The elliptic umbilic catastrophe for $n = 2$, $m = 0.25$. The separation at which the catastrophe occurs is $s_{euc} = 0.774$.

For any n, m, γ we found the boundaries for s_{CI}, given only numerically, and the analytical expression for s_{IW}.

The caustic evolution in the extreme limit $\theta_{E,B} << \theta_{E,A}$, in the case of two Schwarzschild objects ($n = m = 1$), is the so-called "planetary" limit. For the caustics of the perturbing object in the wide case we have an extension of the caustics in the parallel and in the vertical direction:

$$\Delta\zeta_{||,wide} = 2(n+1)\frac{\gamma}{s^{\frac{m(n+1)}{m+1}}\left(s^{n+1}-1\right)^{\frac{1}{m+1}}} \tag{3}$$

$$\Delta\zeta_{\perp,wide} = 2(n+1)\frac{\gamma}{s^{\frac{m(n+1)}{m+1}}\left(s^{n+1}+n\right)^{\frac{1}{m+1}}}. \tag{4}$$

7. Conclusions

These mixed binary lenses are important from the astrophysical point of view in the investigation of pairs of galaxies with different halos ($n, m < 1$), in the opening of a new channel in the search for wormholes when they appear in a non-isolated environment ($n = 1$, $m = 2$), in the case in which one object is made up of exotic matter and the other one is a normal star ($n \geq 2$, $m = 1$).

Hyper-fast positive energy warp drives

E. W. Lentz
Pacific Northwest National Laboratory, Richland, WA 99354 USA
E-mail: erik.lentz@pnnl.gov

Solitons in space–time capable of transporting time-like observers at superluminal speeds have long been tied to violations of the weak, strong, and dominant energy conditions of general relativity. This trend was recently broken by a new approach that identified soliton solutions capable of superluminal travel while being sourced by purely positive energy densities. This is the first example of hyper-fast solitons satisfying the weak energy condition, reopening the discussion of superluminal mechanisms rooted in conventional physics. This article summarizes the recent finding and its context in the literature. Remaining challenges to autonomous superluminal travel, such as the dominant energy condition, horizons, and the identification of a creation mechanism are also discussed.

Keywords: Warp Drive; Energy Conditions; Weak Energy Condition; Superluminal Travel.

1. Introduction

One of the most prominent critiques of superluminal travel within Einstein's general relativity (GR) is that any geometry that facilitates such travel must be largely sourced by a form of negative energy density.[1–18] Other concerns include the immense (magnitude) energy requirements to create a soliton, the difficulty associated with constructing a soliton from a nearly flat spacetime up to the superluminal phase, where the transported central observers become surrounded by a horizon, and the equal difficulties of driving the superluminal phase back the nearly flat spacetime.

There has been a recent uptick in interest regarding warp drives due to a set of papers made available in 2020 and 2021 claiming the construction of solutions that do not require sources with negative energy density,[19–22] obeying the weak energy condition (WEC). These increasingly physical warp drives were the focus of a mini-session at the 16^{th} Marcel Grossmann meeting that covered the history of warp drive research in academia, the recent positive energy warp drive research papers, and two articles regarding their reception.[23,24] This article will concern only the paper written by the author,[19] summarizing its findings and discussing its standing in the literature. Mathematical notation will largely follow that of the original paper.

2. Natário Class Spacetimes

The class of relativistic spacetime metrics describing warp drive geometries in the literature are decomposed according to "3+1" Arnowitt-Deser-Misner (ADM)

formalism[25]

$$ds^2 = -\left(N^2 - N^i N_i\right) dt^2 - 2N_i dx^i dt + h_{ij} dx^i dx^j, \tag{1}$$

where the time coordinate t stratifies spacetime into space-like hypersurfaces, the space metric components h_{ij} evaluated at t provide the intrinsic geometry of that hypersurface, and the similarly-evaluated shift vector components N^i at t provide the coordinate three-velocity of the hypersurface's normal. The time-like unit normal one-form is therefore proportional to the coordinate time element $\mathbf{n}^* = N dt$, and the unit normal vector $\mathbf{n}$ to the hypersurface has components

$$n^\nu = \left(\frac{1}{N}, \frac{N^i}{N}\right). \tag{2}$$

For simplicity, we will use natural units $G = c = 1$.

The majority of previous warp drive papers including Lentz 2021[19] set the lapse function N to unity and the hypersurface metric to be flat under Cartesian coordinates $h_{ij} = \delta_{ij}$. The non-flat geometry is therefore encoded in the three-component shift vector, N_i. The class of spacetimes described in this way have been coined as "Natário spacetimes".[20,23,24]

The projection of the Einstein equation onto the hypersurface normal gives the Hamiltonian constraint of a Natário spacetime

$$G^{\mu\nu} n_\mu n_\nu = 8\pi T^{\mu\nu} n_\mu n_\nu, \tag{3}$$

with the projected stress-energy being referred to as the Eulerian energy density

$$T^{\mu\nu} n_\mu n_\nu = T^{00} = E. \tag{4}$$

The geometric side of this energy constraint equation can be expressed in terms of the extrinsic curvature's trace $K = K^i_i$ and its quadratic hypersurface scalar $K^i_j K^j_i$

$$8\pi E = \frac{1}{2}\left(-K^i_j K^j_i + K^2\right). \tag{5}$$

The combination of extrinsic curvatures expanded in terms of the shift vector components take the form

$$\begin{aligned} K^2 - K^i_j K^j_i = {} & 2\partial_x N_x \partial_y N_y + 2\partial_x N_x \partial_z N_z + 2\partial_z N_z \partial_y N_y \\ & - \frac{1}{2}\left(\partial_x N_y + \partial_y N_x\right)^2 - \frac{1}{2}\left(\partial_x N_z + \partial_z N_x\right)^2 - \frac{1}{2}\left(\partial_z N_y + \partial_y N_z\right)^2. \end{aligned} \tag{6}$$

The warp drive solution of Alcubierre[1] set the precedent for WEC violation by requiring negative Eulerian energy throughout. Specifically, utilizing only a single component of the shift vector in the direction of motion, here taken to be along the positive z-axis, produces the renowned toroid of negative energy density about the soliton bubble of N_z, here displayed in Cartesian coordinates,

$$E_{\text{Alc}} = \frac{-1}{32\pi}\left(\left(\partial_x N_z\right)^2 + \left(\partial_y N_z\right)^2\right). \tag{7}$$

The expansionless ($K = -1/2(\partial_x N_x + \partial_y N_y + \partial_z N_z) = 0$) elliptic relation of Natário 2002[11] restricted the energy form to the negative definite square of the extrinsic curvature

$$E_{\text{Nat}} = \frac{-1}{16\pi} K^i_j K^j_i. \tag{8}$$

Parabolic and hyperbolic relations remained to be explored at the start of 2020.

3. Positive Energy Warp Drives

The soliton geometry of Lentz 2021[19] distinguishes itself from the previous literature in that it satisfies the WEC, even when moving at superluminal speeds. The WEC states that the energy of a spacetime is nowhere negative for any time-like observer. Mathematically, this means that for any time-like vector field X, the projection with the stress-energy tensor T must be non-negative

$$X_\mu T^{\mu\nu} X_\nu \geq 0. \tag{9}$$

The positive-energy soliton was identified through the construction of a set of rules sufficient to define geometries with everywhere non-negative energy. A brief presentation of the rules is given below.

Recall the expansion of the Hamiltonian constraint of Eqn. 6. Observe that the last three elements of the above expression are negative definite, while the first three are of indeterminant type. These first three terms provide opportunity for the Eulerian energy density function to be non-negative under particular configurations, so long as they are everywhere dominate over the first three terms. The next steps focus on such configurations.

The first rule is to reduce the 3D shift vector field to a single potential function, a real-valued function ϕ with spatial gradient relating the shift vector components

$$N_i = \partial_i \phi, \tag{10}$$

satisfying a linear wave equation over the spatial coordinates

$$\partial_x^2 \phi + \partial_y^2 \phi - \frac{2}{v_h^2} \partial_z^2 \phi = \rho, \tag{11}$$

where $v_h/\sqrt{2}$ is the dimensionless wave front 'speed' on the hypersurface, and ρ is the wave equation source function, not to be confused with mass or energy density. This step provides nearly all the structure needed to find the first example positive energy drives.

Two more simplifications are used to set sufficient rules for positive Eulerian energy. The energy functional is reduced to a two-coordinate form (z, x) by restricting ρ and ϕ to be parameterized in the (x, y) plane by the l_1 norm $s = |x| + |y|$,

$$E = \frac{1}{16\pi} \left(2\partial_z^2 \phi \left(\rho + \frac{2}{v_h^2} \partial_z^2 \phi \right) - 4 \left(\partial_z \partial_x \phi \right)^2 \right), \tag{12}$$

which can be bounded from below by

$$16\pi E \geq 2\rho \times \partial_z^2 \phi$$
$$= \rho \times \frac{1}{2v_h} \int_{-\infty}^{\infty} dx' \partial_r \rho(r, |x'| + |y|)|_{r=z-|\Delta x|/v_h}, \tag{13}$$

where the Green's expressions for the shift vector is used in the last expression. From the lower bound expression, the last rule is formed to ensure the Eulerian energy density is everywhere non-negative: the energy function will be non-negative for configurations such that the local source density and the z-component source density gradient integrated along the intersecting 'past' wave trajectories are of the same sign. In other words, the two factors in Expr. 13 must have the same sign.

It is from this sequence of rules that the Eulerian energy can be constrained to be non-negative. Demonstrating the fullness of the WEC takes several additional steps to understand the contributions of the Eulerian momentum and stress components, and is covered in detail in the original publication,[19] but are omitted here in the interest of space. The rules invoked are not strictly necessary to positive-energy warp drives. The solution space of physical warp drives is expected to be much larger and more diverse.

The shift vector of the positive-energy soliton created in Lentz 2021[19] is given in Fig. 1. The soliton moves along the positive z axis at a speed set by the value of the shift vector at the origin of the co-moving coordinate coordinates in Fig. 1, which may be given arbitrary positive value. The transport logistics of the solitons are then similar to that of the Alcubierre solution. The solitons are constructed to contain a central region with minimal tidal forces, where proper time coincides with asymptotic coordinate time, and any Eulerian observer – which in this case is free falling and whose velocity matches the shift vector – within the central region would remain stationary with respect to the soliton. This is the region where a spacecraft would be placed.

The total energy requirements of the positive-energy solitons closely follow that of Pfenning & Ford 1997[3] as applied to the Alcubierre solution

$$E_{tot} = \int E\sqrt{-g} d^3x. \tag{14}$$

For solitons where the radial extent of the central region R is much larger than the thickness of the energy-density laden boundary shell w ($w \ll R$), the energy is estimated to be

$$E_{tot} \sim C v_s^2 \frac{R^2}{w} \tag{15}$$

where C is a form factor typically of order unity. The required energy for a positive-energy soliton with central region mean radius $R = 100$ m and average source thickness along the z-axis $w = 1$ m approaches a mass equivalent of $E_{tot} \sim$ (few) $\times$ $10^{-1} M_{\odot} v_s^2$, which is of the same magnitude as the estimate of an Alcubierre solution of the same dimensions.

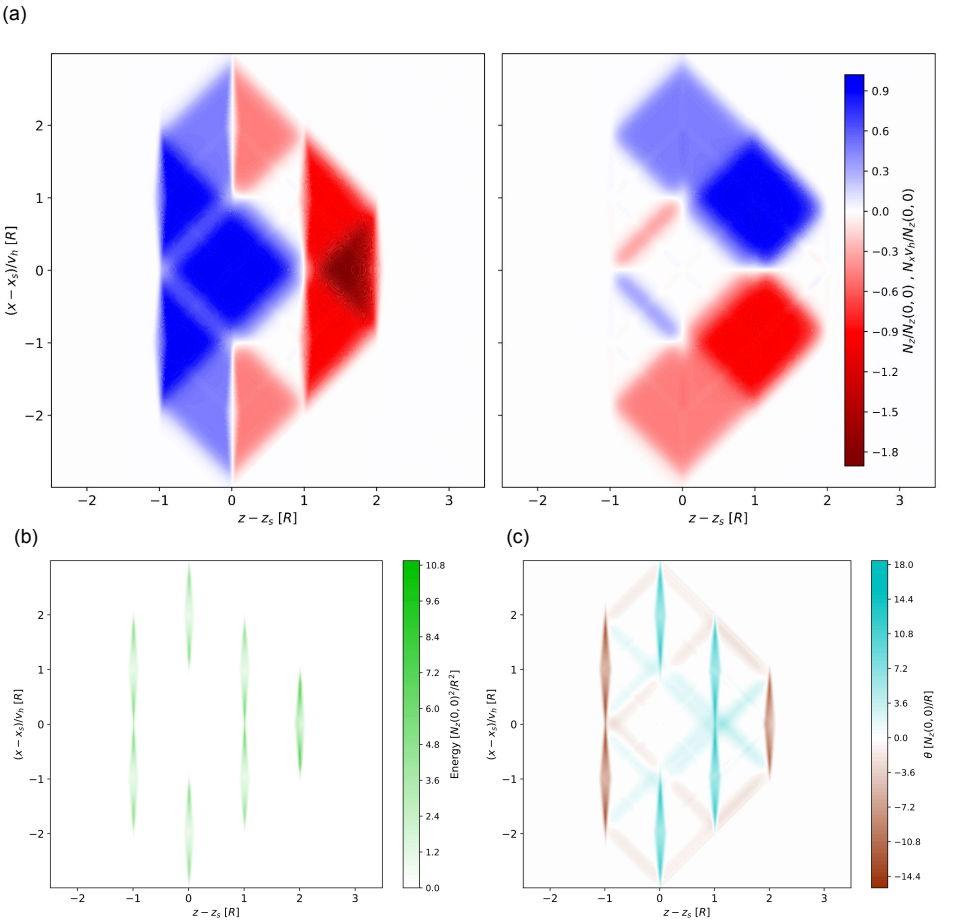

Fig. 1. (a) Projection of the shift vector components N_z (left) and N_x (right) along $(x, 0, z)$. Propagation direction of the soliton is from left to right along the z-axis. The multi-compartment structure is a distinct departure from the single top-hat soliton found in Alcubierre 1994[1] and Natário 2002.[11] Total integrated shift in each direction is 0. Note that the shift vector components are normalized with respect to the value of N_z a the co-moving origin. (b) Projection of the local energy density. The energy density is dominated by those regions containing hyperbolic source ρ, but also extends weakly to the boundaries of the wavefronts. The energy density is everywhere positive for Eulerian observers. (c) Projection of the local volume expansion factor θ. Positive and negative expansion factor are largely associated with negative and positive hyperbolic sources respectively. Non-zero expansion factor also exist in the spaces in-between hyperbolic sources along the hyperbolic wavefronts. Total integrated expansion factor is 0. These plots are taken from Lentz 2021.[19]

4. Addressing the Literature

The findings of Lentz 2021[19] run against the common wisdom of the warp drive literature to that point and the proofs set forth in Olum 1999[6] and Lobo & Crawford

2003[13] stating that any superluminal spacetime must violate the WEC via violations of the null energy condition (NEC). The proofs are both based on an analysis of the Raychaudhuri equation for null geodesics, confined to spacetimes with only a single fastest (superluminal) causal path between two space-like 2-surfaces. The pre-conditions of these proofs are very local in nature and appear analogous to collapsing the interior of a warp drive soliton to a point in order to produce a single fastest causal path. The solitons of the early literature, such as Alcubierre 1994[1] and Natário 2002,[11] have simple structures and can survive this limit. The example positive energy warp drive of Lentz 2021[19] cannot undergo this limit without being destroyed. This drive therefore does not meet the pre-conditions of the proofs and exists outside their scope, implying that the proofs are not applicable.

Several warp drive papers have addressed the findings of Lentz 2021[19] since an early manuscript of it was made publicly available.[20,22,23,23,26] Of particular note, the papers of[23,24] have made several assertions claiming that the solution of Lentz 2021[19] cannot satisfy the WEC. Follow-up correspondence with the authors as well as discussion captured at the recent Marcel Grossmann meeting have demonstrated that these papers did not adequately analyze the contents of Lentz 2021.[19] To summarize the discussions, Santiago et al.[23,24] argue that the Eulerian energy density of a soliton in a Natário class spacetime can be written as the sum of a total divergence and a negative definite term

$$E = \frac{1}{16\pi}\left(\partial_i\left(N_i\partial_j N_j - N_j\partial_j N_i\right) - \frac{1}{2}\omega_i\omega_i\right), \tag{16}$$

where $\omega_i = \epsilon_{ijk}\partial_k N_j$ is the shift vector vorticity. The divergence term is then argued to produce zero net energy if the warp drive is finite in size due to an application of the divergence theorem on the hypersurface where the integral's volume boundary is extended towards infinity where the divergence kernel quickly vanishes, implying that the total Eulerian energy of a Natário spacetime is non-positive. This argument does not hold in the case of Lentz 2021[19] as the Eulerian energy density of the example positive energy soliton is smooth save for the boundaries $x = 0$ and $y = 0$ where stress-energy sources are only continuous, while a requirement of the divergence theorem is that the total divergence be at least first order smooth everywhere. The integral volume boundary therefore cannot be separated from the soliton and instead must be applied in a patchwork,[27] with some boundaries running adjacent to the 2-surfaces $x = 0$ and $y = 0$, where the divergence kernel is non-vanishing. Expansion beyond Natário class of spacetimes may smooth the geometry and sources of positive energy warp drives further.

5. Further Challenges and Future Prospects

There are still numerous challenges between the current state of physical warp drive research and a functioning prototype. I list here several of the more near-term challenges and give my perspective as to how research in these areas may be approached.

The most glaring challenge is the astronomical energy cost of even a modest warp drive, currently measured in solar masses where kilograms is closer to the threshold of human technology. Extreme energy savings is going to be necessary – tens of orders of magnitude – to bring the energy required for a warp drive down to a level that can be tested in a laboratory setting let alone be considered a viable transportation technology.

There exist numerous techniques for reducing the energy requirements of the Alcubierre solution, several of which have been very successful in reducing the (magnitude) energy requirements of the system in excess of thirty orders of magnitude.[7, 10, 16, 18, 28] Unfortunately, each one of these methods in their presented forms require negative energies themselves. One possible approach to uncovering significant energy savings is to modify one of these existing techniques to obey the WEC.

If the required energy can be sufficiently reduced, the next hurdle to approach is modeling the full life cycle of a physical warp drive (creation, acceleration, inertial motion, deceleration, and diffusion). Every previous publication in the field of warp drives has either assumed inertial motion (constant velocity) or has produced an accelerating/decelerating drive that violates the law of covariant conservation of stress-energy-momentum

$$\nabla \cdot \mathbf{T} = \mathbf{0}, \tag{17}$$

that accompanies the Einstein equation. Deriving mechanisms for creation and acceleration is crucial to any experimental test.

The last hurdle I will mention is the full characterization of the sourcing fields, whether it be a plasma or other state of matter and energy. As stated by Matt Visser in the Q&A of my talk, the specification of the drive geometry only is an incomplete description of the full solution. Stress-energy sources must be specified to close the system. In the hypothetical plasma of Lentz 2021,[19] the stress-energy governing equations include the Maxwell equations for the electric and magnetic fields, the equations of motion for each species of matter, and various constituent equations governing the state of the Einstein-Maxwell-matter system. The total system is expected to be far too complex to provide analytical solutions, requiring numerical simulation as the primary means to specify each field of a soliton at any point in its life cycle.

From black-bounce to traversable wormhole, and beyond

Alex Simpson

School of Mathematics and Statistics, Victoria University of Wellington, PO Box 600, Wellington 6140, New Zealand
E-mail: alex.simpson@sms.vuw.ac.nz

Key results from the literature pertaining to a class of nonsingular black hole mimickers are explored. The family of candidate spacetimes is for now labelled the 'black-bounce' family, stemming from the original so-called 'Simpson–Visser' spacetime in static spherical symmetry. All model geometries are analysed through the lens of standard general relativity, are globally free from curvature singularities, pass all weak-field observational tests, and smoothly interpolate between regular black holes and traversable wormholes. The discourse is segregated along geometrical lines, with candidate spacetimes each belonging to one of: static spherical symmetry, spherical symmetry with dynamics, and stationary axisymmetry.

Keywords: Black-bounce, regular black hole, traversable wormhole, Simpson–Visser, Vaidya, thin-shell, black hole mimic.

1. Introduction

In classical general relativity (GR), solutions to the Einstein equations representing black holes typically contain curvature singularities at their cores. These singularities occur at a distance scale that only a complete theory of quantum gravity could adequately describe. In the absence of such a theory, or at least in the absence of one that has any phenomenological verification, one desirable approach is to appeal to the recent advances made in observational and gravitational wave astronomy. In view of the propagation of gravitational waves emanating from an astrophysical source being directly observed in the recent LIGO/VIRGO merger events,[1,2] it is well-motivated to explore mathematically tractable candidate spacetimes, which are curvature-singularity-free alternatives to classical black holes, through the lens of standard GR. The community hopes that LIGO/VIRGO (or more likely LISA[3]) will eventually be able to provide phenomenological evidence that allows us to delineate between specific candidate spacetimes based on their astrophysical accuracy. Theoretical physicists would then have experimentally informed clues as to which modifications to the Einstein equations are most desirable in working towards a so-called 'theory of everything' (or, indeed, whether an entirely different framework is required). Discussion regarding the extraction of astrophysical observables for nonsingular sample spacetimes in several frameworks can be found in references 4–14.

One such family of candidate geometries which models alternatives to classical black holes is the family of 'black-bounce' spacetimes.[15–20] All of these black hole mimickers are globally free from curvature singularities, pass all weak-field

observational tests of standard GR, and belong either to the class of regular black holes or traversable wormholes. By 'regular black hole', one means in the sense of Bardeen,[21] with regularity defined *via* enforcing global finiteness on nonzero curvature tensor components and Riemann curvature invariants. Regular black holes have a well-established lineage in the historical literature.[21–27] By 'traversable wormhole', one means in the sense of Morris and Thorne;[28] a horizon-free geometry with a centralised throat connecting two asymptotically Minkowski regions of spacetime and satisfying the 'flare-out' condition for the area function: $A''(r_{throat}) > 0$. Various intriguing wormhole spacetimes have been developed and explored in references 28–31.

For exposition, it is prudent to separate the discourse surrounding the family of black-bounce spacetimes along geometrical lines. Broadly speaking, there are three relevant geometrical categories: static spherical symmetry, spherical symmetry with dynamics, and stationary axisymmetry (this also *somewhat* follows the chronological development of the literature). Unless otherwise stated, all candidate spacetimes discussed have metric signature $(-,+,+,+)$ outside any would-be horizons.

2. Static spherical symmetry

2.1. *Simpson–Visser*

The so-called 'Simpson–Visser' (SV) spacetime, initially presented in reference 15, is represented by the line element

$$\mathrm{d}s^2 = -\left(1-\frac{2m}{\sqrt{r^2+\ell^2}}\right)\mathrm{d}t^2 + \frac{\mathrm{d}r^2}{\left(1-\frac{2m}{\sqrt{r^2+\ell^2}}\right)} + \left(r^2+\ell^2\right)\mathrm{d}\Omega_2^2\,. \tag{1}$$

It should be noted that the parameter 'ℓ' was in fact labelled 'a' in the original article.[15] This minor alteration is performed for consistency with the remainder of the discourse herein, as when in the axisymmetric environment of § 4, it is prudent to use ℓ in order to avoid confusion with the spin parameter from Kerr spacetime, a.

The original motivation for the construction of the metric specified by Eq. (1) was to minimally modify the Schwarzschild solution in common curvature coordinates such that the resulting candidate spacetime was globally nonsingular. It was considered that the most straightforward way to achieve this was to introduce a new scalar parameter to the line element in a tightly controlled manner; this is ℓ in Eq. (1). By minimally modifying Schwarzschild, it was hoped the result would have a high degree of mathematical tractability. When viewed as a modification of Schwarzschild, there are the following two alterations:

- $m \mapsto m(r) = \frac{mr}{\sqrt{r^2+\ell^2}}$;
- The coefficient of $\mathrm{d}\Omega_2^2$ is modified from $r^2 \to r^2+\ell^2$.

Analysis of the nonzero curvature tensor components and Riemann curvature invariants concludes that for $|\ell| > 0$, the resulting candidate spacetime is globally

regular. It was also noticed that Eq. (1) has very neat limiting behaviour. In the limit as $m \to 0$, one obtains

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + \mathrm{d}r^2 + \left(r^2 + \ell^2\right)\, \mathrm{d}\Omega_2^2 \,. \tag{2}$$

This is precisely the two-way traversable wormhole solution as presented in Morris and Thorne's aforementioned seminal paper[28] (and arguably the most straightforward of all traversable wormhole geometries). In the limit as $\ell \to 0$, Eq. (1) becomes the Schwarzschild solution in the usual curvature coordinates. The newly introduced scalar parameter ℓ can hence be viewed as quantifying the extent of the deviation away from Schwarzschild, and it invokes a rich, ℓ-dependent horizon structure. The causal structure is characterised by

$$r_H = \sqrt{(2m)^2 - \ell^2} \,, \tag{3}$$

and the candidate spacetime neatly interpolates between the following qualitatively different geometries:

- $\ell = 0$ corresponds to the Schwarzschild black hole;
- $|\ell| \in (0, 2m)$ corresponds to a regular black hole in the sense of Bardeen;
- $|\ell| = 2m$ corresponds to a one-way wormhole with an extremal null throat;
- $|\ell| > 2m$ corresponds to a two-way traversable wormhole geometry in the canonical sense of Morris and Thorne.

The Carter–Penrose diagrams for the two lesser known cases are worth closer examination; this is when $|\ell| \in (0, 2m)$ (see Fig. 1), and when $|\ell| = 2m$ (see Fig. 2).

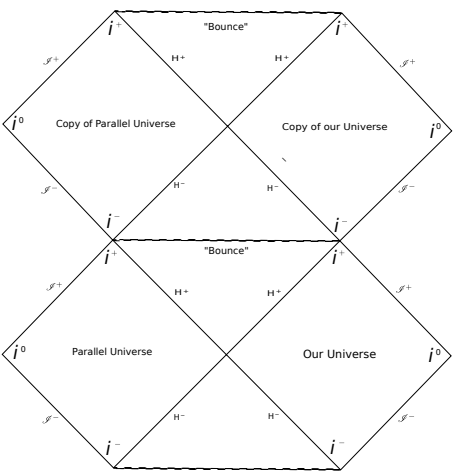

Fig. 1. Carter–Penrose diagram for the maximally extended spacetime when $|\ell| \in (0, 2m)$. In this example one 'bounces' through the $r = 0$ hypersurface in each black hole region into a future copy of the universe *ad infinitum*.

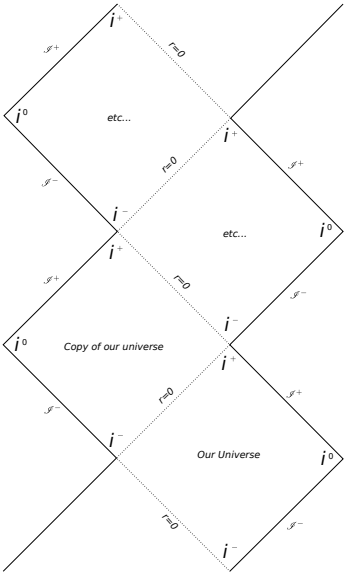

Fig. 2. Carter–Penrose diagram for the maximally extended spacetime in the case when $|\ell| = 2m$. In this example one has a one-way wormhole geometry with an extremal null throat.

Analysing the satisfaction/violation of the standard point-wise energy conditions of GR, one concludes that when $|\ell| > 0$, the radial 'null energy condition' (NEC) is manifestly violated in the region $\sqrt{r^2 + \ell^2} > 2m$. This is *outside* any would-be horizons. In the context of static spherical symmetry, this is sufficient to conclude that all of the standard point-wise energy conditions shall be similarly violated. If horizons are present, then the geometry has surface gravity

$$\kappa = \frac{\sqrt{(2m)^2 - \ell^2}}{8m^2} = \kappa_{Sch.} \sqrt{1 - \frac{\ell^2}{(2m)^2}} \,, \tag{4}$$

and hence associated Hawking temperature

$$T_H = \frac{\hbar\sqrt{(2m)^2 - \ell^2}}{16\pi\, k_B\, m^2} = T_{H,Sch.} \sqrt{1 - \frac{\ell^2}{(2m)^2}} \,. \tag{5}$$

SV spacetime is amenable to the extraction of astrophysical observables, and the coordinate locations of the photon sphere for null orbits and the ISCO for timelike orbits are straightforward, given by

$$r_\gamma = \sqrt{(3m)^2 - \ell^2} \,; \qquad r_{ISCO} = \sqrt{(6m)^2 - \ell^2} \,. \tag{6}$$

Further research analysing SV spacetime has been performed in a plethora of other papers; please see reference 32 for details. These analyses include discussion of the quasi-normal modes and associated ringdown,[33,34] calculations pertaining to shadows and gravitational lensing effects,[35–40] as well as discourse surrounding precession phenomena.[41]

2.2. *Black-bounce Reissner–Nordström*

The extension of SV spacetime which represents the black-bounce analog to Reissner–Nordström (RN) spacetime was constructed and analysed in reference 20. There is a simple regularisation procedure which can be applied to any spherically symmetric or axisymmetric geometry in possession of a curvature singularity at $r = 0$ in the standard (t, r, θ, ϕ) curvature coordinates. The procedure outputs a candidate geometry which is globally nonsingular, and maintains the manifest symmetries. It is as follows:

- Leave the object $\mathrm{d}r$ in the line element undisturbed;
- Whenever the metric components $g_{\mu\nu}$ have an explicit r-dependence, replace the r-coordinate with $\sqrt{r^2 + \ell^2}$, where ℓ is some length scale, performing the same holistic role as the ℓ parameter in SV spacetime (such parameters are often identified with the Planck scale; $\ell \sim m_p$).

It should be emphasised that this procedure is *not* a coordinate transformation. Application of this procedure to the usual RN spacetime in standard curvature coordinates yields the following line element, the 'black-bounce Reissner–Nordström' (bbRN) spacetime:

$$\mathrm{d}s^2 = -\left(1 - \frac{2m}{\sqrt{r^2+\ell^2}} + \frac{Q^2}{r^2+\ell^2}\right)\mathrm{d}t^2 + \frac{\mathrm{d}r^2}{1 - \frac{2m}{\sqrt{r^2+\ell^2}} + \frac{Q^2}{r^2+\ell^2}} + (r^2+\ell^2)\,\mathrm{d}\Omega_2^2 \ . \quad (7)$$

For $|\ell| > 0$, this spacetime neatly interpolates between nonsingular electrovac black holes and traversable wormholes in standard GR, depending on the value of the charge parameter Q and the 'bounce' parameter ℓ. When compared with standard RN spacetime, the domain for the r coordinate is extended from $r \in [0, +\infty)$ to $r \in (-\infty, +\infty)$. The presence of the additional charge term invokes a richer causal structure than that of SV spacetime. Horizons are characterised by

$$r_H = S_1\sqrt{(m + S_2\sqrt{m^2 - Q^2})^2 - \ell^2} \ . \quad (8)$$

Here $S_1 = S_2 = \pm 1$, with S_1 fixing which universe one is in, and S_2 determining whether it is an outer ($S_2 = +1$) or inner ($S_2 = -1$) horizon. There are several qualitatively different geometries:

- $|Q| > m$: There are no horizons, and the geometry models a two-way traversable wormhole in the sense of Morris and Thorne;
- $|Q| \leq m$ but $|\ell| > m \pm \sqrt{m^2 - Q^2}$: first the inner, and then the outer horizons vanish, leaving a traversable wormhole;
- $|Q| = m$ and $|\ell| \leq m$: one finds extremal horizons at $r_H = \pm\sqrt{m^2 - \ell^2}$;
- $|Q| \leq m$ and $|\ell| < m - \sqrt{m^2 - Q^2}$: one observes the 'standard' causal structure of both an inner and outer horizon present in each universe.

If horizons are present, the surface gravity of the outer horizon is given by

$$\kappa = \frac{\sqrt{(m+\sqrt{m^2-Q^2})^2-\ell^2}\sqrt{m^2-Q^2}}{(m+\sqrt{m^2-Q^2})^3} = \kappa_{\rm RN}\sqrt{\frac{r_H^2}{r_H^2+\ell^2}}\ . \tag{9}$$

The following astrophysical observables are amenable to extraction; firstly the location of the photon sphere

$$r_\gamma = \sqrt{\frac{m}{2}(9m+3\sqrt{9m^2-8Q^2})-2Q^2-\ell^2}\ , \tag{10}$$

and also the location of the ISCO for timelike particles

$$r_{ISCO} = \frac{\sqrt{9m^4Q^4-6m^2Q^2(A^2+2Am^2+4m^4)+(A^2+2Am^2+4m^4)^2-A^2\ell^2m^2}}{mA},$$

$$A = \left[2m^2Q^4+m^2(\pm B-9m^2)Q^2+8m^6\right]^{\frac{1}{3}}\ , \quad B=\sqrt{4Q^4-9m^2Q^2+5m^4}\ . \tag{11}$$

In standard GR, the stress-energy tensor takes the following form outside the outer horizon (or inside the inner horizon):

$$\frac{1}{8\pi}G^{\hat\mu}{}_{\hat\nu} = T^{\hat\mu}{}_{\hat\nu} = [T_{\rm bb}]^{\hat\mu}{}_{\hat\nu} + [T_Q]^{\hat\mu}{}_{\hat\nu} = {\rm diag}(-\rho,p_r,p_t,p_t)\ , \tag{12}$$

whilst in between the two horizons one has

$$\frac{1}{8\pi}G^{\hat\mu}{}_{\hat\nu} = T^{\hat\mu}{}_{\hat\nu} = [T_{\rm bb}]^{\hat\mu}{}_{\hat\nu} + [T_Q]^{\hat\mu}{}_{\hat\nu} = {\rm diag}(p_r,-\rho,p_t,p_t)\ , \tag{13}$$

where $[T_{\rm bb}]^{\hat\mu}{}_{\hat\nu}$ is the gravitational stress-energy tensor (identical to that of SV spacetime), and $[T_Q]^{\hat\mu}{}_{\hat\nu}$ is the charge-dependent contribution, corresponding to the electromagnetic stress-energy tensor. Isolating the charge-dependent components, it is straightforward to make the following decomposition

$$[T_Q]^{\hat\mu}{}_{\hat\nu} = \frac{Q^2r^2}{8\pi(r^2+\ell^2)^3}\left[{\rm diag}(-1,-1,1,1)+{\rm diag}(\frac{2\ell^2}{r^2},0,0,0)\right]$$

$$= [T_{\rm Maxwell}]^{\hat\mu}{}_{\hat\nu} + \Xi\, V^{\hat\mu}V_{\hat\nu}\ , \tag{14}$$

where $[T_{\rm Maxwell}]^{\hat\mu}{}_{\hat\nu}$ is the usual stress-energy associated with standard Maxwell electromagnetism, and $\Xi\, V^{\hat\mu}V_{\hat\nu}$ is interpreted as the stress-energy of "charged dust", with $V^{\hat\mu}$ being the normalised time-translation Killing vector. The density of the charged dust, Ξ, is given by

$$\Xi = -\frac{1}{4\pi}\frac{Q^2\ell^2}{(r^2+\ell^2)^3}\ , \tag{15}$$

while the electric field strength is determined *via*

$$[T_Q]^{\hat t}{}_{\hat t} = -\rho_{\rm em} = [T_{\rm Maxwell}]^{\hat t}{}_{\hat t} - \Xi = -\frac{1}{8\pi}E^2 - \Xi\ ;$$

$$\implies \quad E = \frac{Qr}{(r^2+\ell^2)^{\frac{3}{2}}} = E_{\rm RN}\left[\frac{r^3}{(r^2+\ell^2)^{\frac{3}{2}}}\right]\ , \tag{16}$$

where $E_{\rm RN}$ is the electric field strength for a usual RN black hole. The electromagnetic potential is readily obtained *via* integration of Eq. (16),

$$A_\mu = (\Phi_{\rm em}(r), 0, 0, 0) = -\frac{Q}{\sqrt{r^2+\ell^2}}(1,0,0,0)\ , \tag{17}$$

which is simply the RN electromagnetic potential under the mapping $r \to \sqrt{r^2+\ell^2}$. All told, one has:

$$[T_Q]^{\hat\mu}{}_{\hat\nu} = \frac{1}{4\pi}\left[-F^{\hat\mu}{}_{\hat\alpha}F^{\hat\alpha}{}_{\hat\nu} - \frac{1}{4}\delta^{\hat\mu}{}_{\hat\nu}F^2\right] - \frac{1}{4\pi}\frac{Q^2\ell^2}{(r^2+\ell^2)^3}\,V^{\hat\mu}V_{\hat\nu}\ ,$$

$$\text{with}\quad F_{\hat\mu\hat\nu} = \nabla_{\hat\mu}A_{\hat\nu} - \nabla_{\hat\nu}A_{\hat\mu}\ . \tag{18}$$

Consequently, in standard GR the bbRN spacetime possesses stress-energy components which are interpreted as everywhere-SV in the gravitational sector, coupled to standard Maxwell's electromagnetism in the presence of charged dust in the electromagnetic sector.

2.3. *Generalised extensions to Simpson–Visser*

Further extensions to the SV line element in the context of static spherical symmetry were explored in reference 16, with some useful general theorems also being presented. The first of these theorems is general to all static spacetimes, and is concerned with expediting the 'usual' test for curvature-regularity; examination of the finiteness of all nonzero components of the Riemann curvature tensor in an orthonormal basis. It is as follows, with the proof provided in reference 16:

Theorem 2.1. *For any static spacetime, in the strictly static region, the Kretschmann scalar is positive semi-definite, being a sum of squares which involves all of the nonzero components* $R^{\hat\mu\hat\nu}{}_{\hat\alpha\hat\beta}$. *Then if this scalar is finite, all of the orthonormal components of the Riemann curvature tensor must also be finite. Consequently, for static candidate spacetimes, confirmation of the global finiteness of the Kretschmann scalar is sufficient to conclude as to curvature-regularity in the sense of Bardeen.*

It is by now well-known that the most general static spherically symmetric line element can always locally be put into the following form, typically known as "Buchdahl" coordinates[42–46] (for § 2.3 only, the metric signature $(+,-,-,-)$ is adopted outside horizons for consistency with the discourse in reference 16)

$$\mathrm{d}s^2 = f(r)\,\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{f(r)} - \Sigma^2(r)\,\mathrm{d}\Omega_2^2\ . \tag{19}$$

Now constrained to Buchdahl coordinates, it is straightforward to establish the following list of sufficient conditions for curvature regularity in the sense of Bardeen (note these constraints exist as an independent result from Theorem 2.1; which of the techniques is preferable/applicable should be determined from context):

- $\Sigma(r) \neq 0$ globally;
- $\Sigma'(r)$ and $\Sigma''(r)$ must be globally finite;
- $f(r)$, $f'(r)$, and $f''(r)$ must be globally finite.

With respect to Buchdahl coordinates, another theorem was presented in reference 16. Concerning satisfaction/violation of the standard point-wise energy conditions of GR, it states:

Theorem 2.2. *For any static anisotropic fluid sphere with line element as in Eq. (19), all of the standard point-wise energy conditions are violated whenever* $f(r) \neq 0$, $\Sigma(r) > 0$, *and* $\Sigma''(r) > 0$.

In the same article,[16] further decomposition of Eq. (19) *via* $f(r) = 1 - 2M(r)/\Sigma(r)$ was performed to allow for a two-parameter extension of SV spacetime. One fixes

$$\Sigma(r) = \sqrt{r^2 + \ell^2}\ , \qquad M(r) = \frac{m r^k \sqrt{r^2 + \ell^2}}{\left(r^{2n} + \ell^{2n}\right)^{\frac{k+1}{2n}}}\ , \tag{20}$$

with the form for $M(r)$ mathematically inspired by the Fan–Wang mass function for regular black holes.[27] The resulting class of geometries has the following properties:

- SV spacetime is recovered *via* fixing $n = 1, k = 0$;
- $\forall\ n, k \in \mathbb{Z}^+$, Schwarzschild in the usual curvature coordinates is recovered as $\ell \to 0$;
- Enforcing $|\ell| > 0$, $\forall\ n, k \in \mathbb{Z}^+$ the candidate geometry is globally regular.

Several models of interest possessing vibrant causal structures can be explored using Eq. (20), each corresponding to various fixed values of both n and k. All models in some fashion smoothly interpolate between regular black holes and traversable wormholes. Several other model geometries were also explored in reference 16, *via* certain modifications to the $M(r)$ present in Eq. (20), all within the geometric context of static spherical symmetry in Buchdahl coordinates.

3. Spherical symmetry with dynamics

3.1. *Vaidya black-bounce*

The SV metric was elevated to the regime of dynamical spherical symmetry in reference 17. One first rewrites the line element from Eq. (1) in Eddington–Finkelstein coordinates, before playing a Vaidya-like 'trick' by allowing the mass parameter m to be a function of the null time coordinate w. The resulting candidate spacetime is given by the following line element

$$\mathrm{d}s^2 = -\left(1 - \frac{2m(w)}{\sqrt{r^2 + \ell^2}}\right) \mathrm{d}w^2 - (\pm 2\,\mathrm{d}w\mathrm{d}r) + (r^2 + \ell^2)\,\mathrm{d}\Omega_2^2\ , \tag{21}$$

where $w = \{u, v\}$ denotes the *outgoing/ingoing* null time coordinate, representing *retarded/advanced* time respectively. In the limit as $m(w) \to m$, SV spacetime is

recovered (in Eddington–Finkelstein coordinates). Introducing dynamics in this specific manner allows for one to discuss simple phenomenological models of an evolving regular black hole/traversable wormhole geometry, either *via* net accretion or net evaporation, whilst still keeping the discourse mathematically tractable. Analysis of the radial null curves yields a dynamical horizon location

$$r_H(w) = \pm\sqrt{[2m(w)]^2 - \ell^2}\ . \tag{22}$$

While this permits analysis of numerous phenomenological models, the most qualitatively interesting are:

- Increasing $m(v)$ crossing the $\ell/2$ limit describing the conversion of a traversable wormhole into a regular black hole *via* the accretion of null dust. This qualitative scenario is depicted in Fig. 3;
- Decreasing $m(u)$ crossing the $\ell/2$ limit describes the evaporation of a regular black hole leaving a traversable wormhole remnant. The causal structure is depicted in Fig. 4. This phenomena is causally equivalent to a regular black hole transmuting into a traversable wormhole *via* the accretion of phantom energy (though mathematically this scenario would instead correspond to increasing $m(v)$ crossing the $\ell/2$ limit).

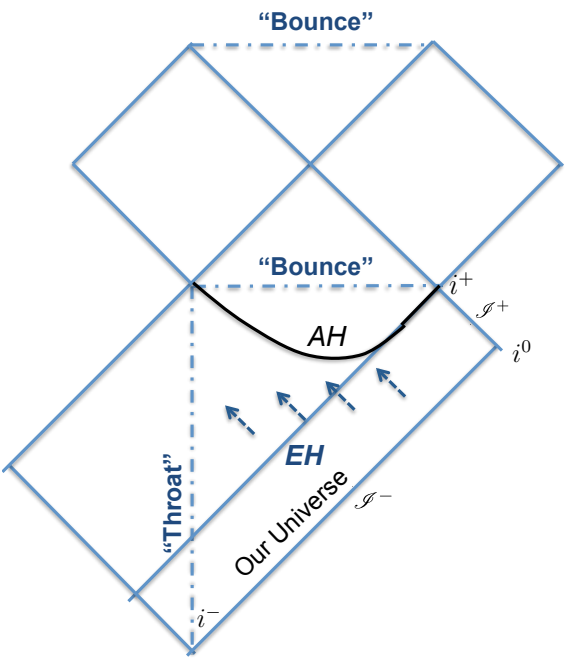

Fig. 3. Carter–Penrose diagram for a wormhole to black-bounce transition *via* accretion of null dust.

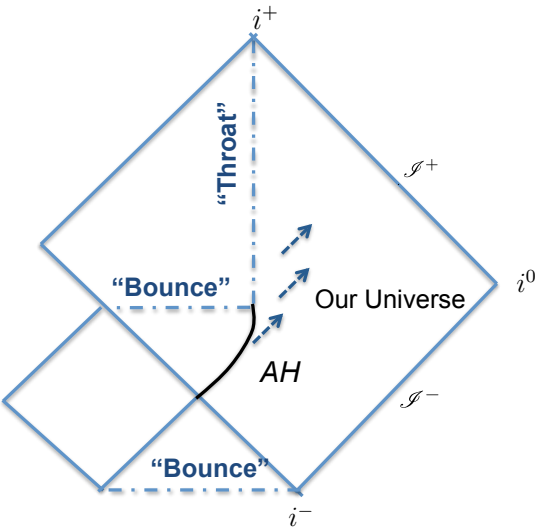

Fig. 4. Carter–Penrose diagram for a black-bounce to wormhole transition due to the emission of positive energy. This is essentially the back reaction of the Hawking evaporation for a semi-classical regular black hole; in this case leaving a wormhole remnant.

General discussion concerning evaporation/accretion models involving both regular black holes and traversable wormholes can be found in references 47–54. It is worth emphasising that one is able to classically describe the transmutation of a wormhole into a regular black hole, or *vice versa*, only because the curvature-regularity of the black hole implies there is no topology change.

In what has become a typical result for nonsingular black hole mimickers in standard GR, the candidate spacetime is found to be in global violation of the NEC. For the 'Vaidya black-bounce' spacetime, the existence of the radial null vector $k^\mu = (0, 1, 0, 0)$ implies that one has

$$T_{\mu\nu}k^\mu k^\nu \propto G_{\mu\nu}k^\mu k^\nu = -\frac{2\ell^2}{(r^2+\ell^2)^2} < 0\ . \tag{23}$$

For a full analysis of the nonzero curvature tensor components and Riemann curvature invariants for the Vaidya black-bounce geometry, as well as a more detailed discussion surrounding energy condition satisfaction/violation and various phenomenological models, please see reference 17.

3.2. *Thin-shell black-bounce traversable wormhole*

A thin-shell traversable wormhole variant of SV spacetime was constructed and analysed in reference 18. The thin-shell surgery is performed *via* a 'cut and paste' procedure which has its mathematical roots in the Darmois–Israel formalism.[55] Physically, the geometrodynamics are kept as close to standard GR as possible

via examination of the Lanczos equations (please see references 56–58 for details pertaining to thin-shell surgery).

In the thin-shell construction,[18] one analyses both the stability and the evolution of an SV thin-shell traversable wormhole under linearized radial perturbation of the throat. The 'bounce' parameter ℓ induces a nonzero flux term arising from the conservation identity due to the second contracted Gauss–Codazzi–Mainardi equation. Consequently, enforcing a nonzero ℓ leads to an additional constraint on the stability analysis. Several qualitative examples from the parameter space are explored, and the viable stability regions in each case are readily extracted.

4. Stationary axisymmetry

4.1. *Black-bounce Kerr–Newman*

The first entry from the family of 'black-bounce' spacetimes belonging to the geometrical regime of stationary axisymmetry was constructed and explored by Liberati *et al.* in reference 19. This spacetime was constructed *via* application of the Newman–Janis procedure to standard SV spacetime, and acts as the black-bounce analog to Kerr spacetime. Given that in any real, astrophysical setting, one shall have both rotation and the condition that $|Q|/m \ll 1$, this is the most astrophysically relevant member of the family of black-bounce spacetimes. The black-bounce analog to Kerr–Newman spacetime was then discovered in reference 20; this was obtained *via* application of the regularisation procedure outlined in § 2.2, applied to the Kerr–Newman geometry in standard Boyer–Lindquist (BL) coordinates. The line element is given by

$$\mathrm{d}s^2 = -\frac{\Delta}{\rho^2}(a\sin^2\theta\,\mathrm{d}\phi-\mathrm{d}t)^2+\frac{\sin^2\theta}{\rho^2}[(r^2+\ell^2+a^2)\,\mathrm{d}\phi-a\,\mathrm{d}t]^2+\frac{\rho^2}{\Delta}\,\mathrm{d}r^2+\rho^2\,\mathrm{d}\theta^2\,, \quad (24)$$

with the usual Kerr quantities modified to be

$$\rho^2 = r^2+\ell^2+a^2\cos^2\theta\,, \qquad \Delta = r^2+\ell^2+a^2-2m\sqrt{r^2+\ell^2}+Q^2\,. \quad (25)$$

In the astrophysically relevant limit as $Q \to 0$, the Kerr-analog explored in reference 19 is recovered precisely. For specifics pertaining to 'black-bounce Kerr' (bbK), please consult reference 19. Generally speaking, if one takes the $Q \to 0$ limit for the relevant results obtained for the 'black-bounce Kerr–Newman' (bbKN) spacetime (Eq. (24)), the analogous result for bbK is recovered precisely. In the limit as the spin parameter $a \to 0$, bbKN reduces to the bbRN geometry from § 2.2.

One can see, somewhat trivially, that the natural domains for the angular and temporal coordinates are unaffected when comparing Eq. (24) with standard Kerr–Newman spacetime in BL coordinates. In contrast, the domain for the radial coordinate extends from $r \in [0,+\infty)$ to $r \in (-\infty,+\infty)$, in exactly the same fashion as was seen for bbRN spacetime in § 2.2. Examination of the Riemann curvature invariants and orthonormal Riemann tensor components reveals that they are globally finite when $|\ell| > 0$, hence the geometry is free from curvature singularities. Consequently,

bbKN qualitatively interpolates between charged rotating regular black holes and charged rotating traversable wormholes. Both the Ricci and Einstein tensors are diagonal in an orthonormal basis.

The causal structure is nontrivial, with horizons characterised by the roots of Δ. This gives the following horizon location(s):

$$r_H = S_1\sqrt{(m + S_2\sqrt{m^2 - Q^2 - a^2})^2 - \ell^2}\ . \tag{26}$$

As it was in § 2.2, $S_1 = S_2 = \pm 1$, with S_1 fixing which universe one is in, and S_2 determining whether it is an outer ($S_2 = +1$) or inner ($S_2 = -1$) horizon. The qualitatively different possible causal structures are the same as explored in § 2.2, with the quantitative aspects slightly shifted due to the presence of the spin parameter a. Notably, in the standard Kerr–Newman geometry in BL coordinates one demands $Q^2 + a^2 \leq m^2$ in order to avoid naked singularities. In the case for bbKN, arbitrary values of both spin and charge may be considered, as in the absence of any horizons one has a traversable wormhole geometry with a rotating throat. Therefore, if one uses bbKN to model astrophysical objects, the weak cosmic censorship conjecture is trivially satisfied.

If horizons are present, their surface gravity is given by

$$\kappa_{S_2} = \frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}r}\left(\frac{\Delta}{r^2 + \ell^2 + a^2}\right)\bigg|_{r=r_H} = \kappa^{\mathrm{KN}}_{S_2}\sqrt{\frac{r_H^2}{r_H^2 + \ell^2}}\ , \tag{27}$$

where S_2 fixes whether one is describing the surface gravity of an outer or inner horizon. The ergosurface is characterised by $g_{tt} = 0$, giving

$$r_{\mathrm{erg}} = S_1\sqrt{(m + S_2\sqrt{m^2 - Q^2 - a^2\cos^2\theta})^2 - \ell^2}\ . \tag{28}$$

An informative result pertaining to circular orbits in the equatorial plane for the bbKN spacetime is as follows: if standard Kerr–Newman in BL coordinates has an equatorial circular orbit at $r_{\mathrm{KN},0}$, then bbKN possesses an analogous equatorial circular orbit at coordinate location $r_0 = \sqrt{r^2_{\mathrm{KN},0} - \ell^2}$, provided that $r^2_{\mathrm{KN},0} \geq \ell^2$.

The candidate spacetime possesses a nontrivial Killing tensor; upon definition of the objects

$$l^\mu = \left(\frac{r^2 + \ell^2 + a^2}{\Delta}, 1, 0, \frac{a}{\Delta}\right)\ ,\quad \text{and } n^\mu = \frac{1}{2\rho^2}(r^2 + \ell^2 + a^2, -\Delta, 0, a)\ , \tag{29}$$

one finds that the following is a Killing tensor, *i.e.*, $K_{(\mu\nu;\lambda)} = 0$:

$$K_{\mu\nu} = \rho^2(l_\mu n_\nu + l_\nu n_\mu) + (r^2 + \ell^2)g_{\mu\nu}\ . \tag{30}$$

In this context, the objects l^μ and n^μ are a pair of geodesic null vectors belonging to a generalised Kinnersley tetrad (see reference 19 for details). The Killing tensor from Eq. (30) has diagonal matrix representation. The existence of a nontrivial Killing tensor directly implies the existence of a generalised Carter constant $\mathcal{C}$, and together with the conserved quantities arising from the temporal and azimuthal

Killing vectors (energy and angular momentum per unit mass), as well as the conserved quantity arising from the metric itself (which is a *trivial* Killing tensor), this gives four constants of the motion. This, in principle, means that the geodesics governing the motion of test particles are integrable on the bbKN spacetime. It should be noted that the resulting integral formulae may or may not be analytic.

In reference 59, a refinement was made to Proposition 1.3 from reference 60. It should also be noted that this result is implicitly present in reference 61. The result is best summarised by the following theorem:

Theorem 4.1. *Let $(\mathcal{M}, g_{\mu\nu})$ be a Lorentzian manifold in possession of a nontrivial Killing tensor $K_{\mu\nu}$. Then upon definition of the Carter operator as: $\mathcal{K}\Phi = \nabla_\mu (K^{\mu\nu}\nabla_\nu\Phi)$, and the D'Alembertian scalar wave operator as: $\Box\Phi = \nabla_\mu (g^{\mu\nu}\nabla_\nu\Phi)$, there is the following result:*

$$[\mathcal{K}, \Box]\Phi = \frac{2}{3}\left(\nabla_\mu [R, K]^\mu{}_\nu\right)\nabla^\nu\Phi \ . \tag{31}$$

A sufficient condition for this operator commutator to vanish is therefore the commutativity of the Ricci and Killing tensors via *matrix multiplication; $R^\mu{}_\alpha K^\alpha{}_\nu = K^\mu{}_\alpha R^\alpha{}_\nu \implies [R, K]^\mu{}_\nu = 0$. Hence for any candidate spacetime with a nontrivial Killing tensor, commutativity of the Ricci and Killing tensors* via *matrix multiplication is sufficient to conclude that the massive minimally coupled Klein–Gordon equation is separable on the candidate geometry.*

In view of Theorem 4.1, given that both the Ricci and nontrivial Killing tensors for the bbKN geometry have a diagonal matrix representation, one may conclude that the scalar wave equation is separable on bbKN spacetime.

Given the existence of a nontrivial Killing tensor, it is natural to ponder the existence of the full 'Killing tower'[62] in bbKN spacetime. One finds a 'would-be' Killing–Yano tensor, of the form

$$\begin{aligned} f_{\mu\nu} = &\begin{pmatrix} 0 & -a\cos\theta & 0 & 0 \\ a\cos\theta & 0 & 0 & -a^2\cos\theta\sin^2\theta \\ 0 & 0 & 0 & 0 \\ 0 & a^2\cos\theta\sin^2\theta & 0 & 0 \end{pmatrix} \\ &+ \sqrt{r^2+\ell^2}\sin\theta \begin{pmatrix} 0 & 0 & a & 0 \\ 0 & 0 & 0 & 0 \\ -a & 0 & 0 & (r^2+\ell^2+a^2) \\ 0 & 0 & -(r^2+\ell^2+a^2) & 0 \end{pmatrix}. \end{aligned} \tag{32}$$

It is not difficult to verify that $f_{\mu\alpha}f^\alpha{}_\nu = K_{\mu\nu}$, and as such this is a genuine 'square root' of the Killing tensor, however it fails to be a genuine Killing–Yano tensor because $f_{\mu(\nu;\alpha)} \neq 0$. It is a known result that a candidate spacetime only possesses a closed conformal Killing–Yano tensor if the spacetime is of Petrov type D.[62] However, it was proven by Liberati *et al.* in reference 19 that the bbK spacetime is Petrov type I, and it is a direct implication of this proof that the bbKN spacetime

is also not algebraically special. Consequently, it is an expected result that one can not find a genuine Killing–Yano tensor on bbKN spacetime.

Now coupling the geometry to the Einstein equations of standard GR, the fact that the Einstein tensor is diagonal in an orthonormal basis proves that the stress-energy tensor for bbKN spacetime is Hawking–Ellis type I.[63–66] The radial NEC is violated in view of

$$\varepsilon + p_r = -\frac{\ell^2 \Delta}{8\pi\rho^6} \ , \tag{33}$$

where ε and p_r are energy density and radial pressure respectively.

The stress-energy tensor can be decomposed into gravitational and electromagnetic contributions (similar to bbRN spacetime in § 2.2):

$$\frac{1}{8\pi} G^{\hat{\mu}}{}_{\nu} = T^{\hat{\mu}}{}_{\nu} = [T_{\text{bbK}}]^{\hat{\mu}}{}_{\hat{\nu}} + [T_Q]^{\hat{\mu}}{}_{\hat{\nu}} \ , \tag{34}$$

where

$$[T_Q]^{\hat{\mu}}{}_{\hat{\nu}} = \frac{1}{8\pi} \frac{Q^2\left(\rho^2 - \ell^2\right)}{\rho^6} \left[\text{diag}\left(-1,-1,1,1\right) + \frac{2\ell^2}{\rho^2 - \ell^2} \text{diag}\left(1,0,0,0\right) \right] \ . \tag{35}$$

When comparing Eq. (35) directly with the charge-dependent contribution to the stress-energy from bbRN spacetime, one simply makes the substitutions

$$\frac{Q^2 r^2}{(r^2+\ell^2)^3} \longleftrightarrow \frac{Q^2\left(\rho^2-\ell^2\right)}{\rho^6} \qquad \text{and} \qquad \frac{2\ell^2}{r^2} \longleftrightarrow \frac{2\ell^2}{\rho^2-\ell^2}. \tag{36}$$

Structurally, the first term in Eq. (35) is of the form of the Maxwell stress-energy tensor. The second term appears to be structurally of the form of charged dust. However, the interpretation of the stress-energy is far less straightforward than the somewhat similar picture present in bbRN spacetime (§ 2.2). If one performs the substitution $r \to \sqrt{r^2+\ell^2}$ to the electromagnetic potential from Kerr–Newman spacetime, one finds

$$A_{\hat{\mu}} = -\frac{Q\sqrt{r^2+\ell^2}}{\sqrt{\rho^2|\Delta|}} \left(1,0,0,0\right) \ , \tag{37}$$

giving the following for the electromagnetic field strength tensor $F_{\hat{\mu}\hat{\nu}}$:

$$F_{\hat{t}\hat{r}} = -F_{\hat{r}\hat{t}} = -\frac{Q}{\rho^4}\sqrt{\frac{r^2}{r^2+\ell^2}}(r^2+\ell^2-a^2\cos^2\theta) \ , \tag{38}$$

$$F_{\hat{\theta}\hat{\phi}} = -F_{\hat{\phi}\hat{\theta}} = \frac{2aQ\cos\theta\sqrt{r^2+\ell^2}}{\rho^4} \ . \tag{39}$$

Immediately it is clear that $F_{[\hat{\mu}\hat{\nu},\hat{\sigma}]} = 0$. For the inhomogeneous Maxwell equation, defining $z = \sqrt{r^2+\ell^2}$, one has

$$\nabla^{\hat{\mu}} F_{\hat{\mu}\hat{\nu}} = J_{\hat{\nu}} = \frac{Q\ell^2}{\rho^7 z} \left(-\frac{\Delta\left(\rho^4 + 2\rho^2 z^2 - 4z^4\right)}{z^2\sqrt{|\Delta|}}, 0, 0, 2a\sin\theta\left(\rho^2 - 2z^2\right) \right). \tag{40}$$

Interpreting this as an effective electromagnetic source, one has $E_{\hat{r}} = F_{\hat{t}\hat{r}}$ and $B_{\hat{r}} = F_{\hat{\theta}\hat{\phi}}$, giving

$$[T_{\text{Maxwell}}]^{\hat{\mu}}{}_{\hat{\nu}} = \frac{E_{\hat{r}}^2 + B_{\hat{r}}^2}{8\pi} \text{diag}\,(-1,-1,1,1) \ , \tag{41}$$

with

$$E_{\hat{r}}^2 + B_{\hat{r}}^2 = \frac{Q^2}{\rho^4} \frac{r^2}{r^2+\ell^2} + \frac{4Q^2\ell^2 a^2 \cos^2\theta}{\rho^8} \ . \tag{42}$$

Comparison with Eq. (35) reveals that a more subtle interpretation of the electromagnetic stress-energy than standard Maxwell's is required. Presented herein are two alternatives.

Nonlinear electrodynamics One can decompose the electromagnetic stress-energy tensor as follows

$$[T_Q]^{\hat{\mu}}{}_{\hat{\nu}} = \mathcal{A}\,[T_{\text{Maxwell}}]^{\hat{\mu}}{}_{\hat{\nu}} + \Xi\, V^{\hat{\mu}} V_{\hat{\nu}} \ . \tag{43}$$

The $\Xi\, V^{\hat{\mu}} V_{\hat{\nu}}$ term is once again appropriate to interpret as charged dust. Comparing Eq's. (41) and (43) allows one to solve for the multiplicative factor $\mathcal{A}$:

$$\mathcal{A} = \frac{Q^2(\rho^2-\ell^2)}{\rho^6\,(E_{\hat{r}}^2 + B_{\hat{r}}^2)} = 1 - a^2\ell^2 \frac{\cos^2\theta[4(r^2+\ell^2)-\rho^2]}{\rho^4 r^2 + 4a^2\ell^2\cos^2\theta(r^2+\ell^2)} \ . \tag{44}$$

It is clear that in both the limit as $\ell \to 0$ (Kerr–Newman), and the limit as $a \to 0$ (bbRN), $\mathcal{A} \to 1$, recovering standard Maxwell's as expected. The fact that $\mathcal{A}$ is independent of the charge Q indicates it is appropriate to interpret this term through the lens of nonlinear electrodynamics (NLED), where generally one has $[T_{\text{NLED}}]^{\hat{\mu}}{}_{\hat{\nu}} \propto [T_{\text{Maxwell}}]^{\hat{\mu}}{}_{\hat{\nu}}$. NLED in the context of regular black holes is prevalent throughout the literature.[22,67–73] In the large distance limit one has

$$\mathcal{A} = 1 - \frac{3\ell^2 a^2 \cos^2\theta}{r^4} + \mathcal{O}(r^{-6}) \ , \tag{45}$$

indicating that standard Maxwell's + charged dust is a safe approximation as $r \to +\infty$. Conversely, for small r one has

$$\mathcal{A} = \frac{\ell^2 + a^2\cos\theta^2}{4\ell^2} + \mathcal{O}(r^2) \ , \tag{46}$$

which allows one to interpret a rescaling of the Maxwell stress-energy deep in the core of the black-bounce. This holistic picture is common in NLED.

Anisotropic fluid One can instead ask that

$$[T_Q]_{\hat{\mu}\hat{\nu}} - [T_{\text{Maxwell}}]_{\hat{\mu}\hat{\nu}} = \text{diag}\,(\varepsilon_f, -p_f, p_f, p_f) \,, \tag{47}$$

which would imply that (recall $z = \sqrt{r^2+\ell^2}$)

$$\varepsilon_f = \frac{Q^2\ell^2}{z^2\rho^8}\left(4z^4 - 7z^2\rho^2 + \rho^4\right), \quad p_f = \frac{Q^2\ell^2}{z^2\rho^8}\left(4z^4 - 5z^2\rho^2 + \rho^4\right). \tag{48}$$

Consequently, $[T_Q]^{\hat{\mu}}{}_{\hat{\nu}}$ can be interpreted as standard Maxwell's in the presence of an anisotropic fluid. The anisotropic fluid can then be written as

$$\varepsilon_f V_{\hat{\mu}} V_{\hat{\nu}} + \frac{p_f}{3}\left(g_{\hat{\mu}\hat{\nu}} + V_{\hat{\mu}} V_{\hat{\nu}}\right) + \pi_{\hat{\mu}\hat{\nu}} \ , \tag{49}$$

with $V^{\hat{\mu}} = (1,0,0,0)$ being the velocity of the fluid, and

$$\pi_{\hat{\mu}\hat{\nu}} = \frac{2p_f}{3}\mathrm{diag}\,(0,-2,1,1) \tag{50}$$

being the (traceless) anisotropic shear.[63]

5. Discussion

The family of black-bounce spacetimes contains many different candidate geometries which smoothly interpolate between regular black holes and traversable wormholes in standard GR, both with and without rotation, both with and without electrical charge, and both with and without dynamics. The high degree of mathematical tractability of the black-bounce spacetimes means that all models are amenable to the straightforward extraction of astrophysical observables, which *may* be falsifiable/verifiable by the experimental community.

Future research options abound. Given the knowledge of Klein–Gordon separability on bbKN spacetime, one should also test for Maxwell separability on the bbKN spacetime. The knowledge of Klein–Gordon separability already implies that bbKN is amenable to a standard spin zero quasi-normal modes analysis, and if Maxwell's equations also separate then this would extend to a spin one analysis. Further investigation into the spin two axial and polar modes may eventually lead to a measurable ringdown signal able to be captured by LIGO/VIRGO (or LISA) and compared with the analogous signal from Kerr-like mergers. Alternative lines of inquiry for future research could involve attempting to provide a physical mechanism for the bounce, or possibly discovering precisely which mathematical modifications to the Einstein equations would be required such that SV is the unique solution in static spherical symmetry in the new framework.

Both traversable wormholes and warp drives, concepts originally developed within the context of science fiction, have now (for some 30 odd years) been studied, debated, and carefully analyzed within the framework of general relativity. An overarching theme of the general relativistic analysis is unavoidable violations of the classical point-wise energy conditions. Another science fiction trope, now over 80 years old, is the tractor beam and/or pressor beam. We shall discuss how to formulate both tractor beams and/or pressor beams, and a variant to be called a stressor beam, within the context of reverse engineering the spacetime metric. (While such reverse engineering is certainly well beyond our civilization's current capabilities, we shall be more interested in asking what an arbitrarily advanced civilization might be able to accomplish.) We shall see that tractor beams and/or pressor beams can be formulated by suitably modifying the notion of warp drives, and that, as for wormholes and warp drives, violations of the classical point-wise energy conditions are utterly unavoidable.

Keywords: Traversable wormholes; warp drives; tractor/pressor/stressor beams

1. Introduction

Traversable wormholes have now been extensively studied for some 33 years.[1–19] The general theoretical framework has been to precisely define, and then reverse engineer, a physically interesting spacetime metric, using the Einstein equations to determine what matter sources some arbitrarily advanced civilization might need to employ in order to generate such interesting spacetime geometries. Perhaps the key feature of reverse engineering is that adopting this point of view reduces the problem of solving the Einstein equations to a relatively simple exercise in differentiation, instead of the much harder problem of integrating the underlying nonlinear PDEs.

A key feature of traversable wormhole spacetimes, at least within the usual context of standard general relativity, is the utterly unavoidable violation of the classical energy conditions.[1–19]

Even if one moves beyond the framework of standard general relativity there are unavoidable purely geometric constraints, violations of both the null convergence condition and also violations of the timelike convergence condition, that place very strong constraints on any "effective" stress-energy tensor that one might use as a source to generate the spacetime.[9]

Similarly, "warp drives" have now been extensively studied for some 27 years.[20–31] As is the case for traversable wormholes once one defines a suitable class of warp field spacetimes it is easy to see that reverse engineering the spacetime metric, at least within the context of standard general relativity, quite unavoidably leads to significant violations of the classical energy conditions.[20–31] Again, even when stepping outside the framework of standard general relativity there are still unavoidable but purely geometric constraints, violations of the null convergence condition and violations of the timelike convergence condition, that place very strong constraints on any "effective" stress-energy tensor.[20–31] (There have recently been several misguided counterclaims regarding these issues which we shall address more fully below, see references 32, 33, 34. For somewhat related but distinct analyses, with somewhat different flaws, see also the discussion in references 35, 36, 37, 38, and in reference 39.)

Much more recently, the last 6 months have seen the current authors reformulate yet another science fiction trope, tractor beams, pressor beams, and stressor beams, within the framework of general relativity.[40] Again we resort to reverse engineering, and again the classical energy conditions are violated.[40] Even if one steps outside the framework of standard general relativity there are still purely geometric constraints, violations of the null convergence condition, and also violations of the timelike convergence condition, that make the underlying physics "exotic" in some purely technical sense.[40]

Of course, in all of these cases one must first precisely define what one means by a traversable wormhole, or a warp drive, or a tractor/pressor/stressor beam. One also needs to carefully assess the extent to which the energy conditions (or more geometrically, the null and timelike convergence conditions) are to be taken as truly fundamental physics.[9, 31, 40, 41]

2. Energy conditions — generalities

It should be emphasized that the energy conditions are not fundamental physics.[41] The energy conditions are instead warning flags: They tell you "here be unusual physics". Violations of the energy conditions are not an absolute prohibition; but they are an indication that one should think very carefully about the underlying physics.

For instance:

- Observational cosmology (either in the current epoch of the accelerating universe, or during the epoch of cosmological inflation) violates the strong energy condition (SEC).[42,43]
- Speculative theoretical cosmologies (asymptotically AdS spacetimes) with a negative cosmological constant violate the weak energy condition (WEC).
- Gravitational vacuum polarization (in the test field limit) can violate all the energy conditions, null, weak, strong, and dominant (NEC, WEC, SEC, and DEC).[44–48]
- Hawking radiation violates all the energy conditions (NEC, WEC, SEC, and DEC).[9]
- Quantum scale anomalies (trace anomalies) violate even the averaged null energy condition (ANEC).[49]

But these known energy condition violating scenarios do not necessarily imply that it is possible to concentrate energy condition violating physics in a sufficiently small region to enable "interesting" effects — such as wormholes, warp drives, and the tractor/pressor/stressor beams.[9,13,16] However, in view of these known energy condition violating scenarios, neither would the necessity of energy condition violations necessarily prohibit "interesting" physics.[50–69]
We emphasise that to verify that the energy conditions are *satisfied*:

- One needs to check *all* relevant "observers" — both *all* physical timelike observers, and in the null limit, *all* null tangent vectors.
- One needs at least *some* information concerning *all* of the stress-energy components.

In contrast, to demonstrate the energy conditions are *violated*:

- It is sufficient to check that *one* timelike observer, (or *one* null curve), violates the energy conditions.
- It is sufficient to check that *some* combination of stress-energy components violates the energy conditions.

3. Generic warp metric and tractor/pressor/stressor metric

A sufficiently generic spacetime metric, (suitable for investigating both warp drives and tractor/pressor/stressor beams), is to consider:[20–31]

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + \delta_{ij}\,\left(\mathrm{d}x^i - v^i(t,\vec{x})\,\mathrm{d}t\right)\,\left(\mathrm{d}x^j - v^j(t,\vec{x})\,\mathrm{d}t\right). \tag{1}$$

This class of metrics has the properties that it is:

- Spatially flat.
- Unit lapse.
- The gradients of the flow vector $v^i(t,\vec{x})$ must satisfy suitable asymptotic fall-off conditions.
  - (Otherwise you do not have a localized warp-field.)
  - (You do not want to accelerate the entire universe.)

  In particular, the spacetime must be asymptotically flat.
- Three special cases are commonly considered:
  - Alcubierre: $\vec{v}(t,\vec{x}) = v(t,z)\,\hat{z}$.
  - Zero-expansion: $\boldsymbol{\nabla}\cdot\vec{v}(t,\vec{x}) = 0$.
  - Zero-vorticity: $\boldsymbol{\nabla}\times\vec{v}(t,\vec{x}) = 0$.
- For tractor/pressor/stressor beam spacetimes one will add extra conditions, such as cylindrical symmetry, and simplify the form of the flow vector $\vec{v}(t,\vec{x})$ by introducing suitable "envelope" and "profile" functions.
- Further generalizations are in principle possible, but very quickly become calculationally intractable.

To start specific computations it is convenient to first pick a co-tetrad:[31,40]

- Take the timelike leg to be:

$$(e^{\hat{0}})_a = (1;0,0,0)_a = n_a. \tag{2}$$

- Take the spatial co-triad to be:

$$(e^{\hat{1}})_a = (-v_x;1,0,0)_a, \quad (e^{\hat{2}})_a = (-v_y;0,1,0)_a, \quad (e^{\hat{3}})_a = (-v_z;0,0,1)_a. \tag{3}$$

This *choice* serves to keep computations more-or-less tractable.

The corresponding tetrad is then fixed:[31,40]

- The timelike leg is:

$$(e_{\hat{0}})^a = (1;v^x,v^y,v^z)^a = n^a. \tag{4}$$

- The spatial triad is:

$$(e_{\hat{1}})^a = (0;1,0,0)^a, \quad (e_{\hat{2}})^a = (0;0,1,0)^a, \quad (e_{\hat{3}})^a = (0;0,0,1)^a. \tag{5}$$

With this choice of tetrad the orthonormal components of the extrinsic curvature are now particularly simple:[31,40]

$$K_{\hat{a}\hat{b}} = \left[\begin{array}{c|c} 0 & 0 \\ \hline 0 & K_{ij} \end{array}\right], \tag{6}$$

where

$$K_{ij} = v_{(i,j)}. \tag{7}$$

(Effectively one can just quietly drop the hats from covariant spatial components of any tensor in this tetrad basis.[31,40])

Brute force computation now yields two easy results, and one somewhat messier result.[31,40]

- Easy (Gauss–Coddazzi):

$$G_{nn} = \frac{1}{2}\left(K^2 - \mathrm{tr}\big(K^2\big)\right), \tag{8}$$

$$G_{ni} = K_{ij,j} - K_{,i}. \tag{9}$$

- Somewhat messier (specialization of ADM formalism):

$$G_{ij} = \mathcal{L}_n K_{ij} + K K_{ij} - 2(K^2)_{ij} - \left(\mathcal{L}_n K + \frac{1}{2}K^2 + \frac{1}{2}\,\mathrm{tr}\big(K^2\big)\right)\delta_{ij}. \tag{10}$$

In order to claim that the energy conditions are satisfied (or claim that the null and timelike convergence conditions are satisfied) one would need to compute and analyze *all* the components of the Einstein tensor. (This is one specific place, there are others, at which the claims made in references 32, 33, 34 simply fail. See reference 31 for an extensive discussion of these issues. The analyses of references 35, 36, 37, 38, and reference 39 exhibit somewhat different pathologies; once the Einstein equations are fully solved, many of those specific examples are actually Riemann flat.)

Standard general relativity (the Einstein equations) now yields the stress-energy:

- Eulerian energy density:

$$\rho = \frac{G_{nn}}{8\pi} = \frac{1}{16\pi}\left\{\boldsymbol{\nabla}\cdot\{\vec{v}\,K - (\vec{v}\cdot\boldsymbol{\nabla})\vec{v}\} - \frac{1}{2}\,(\vec{\omega}\cdot\vec{\omega})\right\}. \tag{11}$$

  Note: (comoving density) = (3-divergence) + (negative semidefinite term).

- Eulerian flux:

$$f_i = \frac{G_{ni}}{8\pi} = \frac{1}{8\pi}(K_{ij,j} - K_{,i}) = \frac{1}{16\pi}\,(\boldsymbol{\nabla}\times(\boldsymbol{\nabla}\times\vec{v}))_i\,. \tag{12}$$

  Note: curl of a curl. (So this can sometimes be set to zero.)

- Eulerian spatial stresses

$$T_{ij} = \frac{G_{ij}}{8\pi} = \frac{1}{8\pi}\left(\mathcal{L}_n K_{ij} + K K_{ij} - 2(K^2)_{ij} - \left(\mathcal{L}_n K + \frac{1}{2}K^2 + \frac{1}{2}\,\mathrm{tr}\big(K^2\big)\right)\delta_{ij}\right). \tag{13}$$

The Eulerian density and Eulerian flux are easy, the Eulerian spatial stresses are more complicated. A key quantity of interest is the average pressure:

$$\bar{p} = \frac{1}{3}\,T_{ij}\,\delta^{ij} = \frac{1}{24\pi}\left(-2\mathcal{L}_n K - \frac{1}{2}K^2 - \frac{3}{2}\,\mathrm{tr}\big(K^2\big)\right). \tag{14}$$

This can also be written as:

$$\bar{p} = \frac{1}{3}\, T_{ij}\, \delta^{ij} = -\frac{1}{24\pi}\left(2\nabla_a(Kn^a) - \frac{3}{2}K^2 + \frac{3}{2}\,\mathrm{tr}\big(K^2\big)\right). \tag{15}$$

Equivalently:

$$\bar{p} = \rho - \frac{1}{12\pi}\,\nabla_a(Kn^a). \tag{16}$$

Furthermore, consider the two combinations:

$$\rho + 3\bar{p} = -\frac{1}{4\pi}\left(\mathcal{L}_n K + \mathrm{tr}\big(K^2\big)\right), \tag{17}$$

$$\rho + \bar{p} = \frac{1}{24\pi}\left(-2\mathcal{L}_n K + K^2 - 3\,\mathrm{tr}\big(K^2\big)\right). \tag{18}$$

These two quantities are relevant to investigating violations of the SEC and NEC, respectively.[31]

4. Forces: Tractor/pressor/stressor beams

For tractor/pressor/stressor beam spacetimes we now make a specific, concrete choice for the form of the generic warp metric. Let us consider a beam pointed in the $\hat{z}$ direction, and specialize the flow vector to be of the form:

$$\begin{aligned} v_x(t,x,y,z) &= k(t,z)\, x\, h(x^2+y^2),\\ v_y(t,x,y,z) &= k(t,z)\, y\, h(x^2+y^2),\\ v_z(t,x,y,z) &= v(t,z)\, f(x^2+y^2). \end{aligned}$$

Note the introduction of two envelope functions, $k(t,z)$ and $v(t,z)$; and two profile functions, $h(x^2+y^2)$ and $f(x^2+y^2)$. Note that for simplicity we have also imposed cylindrical symmetry (in Cartesian coordinates).

Now consider the forces such a tractor/pressor/stressor beam spacetime would exert on a target with cross-section $\mathbb{S}$ that is at time t placed at position z.

$$F(t,z) = \pm \int_{\mathbb{S}} T_{zz}(t,x,y,z)\,\mathrm{d}x\,\mathrm{d}y. \tag{19}$$

There are two special cases to consider depending on whether the beam is wide or narrow compared to the cross-sectional area $A(\mathbb{S})$ of the tatget.

- Narrow beam:

$$F(t,z) = \pm \int_{\mathbb{R}^2} T_{zz}(t,x,y,z)\,\mathrm{d}x\,\mathrm{d}y. \tag{20}$$

- Wide beam:

$$F(t,z) = \pm T_{zz}(t,0,0,z)\, A(\mathbb{S}). \tag{21}$$

Let us now calculate, setting $u = x^2 + y^2$ for conciseness.

- Narrow beam:

$$F(t,z) = -\frac{1}{2} v(t,z)^2 \int_0^\infty u[f'(u)]^2 \mathrm{d}u + \frac{1}{8}\int_0^\infty u\left[v(t,z) f'(u) + \frac{1}{2}\partial_z k(t,z) h(u)\right]^2 \mathrm{d}u.$$

  This is of indefinite sign, depending delicately on the envelope functions and profile functions, potentially allowing either tractor/pressor behaviour.

- Wide beam:

$$F(t,z) = -\frac{h(0)}{8\pi}\left\{2f(0)\; v(t,z)\partial_z k(t,z) + 2\;\partial_t k(t,z) + 3h(0)\; k(t,z)^2\right\} A(\mathbb{S}). \tag{22}$$

  This is of indefinite sign, depending delicately on the envelope functions, potentially allowing either tractor/pressor behaviour.

There are very many special cases to study, depending on one's choice of envelope and profile functions. See reference 40 for extensive details and discussion.

Generic Natário	**Modified Alcubierre**	**Zero Expansion**	**Zero Vorticity**
envelope $k(t,z)$	0	$-\partial_z v$	Φ
envelope $v(t,z)$	v	v	$\partial_z \Phi$
profile $h(u)$	0	h	$2f'$
profile $f(u)$	f	$2(h + uh')$	f

One can easily tune the resulting forces in a wide variety of ways. In particular we can define a *stressor* beam to be one where the *net* force is zero, but forces alternate between attractive and repulsive as one moves across the cross section of the target, thereby stressing the target in a (in principle) controllable manner.

5. Energy conditions — specifics

In this context, all of the classical point-wise energy conditions are violated. The arguments are fully generic to tractor/pressor/stressor beam spacetimes, and, with suitable subsidiary conditions, apply also to warp drive configurations. (In the warp drive context, many special cases have been well known for over 20 years.)

Generically for either tractor/pressor/stressor or warp drive configurations we have:

$$\rho = (\text{3-divergence}) - \frac{1}{32\pi}\,(\vec{\omega}\cdot\vec{\omega}). \tag{23}$$

Then for all tractor/pressor/stressor beams (where by construction all fields fall off sufficiently rapidly at spatial infinity):

$$\int \rho \, \mathrm{d}^3x = -\frac{1}{32\pi} \int (\vec{\omega} \cdot \vec{\omega}) \, \mathrm{d}^3x \leq 0. \tag{24}$$

This kills off the WEC for all tractor/pressor/stressor beams. For warp drives one must sometimes be more careful, see the Appendix, and to prove or disprove the WEC one must check both the Eulerian energy density ρ *and* the NEC ($\rho + \bar{p} \geq 0$).

Generic to either tractor/pressor/stressor or warp drive configurations we have:

$$\bar{p} = \rho - \frac{1}{12\pi} \nabla_a (K n^a). \tag{25}$$

$$\int \bar{p} \, \mathrm{d}^3x = \int \rho \, \mathrm{d}^3x - \frac{1}{12\pi} \int \partial_t K \, \mathrm{d}^3x. \tag{26}$$

$$\int (\rho + \bar{p}) \, \mathrm{d}^3x = -\frac{1}{16\pi} \int (\vec{\omega} \cdot \vec{\omega}) \, \mathrm{d}^3x - \frac{1}{12\pi} \int \partial_t K \, \mathrm{d}^3x. \tag{27}$$

For any tractor/pressor/stressor/beam configuration (and for any suitably localized warp bubble):

$$\int (\rho + \bar{p}) \, \mathrm{d}^3x = -\frac{1}{16\pi} \int (\vec{\omega} \cdot \vec{\omega}) \, \mathrm{d}^3x - \frac{1}{12\pi} \partial_t \int K \, \mathrm{d}^3x. \tag{28}$$

Furthermore, for any tractor/pressor/stressor/beam configuration (and for any suitably localized warp bubble) we also have:

$$\int K \, \mathrm{d}^3x = 0. \tag{29}$$

Therefore, for any tractor/pressor/stressor/beam configuration (and for any suitably localized warp bubble) we conclude:

$$\int (\rho + \bar{p}) \, \mathrm{d}^4x = -\frac{1}{16\pi} (\vec{\omega} \cdot \vec{\omega}) \, \mathrm{d}^4x \leq 0. \tag{30}$$

This kills off the NEC.

That is, all of the classical point-wise energy conditions are violated. This certainly holds for any tractor/pressor/stressor/beam configuration, and for any suitably localized warp bubble, will also work for warp drive spacetimes. An example of a more delocalized warp bubble is considered in the Appendix.

6. Conclusions

- Traversable wormholes, warp drives, and tractor/pressor/stressor beams can all usefully be "reverse engineered", debated, analyzed, and studied within the framework of standard general relativity.
- Reverse engineering a specified interesting spacetime reduces the task of solving the Einstein equations to a relatively straightforward exercise of differentiation, rather than the more complicated task of integration.

- Traversable wormholes, warp drives, and tractor/pressor/stressor beams all violate all of the standard point-wise energy conditions.
- Even in various modified theories of gravity, wormholes, warp drives, and tractor/pressor/stressor beams violate the null convergence condition and timelike convergence condition.
- Violation of the classical energy conditions is not an absolute prohibition on "interesting" physics — it is merely an invitation to think very carefully about the underlying physics.

Appendix A. Falloff conditions at spatial infinity

For tractor/pressor/stressor beams suitable falloff conditions at spatial infinity are inherent to the definition, and utterly automatic. Similarly, for Alcubierre warp drives and zero-expansion warp drives suitable falloff conditions at spatial infinity are also inherent to the definition and utterly automatic. For zero vorticity warp drives one must be just a little more careful.

As an example, consider the general framework

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + \delta_{ij}\, \left(\mathrm{d}x^i - v^i(t,\vec{x})\,\mathrm{d}t\right)\, \left(\mathrm{d}x^j - v^j(t,\vec{x})\,\mathrm{d}t\right), \tag{A.1}$$

and for one's warp field take the specific case

$$v^i(t,\vec{x}) = -\sqrt{\frac{2m}{r}}\,\hat{r}^i + v^i_\infty(t). \tag{A.2}$$

This corresponds to a warp bubble, centred at the origin, in a coordinate system that is moving with the warp bubble. The presence of the warp velocity term, $v^i_\infty(t)$, is essential, since otherwise the warp bubble is not moving with respect to spatial infinity, (the "fixed stars"), which would make the warp field trivial.

For the specific warp field (A.2) it is easy to calculate

$$K = \boldsymbol{\nabla}\cdot\vec{v} = -\frac{3}{2}\frac{\sqrt{2m}}{r^{3/2}}, \tag{A.3}$$

and see that this is independent of the warp velocity $v^i_\infty(t)$.

Then for the Eulerian energy density and flux one has the particularly simple results:

$$\rho = 0; \qquad \text{and} \qquad \vec{f} = 0. \tag{A.4}$$

This does *not* mean that the WEC is satisfied since one still has to check $\rho + \bar{p}$.

Specifically, in this particular warp field we have

$$\rho + \bar{p} = \bar{p} = -\frac{1}{12\pi}\,\nabla_a(K\,n^a) = -\frac{1}{12\pi}\,\boldsymbol{\nabla}\cdot(K\,\vec{v}(t,\vec{x})). \tag{A.5}$$

That is

$$\rho + \bar{p} = -\frac{1}{12\pi}\,\boldsymbol{\nabla}\cdot\left(\frac{3}{2}\,\frac{2m}{r^2}\,\hat{r} + K\vec{v}_\infty\right) = -\frac{1}{12\pi}\,\vec{v}_\infty(t)\cdot\boldsymbol{\nabla}K. \tag{A.6}$$

Finally

$$\rho + \bar{p} = -\frac{3}{16\pi} \frac{\sqrt{2m}}{r^{5/2}} \ \vec{v}_\infty(t) \cdot \hat{r}. \tag{A.7}$$

But the factor $\vec{v}_\infty(t) \cdot \hat{r}$ explictly changes sign depending on whether one is "in front of" or "behind" the warp bubble. Thus this warp bubble explicitly violates the NEC, and so violates the WEC as well — this is a specific and explicit example of why merely checking the non-negativity of the Eulerian density is simply insufficient for checking the WEC.

More generally, note that an *asymptotic* version of this argument will still apply to any warp field that is asymptotically of the form (A.2):

$$v^i(t, \vec{x}) = -\sqrt{\frac{2m}{r}} \ \{1 + o(1/r)\} \ \hat{r}^i + v^i_\infty(t). \tag{A.8}$$

This now applies to any warp bubble that asymptotes to Schwarzschild spacetime at large distances.

The classical singularity theorems of General Relativity rely on energy conditions that are easily violated by quantum fields. Here, we provide motivation for an energy condition obeyed in semiclassical gravity: the smeared null energy condition (SNEC), a proposed bound on the weighted average of the null energy along a finite portion of a null geodesic. Using SNEC as an assumption we proceed to prove a singularity theorem. This theorem extends the Penrose singularity theorem to semiclassical gravity and has interesting applications to evaporating black holes.

Keywords: Quantum fields, gravity, energy conditions, quantum inequalities, singularities

1. Introduction

The classical or pointwise energy conditions are bounds on components of the stress-energy tensor and were introduced early on in the history of general relativity. Their purpose is to encode properties of what is considered "reasonable" matter, and predict the evolution of gravitational systems in a model-independent way.

The energy condition of interest in this work is the null energy condition (NEC). The NEC states that the stress-energy tensor contracted with two null vectors is non-negative everywhere. Using the Einstein Equation, we get the geometric form of the NEC or the null convergence condition. Using a perfect fluid stress-energy tensor, we can give a physical interpretation of the NEC: the sum of energy density and pressure cannot be negative. The three forms are summarized in Table 1.

Table 1. The different forms of the NEC. Here ℓ^μ is a null vector.

Physical form	Geometric form	Perfect fluid
$T_{\mu\nu}\ell^\mu\ell^\nu \geq 0$	$R_{\mu\nu}\ell^\mu\ell^\nu \geq 0$	$\rho + P \geq 0$

*Presenting author.

The NEC is obeyed by minimally coupled scalar fields but as with all pointwise energy conditions, it is violated by quantum fields.[1] Ford[2] was the first to introduce *quantum energy inequalities* (QEIs), restrictions on the possible magnitude and duration of any negative energy densities within a quantum field theory.

QEIs have since been derived for flat and curved spacetimes, bosonic and fermionic fields (see Ref. 3 and 4 for recent reviews). Those bounds are for averages over timelike curves or worldvolumes. As an example, the renormalized null energy of the quantum massless minimally coupled scalar field in Minkowski spacetime averaged over a smooth timelike curve γ obeys the following QEI[5]

$$\int dt \langle :T_{\mu\nu}:\ell^\mu \ell^\nu \rangle_\omega f^2(t) \geq -\frac{(v^\mu \ell_\mu)}{12\pi^2} \int dt f''(t)^2 \,, \tag{1}$$

for all Hadamard states ω and any smooth, real-valued compactly supported function f. Here v^μ is the timelike vector tangent to γ. For f a normalized Gaussian with zero mean and t_0 variance the right hand side of (1) becomes

$$\int dt \langle :T_{\mu\nu}:\ell^\mu \ell^\nu \rangle_\omega f^2(t) \geq -\frac{(v^\mu \ell_\mu)}{64\pi^2 t_0^4} \,. \tag{2}$$

Then we can see the physical interpretation of the QEI: the longer the timescale t_0, the less negative null energy is allowed.

Important classical relativity results such as the Penrose singularity theorem[6] have the NEC in their hypotheses. If one wants to apply such theorems in a semiclassical setting it is necessary to replace the pointwise energy condition with a condition obeyed by quantum fields, namely a QEI. As the Penrose theorem proves null geodesic incompleteness, the relevant QEI would be a null averaged one.

The purpose of this contribution is to motivate a null QEI, the smeared null energy condition (SNEC) and use it to prove a semiclassical singularity theorem for null geodesic incompleteness. This theorem is applicable to the case of evaporating black holes. We begin with a description of the challenges to develop a null QEI and motivation for SNEC in Sec. 2. In Sec. 3 we state the singularity theorem of Ref. 7 and show that SNEC can be used as an assumption. In Sec. 4 we apply the theorem to a toy model of evaporating black holes. We conclude in Sec. 5 with a summary and discussion of future work.

2. Null quantum energy inequalities

2.1. *The Fewster-Roman counterexample*

In the expression of Eq. (1) the renormalized null energy is averaged over a timelike curve. A similar expression integrated over a null geodesic has been derived two-dimensions. In particular, Fewster and Hollands[8] showed that

$$\int_{-\infty}^{+\infty} f(\lambda) \langle :T_{\mu\nu}:\ell^\mu \ell^\nu \rangle_\omega \geq -\frac{c}{48\pi} \int_{-\infty}^{+\infty} \frac{(f')^2}{f} d\lambda \,, \tag{3}$$

holds for a class of interacting quantum fields, namely the unitary, positive energy conformal field theories (CFTs) with stress-energy tensor in Minkowski spacetime. Here c is the central charge of the theory. We recently generalized that result for a large class of curved backgrounds.[9]

The situation is different in more than two dimensions. Fewster and Roman[5] showed using an explicit construction, that the renormalized null energy averaged over a null geodesic is unbounded from below for the massless minimally coupled scalar field. So there are no null QEIs in four-dimensional Minkowski space.

Their construction was a sequence of vacuum-plus-two-particle states. Then they allowed the three-momenta of excited modes to become increasingly parallel to the spatial part of the null vector ℓ^μ. As the three momenta grows, the lower bound of the inequality diverges to negative infinity.

2.2. *The smeared null energy condition*

To overcome the problem encountered by Fewster and Roman, Freivogel and Krommydas proposed the smeared null energy condition (SNEC).[10] The main concept behind it is that in quantum filed theory there often exists an ultraviolet cutoff $\ell_{\rm UV}$. It was shown[9,10] that the existence of a cutoff restricts the three momenta of the excited modes in the Fewster-Roman counterexample, leading to a finite lower bound.

The SNEC can be written as

$$\int_{-\infty}^{+\infty} d\lambda g^2(\lambda)\langle T_{kk}(x^\mu(\lambda))\rangle \geq -\frac{4B}{G_N}\int_{-\infty}^{+\infty} d\lambda \left(g'(\lambda)\right)^2 , \tag{4}$$

where $x^\mu(\lambda)$ is a null geodesic, $g(\lambda)$ is a differentiable 'smearing function' that controls the region where the null energy is averaged, B is a constant and G_N is the Newton constant. In four-dimensional field theory we can write

$$NG_N \lesssim \ell_{\rm UV}^2 , \tag{5}$$

where N is the number of fields. This relationship means the SNEC provides a finite lower bound even for a large number of fields. This is particularly useful for applications where the negative energy arises from multiple fields with small negative energy fluctuations (see e.g. 11).

To have B be an order one number, we need to saturate that inequality. This is the case for the induced gravity proof of 12 where they derived $B = 1/32\pi$. However, it is reasonable to consider a $B \ll 1$ since (5) is typically not saturated in controlled constructions.

SNEC has been proven to hold for free fields on Minkowski spacetime.[9,13] The proof utilizes the fact that free field theory factorizes on the lightsheet in a collection of two-dimensional CFTs. For each of those CFTs the two-dimensional null QEI of Eq. (3) holds leading to a proof for the higher dimensional theory.

2.3. *The double smeared null energy condition*

It is unclear if the proof of SNEC described in the previous subsection can be generalized to curved spacetimes and interacting fields. Additionally, the bound diverges fro $\ell_{\rm UV} \to 0$, with the ultraviolet cutoff depending on the theory.

Those disadvantages of SNEC led to the proposal of a different bound, the double smeared null energy condition (DSNEC). The idea is to average the renormalized null energy density in both null directions, denote + and −. Schematically the DSNEC can be written as

$$\int d^2x^{\pm} g^2(x^+, x^-) \langle :T_{--}: \rangle_\omega \geq -\frac{\mathcal{N}}{\delta_+ \delta_-^3}\,, \tag{6}$$

where $\mathcal{N}$ depends on the number of fields and the smearing function, and $\delta_\pm$ is the smearing length in each of the null directions.

For a massless scalar in Minkowski the DSNEC can be explicitly written as

$$\int d^2x^{\pm} g^2(x^+, x^-) \langle :T:_{--} \rangle_\omega \geq -A \left[\int dx^+ (g''_+(x^+))^2\right]^{1/4} \left[\int dx^- (g''_-(x^-))^2\right]^{3/4}\,, \tag{7}$$

where A is a number and we assumed that the smearing function factorizes as $g^2 = g_+(x^+)^2 g_-(x^-)^2$.

The DSNEC was motivated in 13 and its rigorous proof will appear in future work.[14] The proof of DSNEC can straightforwardly generalized for curved spacetimes as it is derived from a general QEI valid in spacetimes with curvature.[15] It includes no theory dependent cutoff and the smearing in each direction can be controlled. However, it is still unclear if the DSNEC can be used to prove singularity theorems. The main obstacle is that the usual proofs of those theorems require bounds on single geodesics.

3. The singularity theorem

3.1. *The Penrose singularity theorem*

In general relativity a spacetime is singular if it possesses at least one incomplete and inextendible geodesic. This definition does not give us information about the nature of the singularity (e.g. if curvature scalars diverge) but it allowed for the first model-independent theorems, the singularity theorems of Penrose[6] and Hawking.[16]

Most singularity theorems have the same three types of hypotheses: the energy condition, the initial or boundary condition and the causality condition. In the case of the Penrose theorem the energy condition is the NEC or more accurately the geometric form of the NEC, the null convergence condition. The boundary condition is the existence of a trapped surface, a co-dimension two spacelike submanifold which has two null normals with negative expansions. Equivalently, a trapped surface has negative null normal curvature everywhere. Finally, the causality condition is the existence of a non-compact Cauchy hypersurface. The conclusion is that the spacetime is future null geodesically incomplete.

Schematically, singularity theorems work in the following way: the initial condition establishes the convergence of a congruence of geodesics. The energy condition guarantees that the convergence will continue and a focal point will form. Finally, the causality condition does not allow the formation of focal points leading to a contradiction that proves the geodesic incompleteness.

3.2. *Singularity theorems with weaker conditions*

As quantum fields violate all pointwise energy conditions, a semiclassical singularity theorem is required to have a weaker energy condition. Examples of singularity theorems with such conditions include Refs. 17, 18 and 19 but none of them address the case of a condition obeyed by quantum fields. First Ref. 20 proved singularity theorems with energy conditions inspired by QEIs. Ref. 7 proved singularity theorems with similar conditions using index form methods. Utilizing these results Ref. 21 proved the first semiclassical singularity theorem for timelike geodesic incompleteness. Here we follow Ref. 21 theorem for null geodesic incompleteness.

To state the theorem we first need to fix a parametrization of the affine parameter of the null geodesic. For a manifold M let P be submanifold of co-dimension 2 with mean normal curvature vector field $H^\mu = H\hat{H}^\mu$ where $\hat{H}^\mu$ is a future-pointing timelike unit vector. Then let γ be a future-directed null geodesic emanating normally from P. Then $\hat{H}_\mu$ is extended by parallel transporting along γ. Now we can choose an affine parameter λ on γ, such that $\hat{H}_\mu d\gamma^\mu/d\lambda = 1$. Now we can state the energy condition from 7

$$\int_0^\ell g(\lambda)^2 R_{\mu\nu}\ell^\mu\ell^\nu d\lambda \geq -Q_m(\gamma)\|g^{(m)}\|^2 - Q_0(\gamma)\|g\|^2\,, \tag{8}$$

where Q_m and Q_0 are unknown constants dependent on the choice of γ and m a positive integer. The notation $\|\cdot\|$ denotes the L^2 norm.

The bound required by the singularity theorem is a geometric assumption, while SNEC is an assumption on the renormalized stress-energy tensor. Classically, the Einstein equation connects curvature to the stress-energy tensor. Semiclassically, the semiclassical Einstein equation (SEE) equates the expectation value of the stress-energy tensor with the classical Einstein tensor

$$8\pi G_N\langle T_{\mu\nu}\rangle_\omega = G_{\mu\nu}\,. \tag{9}$$

Using the SEE the bound of Eq. (4) can be written as

$$\int_{-\infty}^{\infty} g(\lambda)^2 R_{kk} d\lambda \geq -32\pi B\|g'(\lambda)\|^2\,. \tag{10}$$

Then this is a bound of the form of Eq. (8) with $m = 1$, $Q_1 = 32\pi B$ and $Q_0 = 0$. Using the SEE assumes that we have a self-consistent solution, which includes a state ω and a metric $g_{\mu\nu}$.

In addition to the energy condition the theorem of Ref. 7 has an assumption on the pointwise null energy density for a finite affine parameter. In particular, there

are two scenarios to describe all possible initial conditions: in scenario 1, initially the NEC is satisfied for an affine length ℓ_0, short compared to the one for the formation of a focal point ℓ. In scenario 2 this requirement is dropped and instead conditions are imposed on the null contracted Ricci tensor for small negative values of the affine parameter. Here we focus on scenario 2.

We first extend γ to $\gamma : [-\ell_0, \ell] \to M$ and assume that Eq. (10) holds on the extended geodesic. Then we define $\rho_{\max} = \max_{[-\ell_0,0]} \rho$ and we can use Lemma 4.7 of Ref. 7 with $m = 1$, $Q_0 = 0$, $A_1 = 1/3$, $B_1 = C_1 = 1$. If we additionally assume that $\rho_{\max} < 0$ we have

Lemma 3.1. *For ρ satisfying Eq. (10) on $[-\ell_0, \ell]$ if*

$$-2H \geq \frac{Q_1 + 2}{\ell} + \frac{Q_1}{\ell_0} + \frac{1}{3}\rho_{\max}\ell_0 \,, \tag{11}$$

then there is a focal point to P along γ in $[0, \ell]$.

Negative null energy in $[-\ell_0, 0]$ region leads to smaller required initial contraction because this negative energy must be over-compensated by positive energy. This effect has been studied and it is known as "quantum interest".[22]

4. Application to evaporating black holes

Penrose proved the first singularity theorem which applies to a classical black hole spacetime. However, this theorem cannot be applied in an evaporating black hole spacetime, where the NEC is violated. Here we apply Lemma 3.1 in a toy model of an evaporating black hole spacetime.

First, we assume that the metric is approximated by Schwarzschild geometry near the classical horizon

$$ds^2 = \left(\frac{R_s}{r} - 1\right) dt^2 - \left(\frac{R_s}{r} - 1\right)^{-1} dr^2 + r^2 d\Omega^2 \,, \tag{12}$$

where R_s is the Schwarzschild radius. We focus on spherically symmetric hypersurfaces P, so that the hypersurface is defined by Schwarzschild coordinates (t_p, r_p) where the mean normal curvature vector field is purely in the r direction.

Inside the horizon, the mean normal curvature H of our surfaces P is given by[23]

$$H(r_P) = -\frac{1}{r_P}\sqrt{\frac{R_s}{r_P} - 1} \,. \tag{13}$$

Since we assumed $\rho_{\max} < 0$ we can drop the last term of Eq. (11)

$$H < -\frac{Q_1}{2\ell} - \frac{1}{\ell} - \frac{Q_1}{2\ell_0} \,. \tag{14}$$

H depends on two parameters, the maximum affine parameter for the formation of the singularity ℓ and the length of the affine parameter that the NEC is violated ℓ_0.

We define the dimensionless parameter x

$$R_s - r_P \equiv x R_s \,, \qquad 0 < x < 1 \,, \tag{15}$$

and y by demanding that the affine distance ℓ is a coordinate distance yR_s. We can consider the case that $y \to \infty$ meaning we have no information about the location of the singularity.

The idea is that if the mean normal curvature of the hypersurfaces P is smaller than the one required by Lemma 3.1 we have a singularity. So we equate the expressions (13) and (14) to find the location of the first hypersurface inside the horizon for which we can apply the Lemma. We want P to be as close to the classical horizon as possible. The setup is shown in Fig. 1.

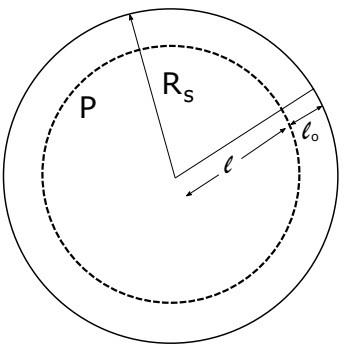

Fig. 1. Schematic representation of a Schwarzschild black hole and the parameters. The dashed circle is constant r and t hypersurface P. Distance ℓ_0 is from the point where the NEC starts being violated, and distance ℓ is from P to the singularity (pictured here at $r = 0$).

A plot of x for different values of y is shown in Fig. 2 for two different values of Q_1. The Ref. 12 value of $B = 1/32\pi$ translates to $Q_1 = 1$. Using this value for Q_1, we find that the minimum x is $1/3$. As discussed earlier, there is also strong motivation to use a value of $B \ll 1$ and so $Q_1 \ll 1$. For small Q_1, we have a singularity theorem for spheres P with

$$R_s - r_P \gtrapprox R_s \frac{Q_1}{2} \qquad \text{for } Q_1 \ll 1 \,. \tag{16}$$

5. Conclusions

In this work we provided motivation for both the smeared null energy condition (SNEC) and the double smeared null energy condition (DSNEC). We proved a semiclassical singularity theorem using SNEC and applied this theorem to establish that spacetimes that approximate the Schwarzschild solution near the horizon must contain a singularity.

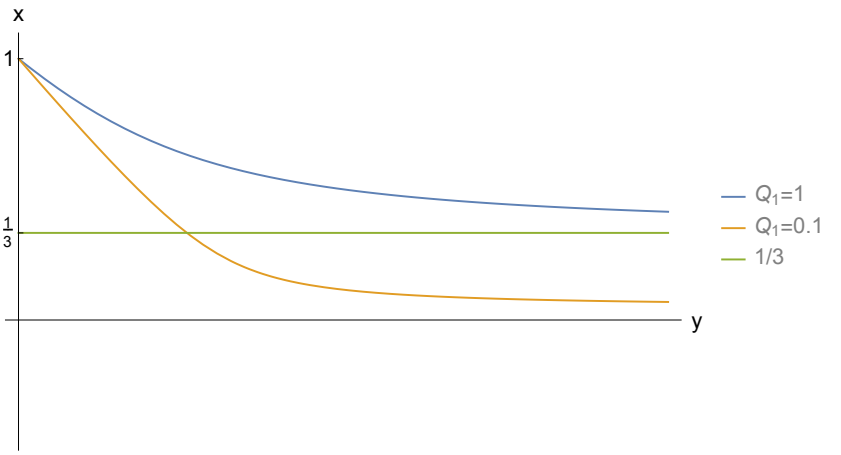

Fig. 2. Required value of x to have a singularity for different values y. For $Q_1 = 0.1$ the minimum value is much smaller compared to $Q_1 = 1$.

As the version of SNEC we use for the singularity theorem has only been proven for Minkowski spacetime, an important future direction is a theorem with a condition that incorporates curvature. There are different ways to approach that. One is to attempt to prove SNEC for spacetimes with curvature. Another is to use the new bound of DSNEC instead. This would require novel concepts as the current singularity theorem proofs are for bounds on single geodesics.

Within the framework of $F(R)$ theories of gravity with (2+1)-dimensions and constant scalar curvature R, we construct a family of thin-shell wormholes with circular symmetry and we analyze the stability of the static configurations under radial perturbations. We show an example of asymptotically anti-de Sitter thin-shell wormholes with charge, finding that stable configurations with normal matter are possible for a suitable range of the parameters.

Keywords: Wormholes; F(R) gravity; Thin shells.

1. Introduction

One of the main goals of alternative theories of gravity is focused on dealing with some fundamental issues in the current cosmological picture, from the early-time inflation scenario to the late-time cosmic accelerated expansion. Basically, the intention is to modify the geometrical side of the gravitational field equations without adding any unknown matter-energy content. Certainly, any alternative approach also intends to provide a geometrical explanation for the spacetime singularities as well as a cornerstone for a quantum version of gravity theory. There is a plethora of different modified gravity models. In particular, $F(R)$ gravity[1–3] is one of the most straightforward modifications to General Relativity (GR), since the Einstein-Hilbert action is replaced by

$$S = \frac{1}{2\kappa}\int d^4x\sqrt{|g|}\left(F(R)+\mathcal{L}_m\right), \tag{1}$$

with $\kappa = 8\pi$ and R the scalar curvature (we adopt units such that $c = G = 1$, with c the speed of light and G the gravitational constant). In the metric formalism, in which the metric tensor is the only dynamical variable to perform the variation of the action, the field equations read

$$F'(R)R_{\mu\nu} - \frac{g_{\mu\nu}}{2}F(R) - \nabla_\mu\nabla_\nu F'(R) + g_{\mu\nu}\nabla_\rho\nabla^\rho F'(R) = \kappa T_{\mu\nu}, \tag{2}$$

where ∇ is the covariant derivative and $T_{\mu\nu}$ is the energy-momentum tensor.

The junction formalism[4–7] in (3+1)-dimensions has been applied within $F(R)$ gravity, for instance, to study thin layers of matter surrounding vacuum (namely, bubbles)[8,9] and black holes.[9,10] Bubbles made of a pure double layer in quadratic

$F(R)$ have been also studied a few years ago.[11] Recently, thin-shell wormholes in $F(R)$ gravity have been explored.[12–16] In this work, we present charged thin-shell wormholes in (2+1)-dimensional $F(R)$ gravity with and we analyze the stability of the static solutions under radial perturbations.

2. Junction conditions

The cut-and-paste formalism is commonly used to construct some wormhole geometries. It is based on the junction conditions of the corresponding theory, which allows to match different solutions across a hypersurface Σ. For convenience, we adopt the usual notation that the jump of any quantity Υ across Σ is $[\Upsilon] \equiv (\Upsilon^2 - \Upsilon^1)|_\Sigma$.

2.1. *General relativity*

In GR, the junction conditions are expressed in the Darmois-Israel formalism,[4,5] which can be sketched as follows:

- Two manifolds $\mathcal{M}_1$ and $\mathcal{M}_2$ are glued at a hypersurface Σ to obtain a geodesically complete manifold $\mathcal{M} = \mathcal{M}_1 \cup \mathcal{M}_2$.
- The first fundamental form (the induced metric) at Σ is

$$h_{ij}^{1,2} = g_{\mu\nu}^{1,2} \frac{\partial X_{1,2}^{\mu}}{\partial \xi^i} \frac{\partial X_{1,2}^{\nu}}{\partial \xi^j}\bigg|_\Sigma , \tag{3}$$

  where $X_{1,2}^{\mu}$ are, respectively, the coordinates that describe $\mathcal{M}_{1,2}$, and ξ^a are the intrinsic local coordinates at the hypersurface, hence $X_{1,2}^{\mu} = X_{1,2}^{\mu}(\xi^a)$.
- The second fundamental form (the extrinsic curvature) at Σ is given by

$$K_{ij}^{1,2} = -n_\gamma^{1,2} \left(\frac{\partial^2 X_{1,2}^{\gamma}}{\partial \xi^i \partial \xi^j} + \Gamma_{\alpha\beta}^{\gamma} \frac{\partial X_{1,2}^{\alpha}}{\partial \xi^i} \frac{\partial X_{1,2}^{\beta}}{\partial \xi^j} \right)\bigg|_\Sigma , \tag{4}$$

  with $n_\gamma^{1,2}$ the unit normal ($n^\gamma n_\gamma = 1$) pointing from $\mathcal{M}_1$ to $\mathcal{M}_2$.
- The matching between $\mathcal{M}_1$ and $\mathcal{M}_2$ at Σ, should fulfill the so-called junction conditions:
  - The line element should be continuous across Σ:

$$[h_{\mu\nu}] = 0. \tag{5}$$

  - The field equations at Σ (Lanczos equations) reduce to

$$\kappa S_{\mu\nu} = -[K_{\mu\nu}] - h_{\mu\nu} K^{\gamma}{}_{\gamma}, \quad n^\mu S_{\mu\nu} = 0 \tag{6}$$

    where $S_{\mu\nu}$ is the energy-momentum tensor at the gluing hypersurface.

The hypersurface Σ is called a *boundary surface* if $S_{\mu\nu} = 0$, or a *thin shell* of matter if $S_{\mu\nu} \neq 0$.

2.2. *F(R) gravity*

The formalism for the junction conditions in $F(R)$ gravity was developed in recent years.[6,7] In this theory, there are two separate cases to take into account:

- General (non-quadratic) case: $F'''(R) \neq 0$
  - At the matching hypersurface Σ, the following continuity relations should be satisfied

$$[h_{\mu\nu}] = 0, \quad [K^{\mu}{}_{\mu}] = 0, \quad [R] = 0, \tag{7}$$

  - The field equations at Σ result

$$\kappa S_{\mu\nu} = -F'(R)[K_{\mu\nu}] + F''(R)[n^{\rho}\nabla_{\rho}R]h_{\mu\nu}, \quad n^{\mu}S_{\mu\nu} = 0. \tag{8}$$

- Quadratic case: $F'''(R) = 0$
  - There is one less restriction in this case, so that the discontinuity of R at Σ is allowed

$$[h_{\mu\nu}] = 0, \quad [K^{\mu}{}_{\mu}] = 0. \tag{9}$$

  - If we write $F(R) = \alpha R^2 + R - 2\Lambda$, the field equations at Σ read

$$\kappa S_{\mu\nu} = -[K_{\mu\nu}] + 2\alpha([n^{\gamma}\nabla_{\gamma}R]h_{\mu\nu} - [RK_{\mu\nu}]), \quad n^{\mu}S_{\mu\nu} = 0. \tag{10}$$

  - In order to guarantee a divergence-free energy-momentum tensor (locally conservation) at Σ, it is necessary to add the following extra contributions[17,18]
    - *The external energy flux vector*:

$$\kappa\mathcal{T}_{\mu} = -2\alpha\nabla_{\mu}[R], \quad n^{\mu}\mathcal{T}_{\mu} = 0,$$

    - *The external scalar pressure/tension*:

$$\kappa\mathcal{T} = 2\alpha[R]K^{\gamma}{}_{\gamma},$$

    - *The double layer contribution*:

$$\kappa\mathcal{T}_{\mu\nu} = \nabla_{\gamma}\left(2\alpha[R]h_{\mu\nu}n^{\gamma}\delta^{\Sigma}\right),$$

      with δ^{Σ} the Dirac delta on Σ (which is analogous to the dipole distributions in classical electrodynamics). It is easy to verify that all these contributions vanish if the scalar curvature is continuous at Σ.

The constraint $[K^{\mu}{}_{\mu}] = 0$ of $F(R)$ gravity, which is not present in GR, has important consequences, as we shall see in the next sections.

3. Charged solutions with constant curvature

$F(R)$ gravity coupled to a nonlinear electromagnetic field is described in (2+1)-dimensions by the action[19]

$$S = \frac{1}{2\kappa}\int d^3x\sqrt{|g|}(F(R) + (-\mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu})^s), \tag{11}$$

where s is a positive parameter ($s \neq 1/2$) and $\mathcal{F}_{\mu\nu} = \partial_\mu \mathcal{A}_\nu - \partial_\nu \mathcal{A}_\mu$ is the electromagnetic tensor. The corresponding energy-momentum tensor becomes traceless for $s = 3/4$, so this value is adopted in what follows.

The dynamical equations given by Eq. (2) for the gravitational sector are completed with the electromagnetic field part

$$\partial_\mu \left(\sqrt{-g}F^{\mu\nu}(-F_{\alpha\beta}F^{\alpha\beta})^{-1/4}\right) = 0. \tag{12}$$

For constant $R = R_0$, the spherically symmetric geometry[19]

$$ds^2 = -A(r)dt^2 + A(r)^{-1}dr^2 + r^2 d\theta^2, \tag{13}$$

with

$$A(r) = -M - \frac{\left(2\mathcal{Q}^2\right)^{3/4}}{2F'(R_0)r} - \frac{R_0 r^2}{6}, \tag{14}$$

is solution of the theory represented by the action (11), where $R_0 = 6\Lambda_{eff}$ can be thought in terms of an effective cosmological constant, M is the mass and $\mathcal{Q}$ is the charge. Notice that this spacetime is asymptotically anti-de Sitter for $R_0 < 0$. The vacuum static BTZ geometry of GR is obtained if $\mathcal{Q} = 0$, so it is also a solution in $F(R)$ gravity. We can define an effective charge with its sign determined by the sign of $F'(R_0)$

$$Z \equiv \frac{\left(2\mathcal{Q}^2\right)^{3/4}}{2F'(R_0)}. \tag{15}$$

The different values of Z establish the horizon structure of the geometry given by Eq. (14).

In the next Section, we use this spacetime to construct thin-shell wormholes by applying the junction formalism in $F(R)$ gravity, and we study the stability of the static configurations by following the standard potential approach.[20]

4. Wormhole geometry: Construction and stability

We proceed to build a class of thin-shell wormholes by cutting the outer parts of the spherically symmetric spacetimes with metrics of the form

$$ds^2_{1,2} = -A_{1,2}(r)dt^2_{1,2} + A_{1,2}(r)^{-1}dr^2 + r^2 d\theta^2, \tag{16}$$

and glueing them on the circle Σ defined by $G(r) = r - a = 0$. In this way, we create the manifold $\mathcal{M} = \mathcal{M}_1 \cup \mathcal{M}_2$, where the regions at the sides of Σ are given

by $\mathcal{M}_{1,2} = \{X^\alpha = (t_{1,2}, r, \theta)/r \geqslant a\}$ and with the metrics $A_{1,2}$, respectively. The only angular coordinate is $0 \leq \theta \leq 2\pi$ and the circle length $2\pi r$ is minimal at Σ, so $\mathcal{M}$ represents a wormhole connecting two regions with a throat of radius a, i.e. the flare-out condition is satisfied there. In order to obtain a traversable wormhole, the radius a is taken large enough to remove the presence of possible event horizons and singularities in both original manifolds. We take $\xi^i = (\tau, \theta)$ as the coordinates on Σ, being τ the proper time. The radius of Σ is taken as a function of time, i.e. $a = a(\tau)$, in order to analyze the stability of the static shells. The proper time should coincide at both sides of Σ, so that $dt_{1,2}/d\tau = \sqrt{A_{1,2}(a) + \dot{a}^2}/A_{1,2}(a)$, with the overdot representing $da/d\tau$ (the free signs are fixed provided that the times $t_{1,2}$ and τ all run into the future).

In the orthonormal basis $\{e_{\hat{\tau}} = e_\tau, e_{\hat{\theta}} = a^{-1}e_\theta\}$, at the hypersurface Σ, the first fundamental form results

$$h^{1,2}_{\hat{i}\hat{j}} = \mathrm{diag}(-1, 1), \tag{17}$$

and the non-null components of the second fundamental form for static configurations are

$$K^{1,2}_{\hat{\tau}\hat{\tau}} = \pm\frac{A'_{1,2}(a_0)}{2\sqrt{A_{1,2}(a_0)}}, \tag{18}$$

$$K^{1,2}_{\hat{\theta}\hat{\theta}} = \mp\frac{1}{a_0}\sqrt{A_{1,2}(a_0)}, \tag{19}$$

where the prime represents derivative with respect to r. In our construction, the equation $[h_{\hat{i}\hat{j}}] = 0$ is automatically satisfied, while the condition $[K^{\hat{i}}{}_{\hat{i}}] = 0$ gives the following relation

$$\frac{A'_2(a_0)}{2\sqrt{A_2(a_0)}} + \frac{A'_1(a_0)}{2\sqrt{A_1(a_0)}} + \frac{1}{a_0}\left(\sqrt{A_1(a_0)} + \sqrt{A_2(a_0)}\right) = 0, \tag{20}$$

that should be always fulfilled by the throat radius a_0.

We can obtain the dynamics of the thin shell from the time dependent version of $[K^{\hat{i}}{}_{\hat{i}}] = 0$, which takes the form

$$\frac{2\ddot{a} + A'_2(a)}{2\sqrt{A_2(a) + \dot{a}^2}} + \frac{2\ddot{a} + A'_1(a)}{2\sqrt{A_1(a) + \dot{a}^2}} + \frac{1}{a}\left(\sqrt{A_1(a) + \dot{a}^2} + \sqrt{A_2(a) + \dot{a}^2}\right) = 0. \tag{21}$$

Then, we can analyze the stability of the configuration by rewriting this dynamical equation of the throat in terms of the potential

$$\dot{a}^2 = -V(a), \tag{22}$$

where

$$V(a) = -\frac{a^2\left(A_1(a) - A_2(a)\right)^2}{4a_0^2\left(\sqrt{A_1\left(a_0\right)} + \sqrt{A_2\left(a_0\right)}\right)^2} - \frac{a_0^2\left(\sqrt{A_1\left(a_0\right)} + \sqrt{A_2\left(a_0\right)}\right)^2}{4a^2} + \frac{A_1(a) + A_2(a)}{2}. \tag{23}$$

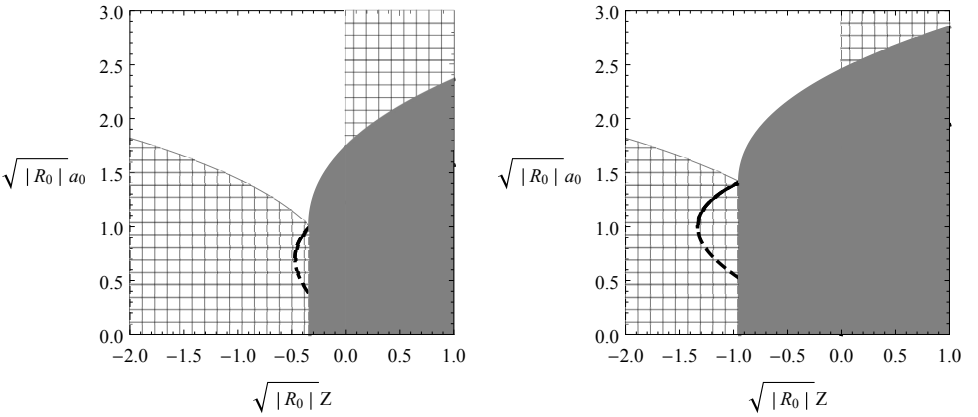

Fig. 1. Wormholes in general $F(R)$ gravity symmetric across the throat. Solid lines represent stable solutions while dashed ones unstable solutions. Meshed zones represent matter satisfying WEC. Grey zones have no physical meaning. Left plot: $M = 0.5$; right one: $M = 1$.

It is straightforward to see that $V(a_0) = 0$ and $V'(a_0) = 0$. Then, the static solutions are stable under radial perturbations when $V''(a_0) > 0$, otherwise they are unstable.

In the following examples, we adopt for our construction the charged solution with constant scalar curvatue introduced in the previous section, so the metric functions read

$$A_i(r) = -M_i - \frac{(2\mathcal{Q}_i^2)^{3/4}}{2F'(R_i)r} - \frac{R_i r^2}{6}, \quad i = 1, 2 \tag{24}$$

where R_i, M_i, and $\mathcal{Q}_i$ are the values of the different parameters in each region $\mathcal{M}_i$.

4.1. *Wormholes in general $F(R)$ with $[R] = 0$*

In the first example, we adopt a symmetric construction across the throat, i.e. $R_1 = R_2 = R_0$, $M_1 = M_2 = M$, and $\mathcal{Q}_1 = \mathcal{Q}_2 = \mathcal{Q}$ so that $A_1(r) = A_2(r) = A(r)$. The throat radius a_0 should fulfill Eq. (20). Then, from Eq. (8), by using that in the orthonormal basis $S_{\hat{i}\hat{j}} = \mathrm{diag}(\sigma_0, p_0)$, we get the surface energy density and the pressure for the static solutions

$$\sigma_0 = \frac{F'(R_0)}{\kappa} \frac{A'(a_0)}{\sqrt{A(a_0)}}, \tag{25}$$

$$p_0 = -2\frac{F'(R_0)}{a_0\kappa}\sqrt{A(a_0)}. \tag{26}$$

If $\sigma_0 \geq 0$ and $\sigma_0 + p_0 \geq 0$, we say that the matter at the throat is normal, because it satisfies the weak energy condition (WEC), otherwise it is exotic. By using Eq. (20), we can see that the matter should satisfy the equation of state $\sigma_0 - 2p_0 = 0$.

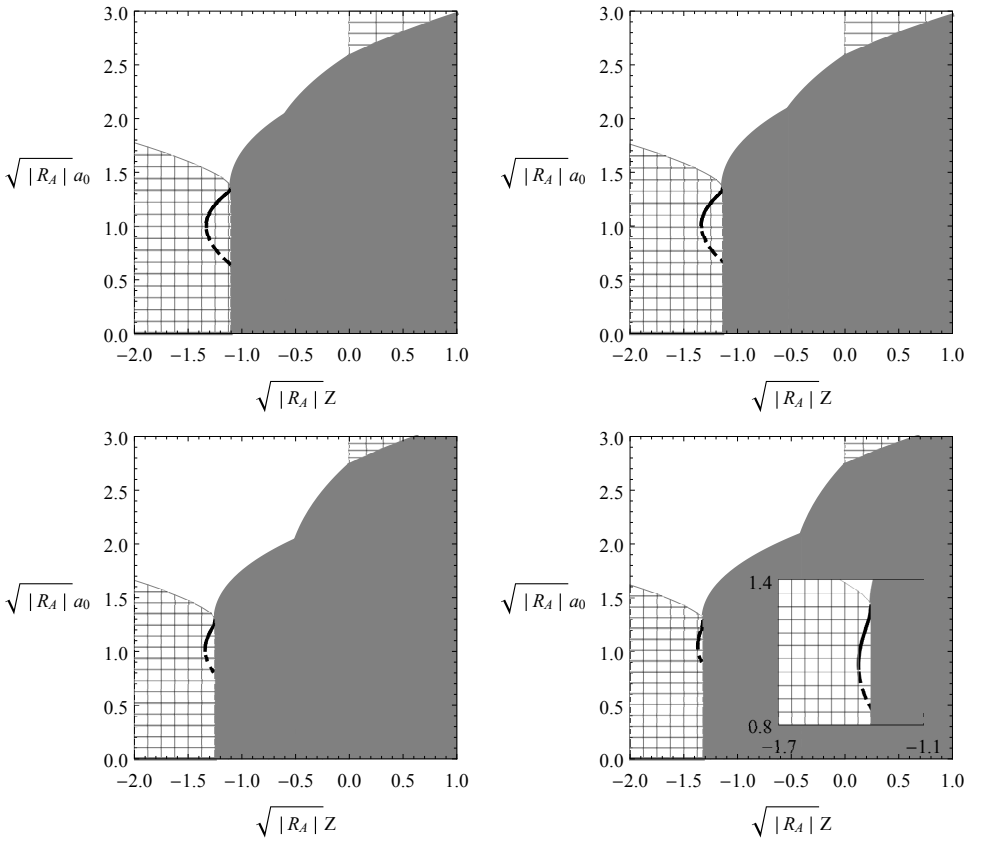

Fig. 2. Wormholes in quadratic $F(R)$ gravity with $R_1 \neq R_2$ at each side of the throat. Solid lines represent stable solutions while dashed ones unstable solutions. Meshed zones represent matter satisfying WEC. Grey zones have no physical meaning. For all plots: $M = 1$, $R_A = (R_1 + R_2)/2$. Upper row: $R_1 = 0.9R_A$ and $R_2 = 1.1R_A$; lower row: $R_1 = 0.8R_A$ and $R_2 = 1.2R_A$. Left column: $\alpha R_A = -0.1$ for $Z > 0$ and $\alpha R_A = -0.9$ for $Z < 0$; right column: $\alpha R_A = -0.2$ for $Z > 0$ and $\alpha R_A = -0.8$ for $Z < 0$.

From Fig. 1, we see that there are two solutions constituted of normal matter for a short range of $\sqrt{|R_0|}Z$ with $Z < 0$. Hence it requires the presence of ghost fields, i.e. $F'(R_0) < 0$. The solution with the largest radius is stable while the other one is unstable under radial perturbations. The qualitative behavior of the solutions is not affected by the different values of M which only represent a change of scale.

4.2. *Wormholes in quadratic $F(R)$ with $[R] \neq 0$*

In the second example, we adopt $M_1 = M_2 = M$, and $\mathcal{Q}_1 = \mathcal{Q}_2 = \mathcal{Q}$ but $R_1 \neq R_2$, so we are restricted to quadratic $F(R)$ gravity. The throat radius a_0 should satisfy Eq. (20). From Eq. (10) the energy density and pressure at the throat in the static

configuration are

$$\sigma_0 = \frac{1+2\alpha R_2}{\kappa}\left(\frac{A_2'(a_0)}{2\sqrt{A_2(a_0)}}\right) + \frac{1+2\alpha R_1}{\kappa}\left(\frac{A_1'(a_0)}{2\sqrt{A_1(a_0)}}\right), \tag{27}$$

$$p_0 = -\frac{1+2\alpha R_2}{\kappa}\left(\frac{\sqrt{A_2(a_0)}}{a_0}\right) - \frac{1+2\alpha R_1}{\kappa}\left(\frac{\sqrt{A_1(a_0)}}{a_0}\right). \tag{28}$$

In this case, there exists an external scalar pressure/tension $\mathcal{T}_0$ that satisfies the equation of state $\sigma_0 - p_0 = \mathcal{T}_0$ which results by using Eq. (20). The other extra contributions are: $\mathcal{T}_\mu^{(0)} = 0$ and $\mathcal{T}_{\mu\nu}^{(0)} \propto (2\alpha[R]/\kappa)h_{\mu\nu}$.

From Fig. 2, we see that there are two solutions made of normal matter for a short range of $\sqrt{|R_A|}Z$ with $R_A = (R_1 + R_2)/2$; since $Z < 0$, ghost fields appear. The solution with the largest radius is stable; the other is unstable. The larger the difference between R_1 and R_2, the smaller the range of $\sqrt{|R_A|}Z$ where solutions exist. The same qualitative behaviour is obtained when α decreases. As in the previous example, the different values of M does not affect the qualitative behavior of the solutions and it only represents a change of scale.

5. Summary

We have constructed a family of circularly symmetric thin-shell wormholes in (2+1)-dimensional $F(R)$ gravity with constant scalar curvature R at each side of the throat. We have studied their stability under perturbations preserving the symmetry. The junction conditions in $F(R)$ gravity are more restrictive than in GR. In fact, the extra condition $[K^\mu{}_\mu] = 0$ forces the type of equation of state: for general $F(R)$, it should be $\sigma_0 - 2p_0 = 0$, while for quadratic $F(R)$, it results $\sigma_0 - 2p_0 = \mathcal{T}_0$. We have analyzed two examples: (i) symmetric wormholes ($R_1 = R_2 = R_0$; $M_1 = M_2 = M$; $\mathcal{Q}_1 = \mathcal{Q}_2 = \mathcal{Q}$) across the throat in general $F(R)$ and (ii) wormholes asymmetric in the scalar curvature ($R_1 \neq R_2$; $M_1 = M_2 = M$ and $\mathcal{Q}_1 = \mathcal{Q}_2 = \mathcal{Q}$) only in quadratic $F(R)$. In both cases, we have found two solutions made of normal matter (i.e., satisfying WEC) for a range of values with the effective charge $Z < 0$. However, for these solution the presence of ghost fields is always required since $Z < 0$ implies $F'(R_0) < 0$. We have found that the solution with the larger radius is stable while the other is unstable. The qualitative behavior of the solutions is not altered by M, resulting only in a change of scale. In particular, for quadratic $F(R)$ as long as the difference between the constant (negative) scalar curvatures R_1 and R_2 grows, the range of the squared charge $\mathcal{Q}^2$ where stable solutions exist becomes smaller; similar behavior can be observed when α decreases. Another example and more references can be found in our recently published work.[20]

Alcubierre proposed in 1994 that the well known special relativistic limitation that particles cannot travel with velocities bigger than the light speed can be bypassed when such trips are considered globally within specific general relativistic frameworks. Although initial results indicated this scenario as being unphysical, since it would seem to require negative mass-energy density, recent theoretical analyses suggest that such an unphysical situation may not always be necessarily true. In this paper, we present solutions of the Einstein equations using the original Alcubierre warp drive metric endowed with various matter-energy sources, namely dust, perfect fluid, anisotropic fluid, and perfect fluid within a cosmological constant spacetime. A connection of some of these solutions featuring shock waves described by the Burgers equation is also shown.

Keywords: Warp drive solutions, perfect fluid, anisotropic fluid, shock waves, electromagnetic field, cosmological constant

1. Introduction

Alcubierre[1] advanced a model based on a specific general relativistic spacetime geometry in which massive particles can travel at superluminal speeds if they are located inside a specially designed spacetime distortion. The physics of this possible propulsion method, named as *warp drive* (WD) after science fiction literature, consists of a special spacetime metric forming a spacetime distortion, called *warp bubble*, such that it generates an expansion behind the distortion and a contraction in front of it. That makes it possible for a massive particle to be in a local sub-luminal speed inside the bubble, as required by special relativity, whereas outside the particle is propelled at superluminal speeds. Therefore, employing of this spacetime distortion a massive particle travels between two points in spacetime with apparent time less than the time a light particle with zero mass would require to travel between the same two points.

The WD metric, as originally proposed by Alcubierre, is based on a general metric that uses the 3+1 formalism.[2,3] It consists of a boost in the direction of one of the spatial coordinates, described by the shift vector, a function of spacetime coordinates and the product of two functions, the velocity of the center of the warp bubble and the shape function that controls the shape of the bubble. Although

Alcubierre did not solve the Einstein equations with his proposed spacetime geometry, he gave an example of a shape function in the form of a hat function.[1] One of the main caveats of the Alcubierre WD spacetime is the requirement of negative mass-energy density and the violation of the dominant and weak energy conditions.

Ford and Roman[4] derived quantum inequalities for free massless quantized scalar fields, electromagnetic fields, and massive scalar fields in four-dimensional Minkowski spacetime and concluded that these constraints have the form of an uncertainty principle limitation on the magnitude and duration of negative mass-energy densities and that the exotic solutions of Einstein equations such as wormholes and WD would have significant limitations in their viability. Pfenning and Ford[5] followed this last work and calculated the upper bound limits necessary for the WD viability, concluding then that the energy required to create a warp bubble is ten orders of magnitude greater than the total mass of the entire visible universe, also negative.

Krasnikov[6] approached the hyperfast interstellar travel problem in general relativity by discussing the possibility of whether or not a mass particle can reach a remote point in spacetime and return sooner than a photon would. Krasnikov argued that it is not possible for a mass particle to win this race under reasonable assumptions for globally hyperbolic spacetimes. He discussed in detail the specific spacetime topologies, but with the constraint that tachyons would be a requirement for superluminal travel to occur. He conjectured a spacetime modification device that can be used to make superluminal travel possible without tachyons. Such spacetime was named as *Krasnikov tube* by Everet and Roman,[7] and they generalized the metric proposed by Krasnikov by hypothesizing a tube along the path of the particle connecting Earth to a distant star.

The Krasnikov metric cannot shorten the time for a one-way trip from Earth to a distant star, but it can make the time for a round trip arbitrarily short for clocks on Earth. However, the Everet and Roman[7] extension of the Krasnikov metric has the property that inside the tube the spacetime is flat and the lightcones are opened in such a way that they allow the superluminal travel in one direction. They also mentioned that even though the Krasnikov tube does not involve closed timelike curves it is possible to construct a time machine with a system of two non-overlapping tubes, and demonstrated that the Krasnikov tube also requires thin layers of negative energy density and large total negative energies.

Lobo and Crawford[8] discussed the Krasnikov metric in detail, addressed the violation of the weak energy condition and the viability of superluminal travel. These authors concluded that with the imposition of the weak energy condition the Olum theorem[9] prohibits superluminal travel and pointed out the necessity of further research on spacetimes with closed timelike curves and the need for a precise definition of superluminal travel. They argued that one can construct metrics that allow superluminal travel but are flat Minkowski spacetimes. The quantum inequalities, brought from quantum field theory,[7] were also discussed. Van de Broeck[10] showed

how a minor modification of the Alcubierre WD geometry can reduce the total energy required for the creation of a warp bubble. He presented a modification of the original WD metric where the total negative mass would be of the order of just a few solar masses.

Natário[11] proposed a new version of the WD theory with zero expansion and questioned the effects that occur in the WD in opposition to his newly proposed metric, namely, the zero expansion Natário WD metric. Natário discussed the nature of the WD spacetime symmetries with a series of propositions and corollaries such as the proof that the WD spacetime is flat whenever the tangent vector to the Cauchy surfaces is a Killing vector field for the Euclidean metric despite being time-dependent and as a particular case. In addition, it is also flat wherever the tangent vector is spatially constant. He also showed that nonflat WD spacetime violate both the *weak energy condition* (WEC) and the *strong energy condition* (SEC), as well as that the WD metric can be obtained from the Natário metric by a particular choice of coordinates. The spherical coordinates were the choice of charts for the zero expansion of the Natário WD spacetime.

Lobo and Visser[12] pointed out that the WD theory is an example of reverse engineering of the solutions of the Einstein equations where one defines a specific spacetime metric and then one finds the matter distribution responsible for the respective geometry. These authors verified that the class of WD spacetimes necessarily violate the classical energy conditions even for low warp bubble velocity. Hence, this is the case of a geometric choice and not of superluminal properties. They proposed a more realistic WD by applying linearized gravity to the weak WD with nonrelativistic warp bubble velocities and argued that for the Alcubierre WD and its version proposed by Natário[11] the center of the bubble must be massless. They found that even for low velocities the negative energy stored in the warp fields must be a significant fraction of the particle's mass at the center of the warp bubble.

White[13,14] described how a warp field interferometer could be implemented at the Advanced Propulsion Physics Laboratory with the help of the original[1] WD ideias. He also pointed out that the expansion behind the warp bubble and contraction in front of it is due to the nature of the WD functions, and that the distortion of spacetime may be interpreted as a kind of Doppler effect or stress and strain on spacetime. Lee and Cleaver[15] argued that external radiation might affect the WD, and that the warp field interferometer proposed by White[13,14] could not detect spacetime distortions. Mattingly et al.[16] discussed curvature invariants in the Natário WD.

Bobrick and Martire[17] proposed a general WD spacetime that encloses all WD definitions removing any alleged issues with the original Alcubierre WD. They presented a general subluminal model with spherical symmetry and positive energy solutions that satisfies the quantum energy inequalities such that it reduces two orders of magnitude the WD requirement for negative energy density. They claimed

that any type of WD, including the original one, is a place of regular or exotic material moving in inertial form with a certain speed.

Lentz[18] claimed that the original warp bubble proposed by Alcubierre[1] can be physically interpreted as hyper-fast gravitational solitons and presented the first solution for superluminal solitons in general relativity satisfying the WEC and the momentum conditions for conventional sources of stress, like energy and momentum, that do not require large amounts of negative energy. The basis for his work is to assume that the shift vector components obey a kind of wave equation giving rise to a positive energy geometry. Fell and Heisenberg[19] also addressed the WD as gravitational solitons and shed light on the Eulerian energies and their relation to the WEC, raising the possibility for superluminal spacetimes with viable amounts of energy density.

Quarra[20] established that within the scope of general relativity certain gravitational waveforms can result in geodesics that arrive at distant points earlier than light signals in flat spacetime, and presented an example waveform that can be used to manifest superluminal behavior.

Santiago et al.[21] claimed that generic WD metrics violate the *null energy conditions* (NEC) and discussed how Eulerian observers are privileged, meaning that these observers may perceive positive energy densities causing the impression of viable WD. They also argue that for the WD to become a possibility it would require that all timelike observers observe positive energy densities. They stated that any WD spacetime will unavoidably violate the energy conditions. In a subsequent work[22] they claimed that exotic spacetimes, such as the WD one will always violate energy conditions. They also provided other examples of such spacetimes relating them to wormholes, tractor beams and stress beams.

For a detailed discussion on the basics of WD theory, the reader is referred to Alcubierre and Lobo.[23] For a nice exposition on WD theory one is referred to the lecture notes of the course given by Shoshany.[24] It is particularly noteworthy the recent results concerning the possibility of WD features in negative energy density distribution of an experimental Casimir cavity,[25] results that open the striking possibility of ingenious experimental avenues on how to create the WD phenomena in a laboratory environment.

In this work, we present a summary of the results we have recently obtained when solving the Einstein equations with the assumption of simple fluid distributions embedded in the original Alcubierre WD spacetime geometry. New results such as the vacuum solutions connecting the WD to shock waves via the Burgers equation are presented.[26] We used the perfect fluid energy-momentum tensor[27] (EMT) which disclosed new exact solutions of the Einstein equations. We also demonstrated that starting with simple forms of mass and energy sources, vacuum solutions for the WD spacetime arise when we impose that the WEC is trivially satisfied by a choice of gauge on the shift vector and the spacetime coordinates.[27] Further results of the Alcubierre WD metric endowed with a charged dust EMT that considers

an electromagnetic tensor in curved spacetime with the cosmological constant are mentioned.[28] Finally, adding the cosmological constant to the Einstein equations coupled with the Alcubierre WD spacetime having perfect fluid as a source has the effect of leading the energy density to possibly becoming positive depending on both the value and sign of the cosmological constant.[29]

The paper is organized as follows. Section 2 reviews very brief the Alcubierre WD metric. Section 3 depicts the perfect and anisotropic fluid cases[27] and Section 4 discusses the relationship between the WD spacetime, vacuum solutions, and shock waves described by the Burgers equations.[26] Section 5 presents a discussion on the role of the cosmological constant in the Einstein equation solutions for the WD spacetime.[29] Section 6 presents the conclusions.

2. The Alcubierre Warp Drive Spacetime Metric

Alcubierre originally used[1] the Arnowitt-Deser-Misner (ADM) approach of general relativity,[2,3] a formalism where the spacetime is described by a foliation of space-like hypersurfaces of constant time coordinate. The general form of the WD metric in this formalism is described by the following equation,

$$\begin{aligned} ds^2 = -\,d\tau^2 &= g_{\alpha\beta} dx^\alpha dx^\beta \\ &= -\left(\alpha^2 - \beta_i \beta^i\right) dt^2 + 2\beta_i\, dx^i\, dt + \gamma_{ij}\, dx^i\, dx^j \ , \end{aligned} \tag{1}$$

where $d\tau$ is the lapse of proper time, α is the lapse function, β^i is the space-like shift vector, and γ_{ij} is the spatial metric for the hypersurfaces. The Greek indices range from 0 to 3, whereas the Latin ones indicate the space-like hypersurfaces and range from 1 to 3. The lapse function α and the shift vector β^i are functions to be determined, γ_{ij} is a positive-definite metric on each of the space-like hypersurfaces, for all values of time, a feature that makes the spacetime globally hyperbolic. The lapse function $d\tau$ is a measure of proper time between two adjacent hypersurfaces by observers moving along the normal direction to the hypersurfaces (Eulerian observers). The shift vector is a tangent vector to the hypersurfaces that relates the spatial coordinate systems on different hypersurfaces.

Alcubierre assumed the following ad hoc particular choices for the parameters of the general ADM metric,[1]

$$\alpha = 1, \tag{2}$$

$$\beta^1 = -v_s(t) f\big[r_s(t)\big], \tag{3}$$

$$\beta^2 = \beta^3 = 0, \tag{4}$$

$$\gamma_{ij} = \delta_{ij}. \tag{5}$$

Rewriting Eq. (1) with these definitions yields the *Alcubierre WD spacetime metric* below,

$$ds^2 = -\left(1 - \beta^2\right) dt^2 - \beta\, dx\, dt + dx^2 + dy^2 + dz^2. \tag{6}$$

3. Einstein Equations Solutions for Simple Fluids

We to find solutions to the Einstein equations with the Alcubierre WD metric as the underlying geometry by coupling simple matter-energy distributions, namely the dust of particles, the perfect fluid and the anisotropic fluid with off-diagonal metric terms to see if those EMTs could lead to a viable WD bubble.

Starting with incoherent fluid, or dust, vacuum solutions of the Einstein equations for the WD metric (6) were recovered, which led to the connection of the WD with shock waves via Burgers equation.[26] Vacuum solutions mean that all the energy conditions are trivially satisfied, but the possibility of vacuum shock waves that could physically represent warp bubbles indicated that other known matter-energy distributions could result in more complex solutions of Einstein equations. Under this perception we proposed two other energy-momentum tensors, the perfect and "parametrized" fluids, where the latter is, in fact, an anisotropic fluid with heat flux.[27]

The EMT for an anisotropic and dissipative fluid may be written by the following equation,

$$T^{\alpha\beta} = \mu u^{\alpha} u^{\beta} + p h^{\alpha\beta} + u^{\alpha} q^{\beta} + u^{\beta} q^{\alpha} + \pi^{\alpha\beta}, \tag{7}$$

where

$$h_{\alpha\beta} = g_{\alpha\beta} + u_a \, u_b \tag{8}$$

projects tensors onto hypersurfaces orthogonal to u^{α}, μ is the matter density, p is the fluid static pressure, q^{α} is the heat flux vector and $\pi^{\alpha\beta}$ is the viscous shear tensor. The world lines of the fluid elements are the integral curves of the four-velocity vector u^{α}. The heat flux vector and the viscous shear tensor are transverse to the world lines, that is,

$$q_a \, u^a = 0, \qquad \text{and} \qquad \pi_{ab} \, u^b = 0 \, . \tag{9}$$

For simplicity we depicted the EMT of the anisotropic fluid in the following matrix form,

$$T_{\alpha\sigma} = \begin{pmatrix} \mu + \beta^2 p & -\beta D & 0 & 0 \\ -\beta D & A & 0 & 0 \\ 0 & 0 & B & 0 \\ 0 & 0 & 0 & C \end{pmatrix}, \tag{10}$$

where p, A, B and C are anisotropic static pressures, D is the momentum density parameter that represents the heat flux for this fluid, and μ is the particles' matter density. Notice that if we choose all pressures and momentum density as being

equal to the static pressure p we recover the perfect fluid form shown below,

$$T_{\alpha\sigma} = \begin{pmatrix} \mu + \beta^2 p & -\beta p & 0 & 0 \\ -\beta p & p & 0 & 0 \\ 0 & 0 & p & 0 \\ 0 & 0 & 0 & p \end{pmatrix} . \tag{11}$$

The EMT for a perfect fluid can be written in terms of the tensor notation as follows,

$$T_{\alpha\beta} = (\mu + p)\, u_\alpha u_\beta + p\, g_{\alpha\beta} \,, \tag{12}$$

where μ is the matter density, p is the fluid static pressure, $g_{\alpha\beta}$ is the metric tensor and u_α is the 4-velocity of an observer inside the fluid. Perfect fluids have no shear stress, rotation, heat conduction or viscosity. To recover the EMT for dust of particles, we have to choose the static fluid pressure to be zero, and the matrix form for the dust is given by the following equation,

$$T_{\alpha\sigma} = \begin{pmatrix} \mu & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} , \tag{13}$$

which can be written in tensor notation as follows,

$$T_{\alpha\beta} = \mu\, u_\alpha u_\beta \,, \tag{14}$$

where μ is the matter density represented by a scalar function of the spacetime coordinates, and u^α are the observers 4-velocity components.

Table 1 lists the solutions of the Einstein equations for the anisotropic fluid defined by Eq. (10),[27] where the two solutions subsets 1b and 2b are considered unphysical because the resulting EMT leads to the anisotropic static pressures A and D equal to zero, whereas $B = C$. The energy density in the T_{00} component of the EMT is equal to zero, resulting in the following equation of state relating the matter density μ, the shift vector β and the static pressure p,

$$\mu = -\beta^2 p \,. \tag{15}$$

We must point out that we made a notational change on the shift vector definition β^1 so that it has the negative sign of the original parameter defined by Alcubierre,[1] yielding the shift vector β used in here as being given as below,

$$\beta = -\beta^1 = v_s(t) f\big[r_s(t)\big] \,. \tag{16}$$

Finally, one should also notice that solutions 1b and 2b brought about the following Burgers equation in dissipative form,

$$\frac{\partial}{\partial x}\left[\frac{\partial \beta}{\partial t} + \frac{1}{2}\frac{\partial}{\partial x}(\beta^2)\right] = -64\pi B \,. \tag{17}$$

Table 1. WD solutions of the Einstein equations with anisotropic fluid as source.

Case	Conditions	Results
1) $\dfrac{\partial\beta}{\partial z}=0$	1a) $\dfrac{\partial\beta}{\partial x}=0$	$\mu=\beta^2(2D-A-p)+\dfrac{A}{3}$ $\beta=\beta(t,y)$ $B=-C=\dfrac{A}{3}$ $\left(\dfrac{\partial\beta}{\partial y}\right)^2=32\pi C,$ $\dfrac{\partial^2\beta}{\partial y^2}=16\pi\beta(A-D)$
	1b) $\dfrac{\partial\beta}{\partial y}=0$	$\mu=-\beta^2 p$ $\beta=\beta(t,x)$ $B=C$ $A=D=0$ $\dfrac{\partial}{\partial x}\left[\dfrac{\partial\beta}{\partial t}+\dfrac{1}{2}\dfrac{\partial}{\partial x}(\beta^2)\right]=-64\pi B$ $\rightarrow$ solution *dismissed* as unphysical
2) $\dfrac{\partial\beta}{\partial y}=0$	2a) $\dfrac{\partial\beta}{\partial x}=0$	$\mu=\beta^2(2D-A-p)+\dfrac{A}{3}$ $\beta=\beta(t,z)$ $B=-C=\dfrac{A}{3}$ $\left(\dfrac{\partial\beta}{\partial z}\right)^2=32\pi C$ $\dfrac{\partial^2\beta}{\partial z^2}=16\pi\beta(A-D)$
	2b) $\dfrac{\partial\beta}{\partial z}=0$	$\mu=-\beta^2 p$ $\beta=\beta(t,x)$ $B=C$ $A=D=0$ $\dfrac{\partial}{\partial x}\left[\dfrac{\partial\beta}{\partial t}+\dfrac{1}{2}\dfrac{\partial}{\partial x}(\beta^2)\right]=-64\pi B$ $\rightarrow$ solution *dismissed* as unphysical

Perfect fluid solutions have equations of state given by the expression below,[30]

$$p = p(\mu) = (\gamma - 1)\mu \ , \tag{18}$$

where $\gamma =$ is a constant which for ordinary fluids can be approximated by $1 \leq \gamma \leq 2$. The incoherent matter, or dust, corresponds to $\gamma = 1$, and radiation corresponds to $\gamma = \frac{4}{3}$. For solutions 1b and 2b in Table 1 it is clear that γ is a function of the shift vector given by the following equation,

$$\gamma = 1 - \frac{1}{\beta^2} \ . \tag{19}$$

Notice that since the shift vector is a function of the warp velocity and it is also the regulating function, we are facing a problem with a discontinuity when $\beta = 0$ since outside the warp bubble the regulating function approaches to zero, but inside the warp bubble $f(r_s) = 1$. So Eq. (19) takes the following form,

$$\gamma = 1 - \frac{1}{v_s^2} \, , \tag{20}$$

where $v_s = v_s(t)$ is the warp bubble velocity. Solutions 1a and 2a shown in Table 1 are very similar, except that for solution 1a the shift vector is a function of spacetime coordinates (t, y), whereas solution 2a is a function of (t, z) coordinates. However, in both of these cases, the shift vector may be a complex-valued function depending on the values of the static pressure C. For these solutions the equations of state relating the matter density μ and the fluid pressures are identical and given by the following expression,

$$\mu = \beta^2(2D - A - p) + \frac{A}{3} \, . \tag{21}$$

The perfect fluid solutions listed in Table 2 are a special case of the anisotropic fluid if we chose all pressures to be equal to p. Table 3 presents the special dust case $(p = 0)$, which leads to vacuum.

4. Warp Drive and Shock Waves

In previous studies[26, 27] it was found an intrinsic relationship between the WD concept and shock waves via the Burgers equation arising from vacuum solutions of Einstein equations for the Alcubierre WD metric. Such a result may mean that the warp bubble could be interpreted as shock waves in vacuum. In other words, the Burgers equation can be seen as a vacuum solution of Einstein equations connecting the Alcubierre WD metric to shock waves.

In the case of the anisotropic fluid, we considered as unphysical the solution which led to a Burgers equation (17) because the parameter values resulted in an EMT with only two static pressures (diagonal terms) and no energy density. Nevertheless, for the perfect fluid and dust EMTs we found the Burgers equation

Table 2. WD solutions of the Einstein equations with perfect fluid as source.

Case	Condition	Results
1) $\frac{\partial\beta}{\partial z}=0$	$1a)$ $\frac{\partial\beta}{\partial x}=0$	$p=3\mu$ $\beta=\beta(y,t)$ $\frac{\partial\beta}{\partial y}=\pm\sqrt{-32\pi\mu}$
	$1b)$ $\frac{\partial\beta}{\partial y}=0$	$p=3\mu=0$ $\beta=\beta(x,t)$ $\frac{\partial\beta}{\partial t}+\frac{1}{2}\frac{\partial}{\partial x}(\beta^2)=h(t)$
2) $\frac{\partial\beta}{\partial y}=0$	$2a)$ $\frac{\partial\beta}{\partial x}=0$	$p=3\mu$ $\beta=\beta(z,t)$ $\frac{\partial\beta}{\partial z}=\pm\sqrt{-32\pi\mu}$ $\frac{\partial\beta}{\partial z}=\pm\sqrt{\pm 96\pi\mu}$
	$2b)$ $\frac{\partial\beta}{\partial z}=0$	$p=3\mu=0$ $\beta=\beta(x,t)$ $\frac{\partial\beta}{\partial t}+\frac{1}{2}\frac{\partial}{\partial x}(\beta^2)=h(t)$

Table 3. WD solutions of the Einstein equations with dust source (leads to vacuum).

Case	Consequence	Results
1) $\frac{\partial\beta}{\partial z}=0$	$\frac{\partial\beta}{\partial y}=0$	$\mu=0$ $\beta=\beta(t,x)$ $\frac{\partial\beta}{\partial t}+\frac{1}{2}\frac{\partial}{\partial x}(\beta^2)=h(t)$
2) $\frac{\partial\beta}{\partial y}=0$	$\frac{\partial\beta}{\partial z}=0$	$\mu=0$ $\beta=\beta(t,x)$ $\frac{\partial\beta}{\partial t}+\frac{1}{2}\frac{\partial}{\partial x}(\beta^2)=h(t)$

in its viscous form describing a dissipative system with the right-hand side being a function of time coordinate only, according to the expression below,

$$\frac{\partial\beta}{\partial t}+\frac{1}{2}\frac{\partial}{\partial x}(\beta^2)=h(t)\ . \tag{22}$$

Here $h = h(t)$ is an arbitrary function to be determined by the boundary conditions. If $h(t) = 0$ Eq. (22) takes its homogeneous form describing a conservative system known as inviscid Burgers equation.

The Burgers or Bateman-Burgers, equation is a well-known partial differential equation that models several physical systems such as gas dynamics, traffic flows, and even stock market, since, for the latter application, it is connected to the symmetries of the Black-Scholes equation. Its most notorious system description is, however, the phenomena arising from conservation laws and formation of shock waves, that is, discontinuities that appears after a finite time and then propagates in a regularly. The physics behind the field solutions of the Burgers equation can be seen as a current density.

The WD is depicted by the shift vector $\beta = v_s(t)f(r_s)$, where v_s is the bubble velocity, $f(r_s)$ is the regulating function of the warp bubble shape and the inviscid Burgers in Eq. (22) can be interpreted and representing a conservation law for this current density. Analyzing each term of Eq. (22), the first one on the l.h.s., $\partial\beta/\partial t$ can be interpreted as a force per unit mass, i.e., the time derivative of momentum. The second term on the l.h.s., $\frac{1}{2}\,\partial(\beta^2)/\partial x$, can be interpreted as the divergence of the total energy, which is entirely kinetic. Physically the result can be understood by considering the WD metric as conservation of both energy and momentum in the direction of the wave propagation. Calculating the divergence of the parametrized, or anisotropic, perfect fluid energy-momentum tensor, and demanding that it should be zero, one arrives at the following system,[27]

$$
\begin{aligned}
&-\frac{\partial\beta}{\partial x}(D+\mu)-\frac{\partial\mu}{\partial t}-\beta\left[\frac{\partial D}{\partial x}+\frac{\partial\mu}{\partial x}+\frac{\partial\beta}{\partial t}(2p+A-3D)\right]\\
&\qquad+\beta^2\left[\frac{\partial D}{\partial t}-\frac{\partial p}{\partial t}+3\frac{\partial\beta}{\partial x}(D-p)\right]+\beta^3\left(\frac{\partial D}{\partial x}-\frac{\partial p}{\partial x}\right)=0, \qquad (23)\\
&\frac{\partial A}{\partial x}+\frac{\partial\beta}{\partial t}(D-A)+\beta\left[3\frac{\partial\beta}{\partial x}(D-A)+\frac{\partial D}{\partial t}-\frac{\partial A}{\partial t}\right]\\
&\qquad+\ \beta^2\left(\frac{\partial D}{\partial x}-\frac{\partial A}{\partial x}\right)=0, \qquad (24)\\
&\frac{\partial B}{\partial y}+\beta\frac{\partial\beta}{\partial y}(D-A)=0, \qquad (25)\\
&\frac{\partial C}{\partial z}+\beta\frac{\partial\beta}{\partial z}(D-A)=0. \qquad (26)
\end{aligned}
$$

The perfect fluid zero divergence is recovered by letting

$$p = A = B = C = D\,, \qquad (27)$$

hence, Eqs. (23) to (26) become,

$$-\frac{\partial\mu}{\partial t}-\beta\left(\frac{\partial p}{\partial x}+\frac{\partial\mu}{\partial x}\right)=0\,, \tag{28}$$

$$\frac{\partial p}{\partial x}=\frac{\partial p}{\partial y}=\frac{\partial p}{\partial z}=0\,, \tag{29}$$

which means that the static pressure p of the perfect fluid does not depend on the spatial coordinates, and Eq. (28) reduces to the expression below,

$$\frac{\partial\mu}{\partial t}+\beta\frac{\partial\mu}{\partial x}=0\,, \tag{30}$$

which is a continuity equation, μ is the fluid density, and β is the flow velocity vector field. Notice that for constant density the fluid has an incompressible flow. Therefore, all partial derivatives of β in terms of the spatial coordinates vanish, and the flow velocity vector field has zero divergence, this being a classical fluid dynamics scenario. The local bubble volume expansion rate is zero, and the WD metric becomes the Minkowski metric in this scenario.

If we want to find these results for the dust of particles as a particular case, we can see that the partial time derivative of the matter-density is zero and we have

$$\mu\frac{\partial\beta}{\partial x}=0\,, \tag{31}$$

which is immediately satisfied since the matter density is zero for the dust EMT and the Einstein equations solution for the WD is the vacuum one. This is also true for the sets of solutions 1b and 2b found for the perfect fluid, as shown in Table 2. This result for the vacuum solutions of the Einstein equations with the WD metric as a background suggests that the necessary energy to create the associate shock wave is purely geometrical. It is interesting evidence that the WD metric can be understood as a spacetime motion equivalent to a shock wave moving in a fluid, where spacetime itself plays the role of the fluid.

Considering all these results one can speculate about vacuum energy, quantum fluctuations and dark matter as fuel for the feasibility of the warp bubble, but one has to overcome possible difficulties caused by the event horizon of the bubble that would require particles with imaginary mass like tachyons.[31]

5. The Cosmological Constant

Bearing in mind the results above led to the next step of adding the cosmological constant in the Einstein equation to seek solutions for Alcubierre WD spacetime geometry.[29] The motivation came from Eq. (19) in the original Alcubierre work,[1] which was obtained by applying the WEC considering Eulerian observers, contracting the EMT and writing the final expression $G_{\mu\nu}=\kappa T_{\mu\nu}$ in the Einstein equation, whose result reads as follows,

$$T^{\mu\nu}u_\mu u_\nu=\alpha^2T^{00}=G^{00}=-\frac{v_s^2\rho^2}{4r_s^2}\left(\frac{df}{dr_s}\right)^2. \tag{32}$$

Here u^μ and u_μ are respectively the contravariant and covariant components of the four-vector velocity of the Eulerian observers given by

$$u^\mu = \frac{1}{\alpha}(1, \beta^1, \beta^2, \beta^3) \quad , \quad u_\mu = -(\alpha, 0, 0, 0)\,, \tag{33}$$

where α is the lapse time between the constant hypersurfaces of the ADM-formalism and β^i are the three-components of the shift vector $\boldsymbol{\beta}$. Using the original parameters from the $3+1$-formalism, its general metric and the chosen chart of coordinates we can write Eq. (32) as below,

$$T_{\alpha\beta}\, u^\alpha u^\beta = -\frac{1}{4}\left[\left(\frac{\partial\beta}{\partial y}\right)^2 + \left(\frac{\partial\beta}{\partial z}\right)^2\right]. \tag{34}$$

The above expression is clearly a non-positive term everywhere, violating the WEC in a nontrivial way. We then showed that if we begin with simple energy and momentum sources and impose Eq. (34) to be as identically zero we arrive at vacuum solutions for the WD spacetime.[26,27] However, if we include the cosmological constant in the Einstein equations the expression (34) is changed, yielding,

$$T_{\alpha\beta}\, u^\alpha u^\beta = \Lambda - \frac{1}{4}\left[\left(\frac{\partial\beta}{\partial y}\right)^2 + \left(\frac{\partial\beta}{\partial z}\right)^2\right] \ . \tag{35}$$

For positive and large enough values of the cosmological constant, it may be possible to construct a WD that does not violate the WEC, because the original negative mass-energy density necessary to create the warp bubble could become positive.

The solutions for the WD metric which include the cosmological constant in the Einstein equations[29] are presented in Table 4. Cases 1b and 2b are just the vacuum solutions connecting the WD spacetime to shock waves via the Burgers equations, and they also require a vanishing cosmological constant, since both the static fluid pressure (p) and the matter density (μ) also vanish. The other two solutions subsets 1a and 2a are also similar to the equally labeled ones in Table 2, but now they include the cosmological constant and the solutions are no longer required to be complex if the following conditions are satisfied,

$$\Lambda - 8\pi\mu \geq 0\,, \tag{36}$$

$$\Lambda - 8\pi p \geq 0\,. \tag{37}$$

Taking all these results into account imply that creating a warp bubble for superluminal travel of massive particles seem to require more complex forms of matter than the dust for stable solutions, and that the requirement of negative mass-energy may not be as strict as originally thought for superluminal spacetime travel with warp speeds. The shift vector in the direction of the warp bubble movement creates a coupling in Einstein equations that requires the off-diagonal source terms in the energy-momentum tensor that represent momentum densities.

Previous authors investigated the WD theory from the geometrical point of view[6,7,10–12] and came up with other types of WD mechnics, but it now seems clear that it is also necessary to consider both the energy and momentum tensors to propose a superluminal propelling system in the WD theory.

Table 4. WD solutions of the Einstein equations with Λ and perfect fluid.

Case	Condition	Results
1) $\frac{\partial\beta}{\partial z}=0$	1a) $\frac{\partial\beta}{\partial x}=0$	$\Lambda=6\pi\left(\mu-\frac{p}{3}\right)$ $\beta=\beta(y,t)$ $\frac{\partial\beta}{\partial y}=\pm\sqrt{4(\Lambda-8\pi\mu)}$ $\frac{\partial\beta}{\partial y}=\pm\sqrt{\frac{4}{3}(\Lambda-8\pi p)}$ $\beta\frac{\partial\mu}{\partial x}+\frac{\partial\mu}{\partial t}=0$ (null divergence)
	1b) $\frac{\partial\beta}{\partial y}=0$	$\Lambda=8\pi\mu=8\pi p=0$ $\beta=\beta(x,t)$ $\frac{\partial\beta}{\partial t}+\frac{1}{2}\frac{\partial}{\partial x}(\beta^2)=h(t)$ Null divergence is trivially satisfied This is the solution found in Ref.[26]
2) $\frac{\partial\beta}{\partial y}=0$	2a) $\frac{\partial\beta}{\partial x}=0$	$\Lambda=6\pi\left(\mu-\frac{p}{3}\right)$ $\beta=\beta(y,t)$ $\frac{\partial\beta}{\partial z}=\pm\sqrt{4(\Lambda-8\pi\mu)}$ $\frac{\partial\beta}{\partial z}=\pm\sqrt{\frac{4}{3}(\Lambda-8\pi p)}$ $\beta\frac{\partial\mu}{\partial x}+\frac{\partial\mu}{\partial t}=0$ (null divergence)
	2b) $\frac{\partial\beta}{\partial z}=0$	$\Lambda=8\pi\mu=8\pi p=0$ $\beta=\beta(x,t)$ $\frac{\partial\beta}{\partial t}+\frac{1}{2}\frac{\partial}{\partial x}(\beta^2)=h(t)$ Null divergence is trivially satisfied This is the solution found in Ref.[26]

6. Conclusions

In this work, we described new exact solutions of the Einstein equations endowed with the Alcubierre warp drive (WD) spacetime geometry having simple energy-momentum tensor (EMT) distributions of matter and energy. The incoherent matter, or dust, the simplest fluid source EMT used with the WD metric, led to vacuum solutions and the weak energy condition being satisfied with null energy density. In addition, we showed that the dynamics of the vacuum WD spacetime are governed by the Burgers equation, which links the WD bubble to shock waves.[26] Both the perfect fluid EMT and an anisotropic fluid recover the Burgers equation as vacuum solutions, but some of these new sets of solutions were considered unphysical, and others showed that the shift vector can be a complex-valued function.[27] The Einstein equations with the cosmological constant were used with the WD metric having the perfect fluid as the source, whose results showed that if the cosmological constant is big enough it would be possible to attain positive energy density for the WD spacetime.[29] This result is in line with recent research activity in WD theory by other authors, who provide examples of different WD spacetimes geometries,[17–19] which suggests that it may be possible to create warp bubbles with positive energy densities.

In this work the geometrical methods and symmetry principles in gravitation are explored motivating a new perspective into the spacetime paradigm. The effects of post-Riemann spacetime geometries with torsion are briefly studied in applications to fundamental fermionic and bosonic fields, cosmology and gravitational waves. The physical implications and related phenomenological considerations are addressed, and the fundamental ideas related to spacetime physics, motivated by geometrical methods and symmetry principles, are also briefly discussed in the context of the possible routes towards a new spacetime paradigm in gravitation and unified field theories

Keywords: Riemann-Cartan spacetime, torsion, fermionic systems, gravitational waves

1. Introduction

The success of Einstein's General Theory of Relativity (GR) to describe the gravitational interaction is quite remarkable. GR has passed all tests performed so far: Solar System observations and binary pulsars,[1] stellar orbits around the central galactic black hole,[2] gravitational waves (GWs) from coalescing compact objects (black holes and neutron stars),[3–6] or the indirect observation of the black hole horizon with the Event Horizon Telescope,[7] among others. At the same time, GR provides us with the observationally valid framework for the standard cosmological paradigm when supplemented with the (cold) dark matter and dark energy hypothesis.[8]

Soon after GR theory, Weyl (1918) introduced the notion of gauge transformations, in an attempt to unify gravity and electromagnetism.[9] By extending the Local Lorentz group to include scale transformations (dilatations) he was led to assume what we call a Riemann-Weyl spacetime geometry, a post-Riemann geometry with (the trace-vector part of) non-metricity beyond curvature. The theory was then

abandoned and Weyl (1929) clarified that the electromagnetic field is intimately related to local internal symmetries, under the U(1) group that act on the 4-spinor fields of charged matter.[10] In the mid 1950's Yang (1954) and Mills (1954)[11] further explored the notion of gauge symmetries in field theories going beyond the $U(1)$ group to include non-abelian Lie groups ($SU(2)$), in order to address nuclear physics, while Utiyama (1956)[12] extended the gauge principle to all semi-simple Lie groups including the Lorentz group. The gauge principle is based on the localization of the rigid, global symmetry group of a field theory, introducing a new interaction described by the gauge potential. The latter is a compensating field that makes it possible for the matter Lagrangian to be locally invariant under the symmetry group and is included in the covariant derivative of the theory. There is a clear geometrical interpretation of the gauge potential as the connection of the fiber bundle, which is the manifold obtained from the base spacetime manifold and the set of all fibers. These are attached at each spacetime point and are the (vector, tensor or spinor) spaces of representation of the local symmetries. In the geometrical interpretation, the imposition of local symmetries implies that the geometry of the fiber bundle is non-Euclidean, and the gauge field strengths are the curvatures of such a manifold.

The gauge formulation of gravity was resumed through the works of Kibble (1961)[13] and Sciama[14] (1964), who gauged the (rigid) Poincaré group of Minkowski spacetime symmetries. This can be viewed as the starting point of a self-consistent gauge theory of gravity. They arrived at what is now known as a Riemann-Cartan (RC) geometry, and to the corresponding Einstein-Cartan-Sciama-Kibble (ECSK) gravity, with non-vanishing torsion and curvature. This is a natural extension of GR, which is able to successfully incorporate the intrinsic spin of fermions as a source of gravity, while passing all weak-field limit tests. The theory has no free parameters but introduces a new scale given by Cartan's density, which yields many relevant applications in cosmology and astrophysics.[15–23] The ECSK is the simplest of all Poincaré gauge theories of gravity (PGTG) in RC spacetime. Beyond the Poincaré group we have, for instance, the Weyl and the conformal groups, which live on a subset of a general metric-affine geometry, with non-vanishing curvature, torsion and non-metricity (for a detailed analysis and reviews on several topics of the gauge approach to gravity see the remarkable works in[24–26]). *By extending the gauge symmetry group of gravity, one is naturally led to extend the spacetime geometry paradigm as well.*

Just as quantum field theories of the standard model are gauge theories with (local) internal symmetries, similarly, classical theories of gravity can indeed be formulated as gauge theories, leading to non-Euclidean geometries. Therefore, the gauge principle (with its geometrical methods) is a convenient formalism in order to address the possible avenues towards unified field theories of matter, gravity and spacetime geometry. The spacetime paradigm changes when we extend the gauge group of gravity and the history of Physics have shown that changing the fundamental ideas about space and time is at the basis of major breakthroughs. Gauge

methods in gravity and post-Riemann geometries deserve further developments with potential applications in astrophysical and cosmological scenarios with very strong gravitational fields. Above all, they are a vital part of the effort to understand the nature of spacetime and gravitation.

In this paper we review the fundamental geometrical objects and its relation to spacetime symmetries in the gauge formulation of gravity, and consider specific applications. We will consider the structure of gauge theories of gravity and have a special focus on PGTG, in particular we will consider some of its predictions and implications including interactions with fermions and bosons, cosmological and gravitational wave applications.

2. The gauge approach to gravity

The gauge approach to the gravitational interaction is based on the localization of the global (rigid) spacetime symmetries of the matter field Lagrangian, under a certain group of spacetime coordinate transformations. In this procedure, the gauge potentials, the field strengths and the Noether currents are clearly identified. The gauge potentials are then interpreted as the geometrical degrees of freedom representing the gravitational interaction, while the corresponding field strengths correspond to well identified objects from differential geometry such as curvature, torsion or non-metricity. The Noether currents associated to the spacetime symmetries represent the sources of the gravitational field and provide also valuable information on the physical properties of matter that couple to gravity, clarifying the appropriate test matter for the probing of spacetime geometry. One of the main lessons from the gauge approach to gravity is the fact that the requirement of local, non-rigid symmetries in a matter field theory under spacetime transformations, leads naturally to non-rigid spacetime geometries, meaning general non-Euclidean geometries with curvature, torsion and non-metricity.

2.1. *From symmetries to spacetime geometry*

The gauge approach to gravity broadens our study of the deep relation between symmetry principles (group theory) and geometrical methods. In this framework, the Metric-Affine Gravity (MAG) formalism,[27] where the metric and the affine connection are both independent degrees of freedom, becomes clearly formulated. In fact, the MAG approach includes a general (metric-affine) geometry with curvature, torsion and non-metricity, that arises naturally from the localization (gauging) of the Affine group A(4,$\Re$) and taking into consideration also a metric structure (although the metric structure can be considered not to be "fundamental" in the so-called pre-metric approaches to field theories).

The Affine group A(4,$\Re$) is the (semi-direct) product of the group of 4-translations T(4) with the "General Linear group" GL(4,$\Re$). The gauge potentials

of T(4) are the vector valued 1-form tetrads (or covector frames)

$$\theta^a = \theta^a{}_\mu dx^\mu, \tag{1}$$

where $\{dx^0, dx^1, dx^2, dx^3\}$ is the holonomic co-vector frame basis, with the vector valued 2-form torsion as the field strength

$$T^a = D\theta^a = d\theta^a + \Gamma^a{}_b \wedge \theta^b, \tag{2}$$

while the gauge potentials of GL(4,$\Re$) are the 2-tensor valued linear connection 1-form fields

$$\Gamma^a{}_b = \Gamma^a{}_{b\mu} dx^\mu, \tag{3}$$

and the corresponding field strength is the curvature, 2-tensor valued 2-form, given by

$$R^a{}_b = d\Gamma^a{}_b + \Gamma^a{}_c \wedge \Gamma^c{}_b. \tag{4}$$

In these expressions D is the (gauge) covariant exterior derivative, d is the exterior derivative, a kind of curl operator that raises the degree of any p-form, $\wedge$ is the wedge product. The torsion 2-form has $4 \times 6 = 24$ independent components

$$T^a{}_{\mu\nu} = 2\partial_{[\mu}\theta^a{}_{\nu]} + 2\Gamma^a{}_{c[\mu}\theta^c{}_{\nu]}, \tag{5}$$

while the curvature 2-form has $16 \times 6 = 96$ independent components

$$R^a{}_{b\mu\nu} = 2\partial_{[\mu}\Gamma^a{}_{b|\nu]} + 2\Gamma^a{}_{c[\mu}\Gamma^c{}_{b|\nu]}. \tag{6}$$

The presence of the linear connection, which is the gauge potential associated to curvature, in the last term of the expression for the torsion in (2) is of high importance in the context of the Poincaré gauge gravity and MAG, as will be discussed. In MAG the Noether currents (the sources of gravity) are the canonical energy-momentum (related to T(4)) and the hyper-momentum (related to GL(4,$\Re$)) which includes a spin part s_{ab}, a term related to dilatations and another connected to shear type of "deformations" $\bar{\Delta}_{ab}$. The hypermomentum can then be decomposed according to

$$\Delta_{ab} = s_{ab} + \frac{1}{4} g_{ab} \Delta^c{}_c + \bar{\Delta}_{ab}\ , \tag{7}$$

including the spin $s_{ab} = -s_{ba}$, the dilatation $\Delta^c{}_c$, and the shear $\bar{\Delta}_{ab}$ currents. The Noether currents are not only the fundamental sources of gravity in MAG, but also represent the physical properties of the appropriate test matter to probe the spacetime geometry.

We can also introduce the Lorentzian metric as the (0,2) tensor $g = g_{ab}\theta^a \otimes \theta^b$, where $a, b = 0, 1, 2, 3$ are anholonomic indices, which is the metric (with constant components) of the tangent space, while the spacetime metric $g_{\mu\nu}$ gives the inner products $g(u, v) = g_{\alpha\beta} u^\alpha v^\beta = u_\alpha v^\beta$ and is given by $g_{\mu\nu} = \theta^a{}_\mu \theta^a{}_\nu g_{ab}$. Therefore, the spacetime metric can be seen as the deformation of the Lorentzian (tangent space)

metric according to $g_{\mu\nu} = \Omega^{ab}{}_{\mu\nu} g_{ab}$, with $\Omega^{ab}{}_{\mu\nu} \equiv \theta^a{}_\mu \theta^a{}_\nu$ being a deformation tensor.

Besides the linear co-frame (tetrads) and the linear connection, the 0-form metric g_{ab} can then be introduced as a kind of potential and the corresponding field strength is the tensor valued 1-form $Q_{ab} = Q_{ab\mu} dx^\mu$, given by

$$Q_{ab} = D g_{ab} = d g_{ab} + \Gamma^c{}_a \wedge g_{cb} + \Gamma^c{}_b \wedge g_{ac} = 2\Gamma_{(ab)}, \tag{8}$$

with $10 \times 4 = 40$ independent components $Q_{ab\mu}$. This field strength corresponds to the non-metricity tensor valued 1-form and one concludes that if the connection is non-Lorentzian ($\Gamma^{ab} \neq -\Gamma^{ba}$), then the non-metricity is non-vanishing. The linear connection 1-form can be decomposed according to

$$\Gamma_{ab} = \tilde{\Gamma}_{ab} + N_{ab} = \tilde{\Gamma}_{ab} + N_{[ab]} + \frac{1}{2} Q_{ab} \ , \tag{9}$$

where $\tilde{\Gamma}_{ab}$ is the Levi-Civita part of the connection and $N^a{}_b$ is the so-called distortion 1-form characterizing the post-Riemannian geometries. In particular, one finds that $Q_{ab} = 2N_{(ab)}$ and $T^a = N^a{}_b \wedge \theta^b$. In the most general case, the connection is non-Lorentzian (which implies the presence of non-metricity in the spacetime geometry) and is linked to gauge symmetry groups that extend the Poincaré group, leading therefore to the breaking of Lorentz invariance and to the physics beyond the standard model. If one restricts the symmetry group to the case of PGTG, then the linear connection is Lorentzian (a spin connection) and the hypermomentum is restricted to the spin current. Therefore the presence of non-metricity is related to the breaking of Lorentz invariance, non-Lorentzian connections and hypermomentum with non-trivial currents beyond the spin part.

2.2. *Metric-Affine gravity revisited*

Let us now summarize the fundamental structures of spacetime and their relation to symmetry groups. We have the fundamental 1-forms, the linear co-frame θ^a and the linear connection $\Gamma^a{}_b$, which are the potentials for the 4-dimensional translations $T(4)$ and the general linear $GL(4, \Re)$ groups, respectively. The corresponding field strengths correspond to well known objects from differential geometry, namely, the torsion $T^a = D\theta^a = d\theta^a + \Gamma^a{}_b \wedge \theta^b$ and curvature $R^a{}_b = d\Gamma^a{}_b + \Gamma^a{}_c \wedge \Gamma^c{}_b$ 2-forms, respectively. The metric is introduced as the 0-form potential with the corresponding field strength being the non-metricity 1-form $Q_{ab} = D g_{ab}$. The linear frame establishes a link between the (symmetries on the) local tangent fibers and the spacetime manifold, while the linear connection can be viewed as a guidance field reflecting the inertial character for matter fields propagating on the spacetime manifold. Finally, the metric allows the determination of spatial and temporal distances and angles. The spacetime geometry with all these structures is called a *metric-affine geometry*, with non-vanishing torsion, curvature and non-metricity, and its fundamental

local group of spacetime symmetries is the affine group $A(4,\Re) = T(4) \rtimes GL(4,\Re)$. As one can see from the expressions for the field strengths, torsion and curvature, in (2) and (4), respectively, the connection potential also enters in the expression for the field strength of the co-frame potential. This term is unavoidably present and is due to the semi-direct product[a] structure of the Poincaré group (or the affine group) and, therefore, curvature and torsion are somehow intertwined.

In the self-consistent metric-affine formalism, the gravitational interaction is described as a gauge theory of the affine group $A(4,\Re)$, together with the assumption of a metric, with the potentials (θ^a, Γ^{ab}) coupled to the corresponding Noether currents $(\tau^a, \Delta^a{}_b)$. The latter are the vector-valued canonical energy-momentum $\tau^a = \delta\mathcal{L}_{mat}/\delta\theta_a$ and the tensor-valued hypermomentum $\Delta^a_b = \delta\mathcal{L}_{mat}/\delta\Gamma_a{}^b$ 3-form currents[b], respectively, while the metric g_{ab} couples to the symmetric (Hilbert) energy momentum $T_{ab} = 2\delta\mathcal{L}_{mat}/\delta g^{ab}$.

A truly independent connection in MAG can be written as

$$\Gamma^{ab} = \Gamma^{[ab]} + \frac{1}{4} g^{ab}\Gamma^c{}_c + \left(\Gamma^{(ab)} - \frac{1}{4} g^{ab}\Gamma^c{}_c\right), \tag{10}$$

including the Lorentzian piece $\Gamma^{[ab]}$, the trace part $\frac{1}{4} g^{ab}\Gamma^c{}_c$ and the shear part $\Gamma^{(ab)} - \frac{1}{4} g^{ab}\Gamma^c{}_c$. The Lorentzian connection couples to the spin current and the trace and shear parts couple to the dilatation and shear currents, respectively. As previously said it is the non-Lorentzian part of the connection that imply the non-vanishing of non-metricity, therefore, the dilatation and shear hypermomentum currents are intimately related to the non-metricity of metric affine spacetime geometry.

The variational principle is applied to the action of this theory (including the gravitational part and the matter Lagrangian) by varying it with respect to the gauge potentials of the affine group, (θ^a, Γ^{ab}). This leads to two sets of dynamical equations, while a third set of equations is obtained by varying the action with respect to the metric potential g_{ab}. At the end, the dynamics is described only via two sets of equations, since the gravitational equation obtained by varying with respect to the metric potential or the one obtained by variation with respect to the translational potential can be dropped out, as long as the other gravitational equation derived from variation with respect to the linear connection is fulfilled (for details we recommend the reader to see[25]). This procedure and the fundamental quantities and relations here exposed summarizes the basics of the MAG formalism.

---

[a]The semi direct product implies that the generators of $T(4)$ and $GL(4,\Re)$ (or $SO(1,3)$) do not commute.

[b]These currents can be represented as 1-forms or as 3-forms. In fact, in the gauge approach to gravity they emerge naturally from Noether equations as 3-forms, being natural objects for integration over volumes. As 1-forms one can write $\tau^a = \tau^a_\mu dx^\mu$ and $\Delta^a{}_b = \Delta^a{}_{b\mu} dx^\mu$.

2.3. *Poincaré gauge theories and its extensions*

The description of the gravitational interaction as a gauge theory opens the door for its inclusion in unifying gauge field theories. Indeed, the analogies with gauge Yang-Mills theories can be easily established, (see[28]). Particularly relevant is of course the PGTG that constitutes a valid and quite promising class of models for an appropriate description of classical gravity including post-Einstein strong gravity predictions. The PGTG arises from restricting the symmetry group to the Poincaré group $P(1,3) = T(4) \rtimes SO(1,3)$, and this leads directly to RC spacetime geometry. If only the translational part is taken as symmetry group, one gets the translational gauge theories (TGTG) that include non-vanishing torsion but zero curvature and non-metricity, while both Weyl(-Cartan) gauge gravity (WGTG) and conformal gauge gravity (CGTG) include curvature, torsion and non-metricity. For the 15-parametric conformal group $C(1,3)$ a generalization of Kibble's gauge procedure is required, since although locally $C(1,3)$ is isomorphic to $SO(2,4)$ its realization in M_4 (Minkowski spacetime) is non-linear.[29] The PGTG can further be extended into the de Sitter or anti-de Sitter (A)dS gauge theories of gravity by localizing the $SO(1,4)$ or $SO(2,3)$ groups, respectively. Another important class of extensions requires going beyond the Lie algebra (by considering also anticommutators), in order to arrive at the super-Poincaré group[30] proper supersymmetry (SUSY) transformations between fermions and bosons. The gauging of these (and other) super-algebras lead directly supergravity (SUGRA), that need to take into account post-Riemannian spacetime geometries.

In PGTG the tetrads and the spin connection 1-forms are the gauge potentials, associated with translations, $T(4)$, and Lorentz rotations, $SO(1,3)$, respectively. Torsion and the curvature 2-forms are the respective field strengths. There are 6 generators in the Lorentz group with the corresponding potentials ($\Gamma^{ab} = -\Gamma^{ba}$) and 6 Noether (spin) currents ($s^{ab} = -s^{ba}$). Analogously, there are 4 generators in the group of spacetime translations, which entail 4 gauge potentials θ^a and 4 conserved Noether (canonical energy-momentum) currents τ^a. By constructing the gravitational Lagrangian with the curvature and torsion invariants, the potentials are coupled to the Noether currents via $24 + 16 = 40$ second order field equations. Let us briefly summarize the PGTG formalism. We consider a physical system, represented by the matter fields Lagrangian $\mathcal{L}_m = \mathcal{L}_m(g_{ab}, \theta^c, D\Psi)$. The covariant derivative with respect to the Riemann-Cartan connection $D\Psi$ allows the Lagrangian to be invariant under local Poincaré spacetime transformations. The canonical energy-momentum tensor density (equivalent to the dynamical tetrad energy-momentum density $\tau_a \equiv \delta\mathcal{L}_m/\delta\theta^a$) and the canonical spin density (equivalent to the dynamical spin density $s_{ab} \equiv \delta\mathcal{L}_m/\delta\Gamma^{ab}$) couple to the gravitational potentials, acting as sources of gravity and obey generalized conservation equations. The gravity sector in the action is constructed with the gauge-invariant gravitational field strengths in the kinetic part associated with the dynamics of the gravitational

degrees of freedom. The total Lagrangian density thus reads

$$\mathcal{L} = \mathcal{L}_G(g_{ab}, \theta^a, T^a, R^{ab}) + \mathcal{L}_m(g_{ab}, \theta^a, D\Psi) \ . \tag{11}$$

By varying this action with respect to the gauge fields of gravity (θ^a, Γ^{ab}) and the matter fields Ψ, we get the corresponding field equations.

2.4. *Applications in PGTG*

Without going into details we will briefly mention here some results from simple applications of PGTG, namely in the case of the ECSK theory with fermions and $(s = 1)$ bosons and some of its extensions. The reader can find details in the references.[31–33]

2.4.1. *Einstein-Cartan-Dirac-Maxwell dynamics*

Considering in the ECSK action

$$S_{\rm EC} = \frac{1}{2\kappa^2}\int d^4x\sqrt{-g}R(\Gamma) + \int d^4x\sqrt{-g}\,\mathcal{L}_m \tag{12}$$

the matter Lagrangian

$$\mathcal{L}_m = \mathcal{L}_{\rm D} + \mathcal{L}_{\rm M} + j^\mu A_\mu, \tag{13}$$

where $\mathcal{L}_{\rm D}$ and $\mathcal{L}_m$ are the Lagrangians for a Dirac spinor field and a bosonic $(s = 1)$ field minimaly coupled to the spacetime torsion, respectively, and the Ricci scalar is computed from the connection of RC spacetime geometry, the full dynamics for the matter and geometrical degrees of freedom can be derived. This results in the non-linear dynamics in the matter sector with both the non-linearities and non-minimal couplings between fermions and bosons induced by torsion, and in the generalized Einstein and Cartan equations for the metric and torsion/contorsion variables. For example, varying the Dirac Lagrangian minimally coupled to torsion[c] (in these expressions all tilde quantities correspond to the case of pseudo-Riemann geometry)

$$\mathcal{L}_{\rm Dirac} = \tilde{\mathcal{L}}_{\rm Dirac} + \frac{i\hbar}{4}K_{\alpha\beta\mu}\bar{\psi}\gamma^{[\mu}\gamma^{\alpha}\gamma^{\beta]}\psi, \tag{14}$$

and the bosonic Lagrangian minimally coupled to torsion,

$$\mathcal{L}_{\rm Max} = \tilde{\mathcal{L}}_{\rm Max} + \lambda\left(K^{\lambda[\mu\nu]}K^{\gamma}{}_{[\mu\nu]}A_\gamma + K^{\lambda[\mu\nu]}\tilde{F}_{\mu\nu}\right)A_\lambda, \tag{15}$$

with respect to the corresponding spinor and vector fields, and substituting the torsion as a function of the matter fields (Cartan equations), one obtains the generalized Dirac and Maxwell dynamics

$$\begin{aligned} i\hbar\gamma^\mu\tilde{D}_\mu\psi + (q\gamma^\mu A_\mu - m)\,\psi = f(A)(\bar{\psi}\gamma^\nu\gamma^5\psi)\gamma_\nu\gamma^5\psi + \alpha^\lambda{}_\alpha(A)(\bar{\psi}\gamma^\alpha\gamma^5\psi)\gamma_\lambda\gamma^5\psi \\ +\beta^\lambda(A,\tilde{F})\gamma_\lambda\gamma^5\psi \ , \end{aligned} \tag{16}$$

[c]We consider the torsion tensor as $T^\lambda{}_{\alpha\beta} \equiv \Gamma^\lambda_{[\alpha\beta]}$ and the contortion given by $K^\lambda{}_{\mu\nu} \equiv T^\lambda{}_{\mu\nu} - 2T_{(\mu}{}^\lambda{}_{\nu)} = T^\lambda{}_{\mu\nu} + 2T_{(\mu\nu)}{}^\lambda$.

and

$$\tilde{\nabla}_\mu \tilde{F}^{\mu\nu} = \lambda^{-1}(j^\nu + J^\nu) \ , \tag{17}$$

where

$$J^\nu \equiv \frac{\partial \mathcal{L}_{\rm M}^{corr}}{\partial A_\nu} - \tilde{\nabla}_\mu \left(\frac{\partial \mathcal{L}_{\rm M}^{corr}}{\partial(\tilde{\nabla}_\mu A_\nu)} \right) ,$$

with $\mathcal{L}_{\rm M}^{corr}$ the correction term to the usual Maxwell Lagrangian in (15), and we have defined

$$\begin{aligned} f(A) &\equiv \frac{3\kappa^2\hbar^2}{8} + \frac{\lambda\kappa^4\hbar^2}{4}A^2, \\ \alpha^{\sigma\varepsilon}(A) &\equiv -\lambda\kappa^4\hbar^2 A^\sigma A^\varepsilon, \\ \beta^\lambda(A,\tilde{F}) &\equiv -\frac{\lambda\kappa^2\hbar}{2}\epsilon^{\lambda\alpha\beta\gamma}A_{[\alpha}\tilde{F}_{\beta\gamma]} \ . \end{aligned} \tag{18}$$

Due to the presence of the cubic terms, this Dirac equation changes under the actions of C (charge conjugation) transformations, resulting in a different dynamics for anti-fermions. This dynamics breaks the U(1) symmetry explicitly and might be relevant in the very early Universe. These non-linear dynamics in the matter fields can be simplified for cases where certain approximations are valid as in cosmological applications for homogeneous fields and random spin distributions.

2.4.2. *Cosmological applications*

The application of this theory, the Einstein-Cartan-Dirac model coupled to ($s = 1$) bosons with explicit $U(1)$ symmetry breaking, to homogeneous and isotropic cosmologies leads to the dynamics of the scale factor given by the generalized Einstein equations (assuming the FLRW metric and isotropic pressure)

$$\left(\frac{\dot{a}}{a}\right)^2 = \frac{\kappa^2}{3}\left(\rho + \rho^{\rm corr}\right) - \frac{k}{a^2}, \tag{19}$$

$$\frac{\ddot{a}}{a} = -\frac{\kappa^2}{6}\left[3(p + p^{\rm corr}) + (\rho + \rho^{\rm corr})\right], \tag{20}$$

where dots over functions represent time derivatives. Effective densities can be defined $\rho^{\rm eff} = \rho + \rho^{\rm corr}$, with the corrections to GR, $\rho^{\rm corr} = \rho^s + \rho^{s-A} + \rho^A$, corresponding to the spin-spin interaction energy, the non-minimal interactions between fermionic spin and the bosonic four-potential, and self-interactions in the bosonic sector, respectively and the same apply to the pressure contributions. Different families of solutions can be derived for the dynamics of the scale factor including cyclic models with early bounce, early acceleration, deceleration and late-bounce, and also cases with early bounce, early acceleration, deceleration and late-time acceleration. Some of these are illustrated in the figures 1 and 2.

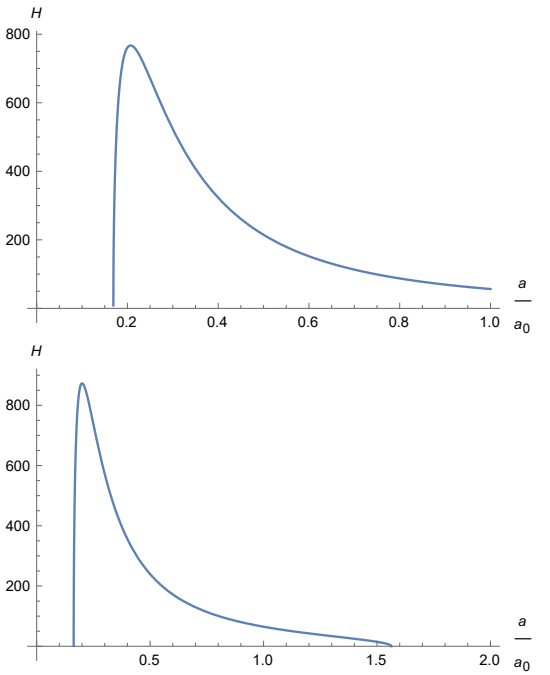

Fig. 1. Evolution of the Hubble parameter $H(a)$ with the scale factor a/a_0 for the ECDM model without (ECSK model, top) and with (bottom) the non-minimal couplings in the matter fields induced by torsion. These corrections to the effective energy density $\rho^{s-A} \sim \rho^s f(A) \sim a^b$ give raise to late-time effects, whereas $\rho^s \sim -\kappa^2 \breve{s}^2$ is the spin-spin interaction term that is responsible for the non-singular behaviour in the early Universe. The plot on the bottom shows a typical solution with a future bounce, a non-singular behaviour at the minimum of the scale factor, and a period of early accelerated expansion.

2.4.3. *Gravitational waves in Riemann-Cartan spacetime*

By considering the quadratic models in PGTG, where the Lagrangian is quadratic in the curvature and torsion, one obtains two sets of field equations for the metric and the contorsion, (or equivalently for the tetrads and the spin connection), where both fields are dynamically coupled and propagate in vacuum. Gravitational waves with torsion modes coupled to the metric modes are then expected and the possibility of measuring these effects with GW astronomy is a relevant open question.

In cosmological backgrounds, one possible parametrization for GW, encompassing a wide class of metric theories of gravity, is provided in the following wave equation

$$h''_{ij} + (2+\nu)\mathcal{H}h'_{ij} + (c_g^2 k^2 + m_g^2 a^2)h_{ij} = \tilde{\Pi}_{ij}. \tag{21}$$

In this equation the parameters (ν, c_g, m_g) and the source term represent deviations from GR and the derivatives are taken with respect to conformal time. The parameter ν represents an additional "friction" term, affecting the decay induced by the

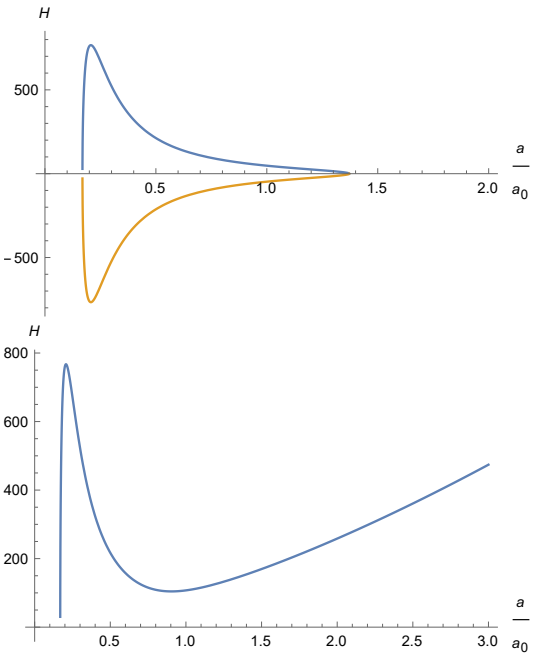

Fig. 2. On the top figure we can see the cyclic behaviour of ECDM model explicitly, with the two branches in $H(a) = \pm\sqrt{\rho^{\text{eff}}(a) - k/a^2}$ smoothly joined together at the bounces. A period of early accelerated expansion is followed by decelerated expansion, bounce and accelerated contraction, decelerated contraction and again the bounce at the minimum of the scale factor, with the repetition of the cosmological cycle. On the bottom we have the relevant case where a late-time accelerated phase is also present.

cosmological expansion. The effect of a propagation speed different than the speed of light is represented by c_g, while m_g stands for an effective mass for the graviton ($s = 2$) field. In GR $\nu = 0$, $c_g = 1$ and $m_g = 0$ and the right-hand side of (21) is equal to zero. The tensor $\tilde{\Pi}_{ij}$ represents an extra "source" term due to additional propagating tensor fields.

In the PGTG, the situation is generalized to include in the dynamics another set of equations. Through the variational principle, the two sets of field equations corresponding to the dynamics of the two gravitational potentials $(\theta^a_\mu, \Gamma^a_{\ b\nu})$, can also be expressed in terms of the equivalent set of dynamical variables $(g_{\alpha,\beta}, K^\alpha_{\ \mu\nu})$. Since in quadratic PGTG models the torsion in general propagates, the contorsion is an extra propagating tensor field with respect to GR and therefore, the wave equation for the metric in the first-order perturbation theory in cosmological backgrounds will have a term as $\tilde{\Pi}_{ij}$ in (21) due to the propagating torsion (or contorsion) tensor degrees of freedom.

One simple approach for the study of GW with torsion modes is to consider the linear perturbation theory in RC spacetime. The background spacetime in general is assumed to have the following metric and connection $(\mathring{g}_{\mu\nu}, \mathring{\Gamma}^\alpha_{\lambda\beta})$. The perturbed

quantities are

$$g_{\mu\nu} = \mathring{g}_{\mu\nu} + h_{\mu\nu}, \quad \Gamma^{\alpha}_{\ \lambda\beta} = \mathring{\Gamma}^{\alpha}_{\ \lambda\beta} + \gamma^{\alpha}_{\ \lambda\beta}, \tag{22}$$

where the perturbations $h_{\mu\nu} \equiv \delta g_{\mu\nu}$ and $\gamma^{\alpha}_{\ \lambda\beta} \equiv \delta\Gamma^{\alpha}_{\ \lambda\beta}$, are assumed to be small. The RC connection is given by $\Gamma^{\alpha}_{\ \beta\nu} = \tilde{\Gamma}^{\alpha}_{\ \beta\nu} + K^{\alpha}_{\ \beta\nu}$, expression also valid at the background level. It can be shown that the perturbation in the connection includes a perturbation in contorsion and another part related to the background metric and metric perturbation. In summary, the relevant quantities in this perturbative approach can be chosen to be

$$g_{\mu\nu} = \mathring{g}_{\mu\nu} + h_{\mu\nu}, \quad K^{\alpha}_{\ \lambda\beta} = \mathring{K}^{\alpha}_{\ \lambda\beta} + \kappa^{\alpha}_{\ \lambda\beta}. \tag{23}$$

From this the generalized curvature tensor, Ricci tensor and Ricci scalar of the linearly perturbed RC spacetime geometry are given by

$$\begin{aligned} R^{\alpha}_{\ \beta\mu\nu} = \tilde{R}^{\alpha}_{\ \beta\mu\nu} + 2\tilde{\nabla}_{[\mu}\mathring{K}^{\alpha}_{\ \beta|\nu]} + 2\tilde{\nabla}_{[\mu}\kappa^{\alpha}_{\ \beta|\nu]} + \mathring{K}^{\alpha}_{\ \lambda\mu}\mathring{K}^{\lambda}_{\ \beta\nu} - \mathring{K}^{\alpha}_{\ \lambda\nu}\mathring{K}^{\lambda}_{\ \beta\mu} \\ + \mathring{K}^{\alpha}_{\ \lambda\mu}\kappa^{\lambda}_{\ \beta\nu} - \mathring{K}^{\alpha}_{\ \lambda\nu}\kappa^{\lambda}_{\ \beta\mu} + \kappa^{\alpha}_{\ \lambda\mu}\mathring{K}^{\lambda}_{\ \beta\nu} - \kappa^{\alpha}_{\ \lambda\nu}\mathring{K}^{\lambda}_{\ \beta\mu}, \end{aligned} \tag{24}$$

$$\begin{aligned} R_{\beta\nu} = \tilde{R}_{\beta\nu} + 2\tilde{\nabla}_{[\alpha}\mathring{K}^{\alpha}_{\ \beta|\nu]} + 2\tilde{\nabla}_{[\alpha}\kappa^{\alpha}_{\ \beta|\nu]} + \mathring{K}^{\alpha}_{\ \lambda\alpha}\mathring{K}^{\lambda}_{\ \beta\nu} - \mathring{K}^{\alpha}_{\ \lambda\nu}\mathring{K}^{\lambda}_{\ \beta\alpha} \\ + \mathring{K}^{\alpha}_{\ \lambda\alpha}\kappa^{\lambda}_{\ \beta\nu} - \mathring{K}^{\alpha}_{\ \lambda\nu}\kappa^{\lambda}_{\ \beta\alpha} + \kappa^{\alpha}_{\ \lambda\alpha}\mathring{K}^{\lambda}_{\ \beta\nu} - \kappa^{\alpha}_{\ \lambda\nu}\mathring{K}^{\lambda}_{\ \beta\alpha}, \end{aligned} \tag{25}$$

and

$$\begin{aligned} R = \tilde{R} - 2\tilde{\nabla}^{\lambda}\mathring{K}^{\alpha}_{\ \lambda\alpha} - 2\tilde{\nabla}^{\lambda}\kappa^{\alpha}_{\ \lambda\alpha} + g^{\beta\nu}(\mathring{K}^{\alpha}_{\ \lambda\alpha}\mathring{K}^{\lambda}_{\ \beta\nu} - \mathring{K}^{\alpha}_{\ \lambda\nu}\mathring{K}^{\lambda}_{\ \beta\alpha}) \\ + g^{\beta\nu}(\mathring{K}^{\alpha}_{\ \lambda\alpha}\kappa^{\lambda}_{\ \beta\nu} - \mathring{K}^{\alpha}_{\ \lambda\nu}\kappa^{\lambda}_{\ \beta\alpha}) + g^{\beta\nu}(\kappa^{\alpha}_{\ \lambda\alpha}\mathring{K}^{\lambda}_{\ \beta\nu} - \kappa^{\alpha}_{\ \lambda\nu}\mathring{K}^{\lambda}_{\ \beta\alpha}), \end{aligned} \tag{26}$$

respectively.

For a torsionless background and at first order in the metric and connection perturbations, we get

$$R^{\alpha}_{\ \beta\mu\nu} = \tilde{R}^{\alpha}_{\ \beta\mu\nu} + 2\tilde{\mathring{\nabla}}_{[\mu}\kappa^{\alpha}_{\ \beta|\nu]} \tag{27}$$

$$R_{\beta\nu} = \tilde{R}_{\beta\nu} + 2\tilde{\mathring{\nabla}}_{[\alpha}\kappa^{\alpha}_{\ \beta|\nu]}, \tag{28}$$

and

$$R = \tilde{R} - 2\tilde{\mathring{\nabla}}^{\lambda}\kappa^{\alpha}_{\ \lambda\alpha}, \tag{29}$$

respectively. These quantities are useful to derive the GW equations for PGTG in the linear perturbation framework. As an example and without going into details, by choosing the quadratic model given by[26]

$$\mathcal{L} = \frac{1}{2\kappa^2}\left(R - 2\alpha T^{\alpha}_{\ \mu\nu}T_{\alpha}^{\ \mu\nu}\right) - \frac{1}{8\lambda}R^{\alpha\beta}_{\ \ \mu\nu}R_{\alpha\beta}^{\ \ \mu\nu} + \mathcal{L}_m, \tag{30}$$

where α and λ are free parameters, one can derive the following coupled wave equations

$$\frac{l_0^2}{2}\left(\Box\partial_{(\alpha}\bar{h}_{\beta)}{}^{\mu}+2\partial_\nu\partial^{[\mu}\kappa_{\alpha\beta}{}^{\nu]}\right)+3\eta^{\mu\nu}\kappa_{[\alpha\beta\nu]}+\delta^{\mu}_{[\alpha}\kappa_{\beta]}=0, \tag{31}$$

$$-\Box\bar{h}_{ij}=2\Lambda^{TT}_{ij}, \tag{32}$$

with $\kappa_\beta \equiv \kappa_{\beta\alpha}{}^{\alpha}$, $\Box \equiv \partial^\alpha\partial_\alpha$, we choose $\alpha = 1$ and define $l_0 \equiv \kappa^2/\lambda$, $\bar{h}_{ij}$ is the metric perturbation in the TT Lorentz gauge, $\eta^{\mu\nu}$ is the Minkowski metric, δ^μ_α is the Kronecker symbol and

$$\Lambda_{\mu\nu}\equiv\partial_{(\nu}\kappa_{\mu)}-\eta_{\mu\nu}\partial_\lambda\kappa^\lambda. \tag{33}$$

In principle one can apply Greens functions methods to get

$$\bar{h}_{ij}(t,\vec{x})\sim\int d^3y\frac{\Lambda^{TT}_{ij}(t_R,\vec{y})}{|\vec{x}-\vec{y}|}. \tag{34}$$

This reinforces the notion that metric and torsion perturbations can be interconvertible. Moreover, the equation (32) can be used to replace in (31) to obtain a second order partial diferential equation for the torsion modes

$$\frac{l_0^2}{2}\left(-2\partial_{(\alpha}\Lambda_{\beta)}{}^{\mu}+2\partial_\nu\partial^{[\mu}\kappa_{\alpha\beta}{}^{\nu]}\right)+3\eta^{\mu\nu}\kappa_{[\alpha\beta\nu]}+\delta^{\mu}_{[\alpha}\kappa_{\beta]}=0, \tag{35}$$

with all quantities calculated in the TT gauge. Now, taking into account the RC curvature tensor in (24) for a RC background and in (27) for a torsionless background (to first order), respectively, one expects generalizations to the geodesic deviation equations. This implies a generalization to the GR effects of the propagating GW in test-masses. For example, in Minkowski backgrounds, useful to compute the weak, linearised GW effects in detectors, we have

$$R_{\alpha\beta\mu\nu}=\tilde{R}_{\alpha\beta\mu\nu}+2\partial_{[\mu}\kappa_{\alpha\beta|\nu]}, \tag{36}$$

and using the TT gauge, the non-zero components of the Riemann part of the RC curvature are given by

$$\tilde{R}_{i0j0}=-\frac{1}{2}\ddot{h}_{ij}. \tag{37}$$

If we take the corresponig components in (36),

$$R_{i\beta j\nu}=-\frac{1}{2}\ddot{h}_{ij}\delta^0_\beta\delta^0_\nu+2\partial_{[j}\kappa_{i\beta|\nu]}, \tag{38}$$

where δ^0_β are defined as Kronecker symbols, and we see explicit extra terms due to the presence of the propagating contorsion perturbation.

The FRWL torsionless background geometry can be taken to illustrate the effects of torsion GW modes propagating over cosmological distances. For simplicity the spatially flat FRWL metric background can be taken. In a more general approach the perturbed versions of the field equations would be computed over a RC

backgroud geometry with a FRWL metric and a background contorion obeying the cosmological principle. Notice also that in curved backgrounds, terms such as $\tilde{\mathring{R}}^2$, $\tilde{\mathring{R}}\kappa$ and $\tilde{\mathring{R}}\tilde{\mathring{\nabla}}\kappa$ would also apear in the field equations, therefore, a far more richer phenomenology is expected than the one derived from a flat, Minkowski, torsionless background. In principle, it should be possible to obtain a set of two wave equations in cosmological backgrounds, similar to and generalizing the expression in (21). From such equations, the general beyond-GR effects can be recognized in the amplitudes, dispersion relation and due to the presence of extra degrees of freedom (for example contorsion d.o.f.). Then these direct consequences can be applied for the general expressions for the GW forms (in the weak source limit) due to binaries, in order to encompass the effects of a propagation over cosmological distances. We will not perform such procedure here, but emphasize the relevance of it in order to search for signatures of propagating torsion modes in the GW signals.

3. Probing post-Riemann geometries

It is known that torsion can give rise to precession effects in systems with intrinsic spin, for example, elementary particles such as the electron, or baryons such as the neutron.[34–36] Moreover, as we will see, torsion effects on the dynamics and energy levels of spinors are expected. Also, the spin-spin contact interactions of the ECSK theory, or the propagating spin-spin interactions mediated by gravitational gauge ($s = 0, 1, 2$) bosons of quadratic PGTG might be tested/constrained in laboratory experiments and cosmological GW probes.

Regarding non-metricity, the gauge approach to gravity clearly shows that the hypermomentum currents, such as the dilatations or the shear currents, couple to the trace and shear parts of the connection (10), respectively and therefore to non-metricity. If torsion can be measured by the spin precession of test matter with intrinsic spin, then the non-metricity of spacetime can be measured by pulsations (mass quadrupole excitations) of test matter with (non-trivial) hypermomentum currents. In order to be "sensitive" to non-Riemann geometries, test matter should carry dilatation, shear, or spin currents, whether macroscopic or at the level of fundamental fields/particles. From the gauge approach to gravity one conclusion is very clear: if matter has neither (intrinsic) spin, nor dilatation/shear currents, then it follows the Riemannian (extremal length) geodesics, regardless of the geometry of spacetime or of the form of the Lagrangian in metric-affine geometry.

3.1. *Effects on fundamental fermionic systems*

From the Dirac Lagrangian of a fermion minimally coupled to the background RC geometry, one can predict torsion effects on the energy levels of quantum systems.[37] Similarly, if non-minimal couplings between the torsion trace vector and Dirac axial vector and/or between torsion axial vector and Dirac vector are present, then the parity symmetry is broken and the corresponding energy level corrections due to

torsion will contain the signatures of those parity breaking interactions. Therefore, tests with advanced spectrographs might be able to probe torsion effects on quantum systems. Without going into details, we present here some simple results concerning predicted effects on the energy levels of fermionic spinors coupled to background torsion quantities, for cases of minimal and non-minimal couplings (including parity breaking effects).[37]

For the minimal coupling case, which can be expressed by the Lagrangian

$$\mathcal{L}_{\rm Dirac} = \tilde{\mathcal{L}}_{\rm Dirac} + 3\breve{T}^{\lambda}\breve{s}_{\lambda}, \tag{39}$$

where

$$\breve{s}^{\lambda} \equiv \frac{\hbar}{2}\bar{\psi}\gamma^{\lambda}\gamma^{5}\psi \tag{40}$$

is the Dirac axial spin vector current and

$$\breve{T}^{\lambda} \equiv \frac{1}{6}\epsilon^{\lambda\alpha\beta\gamma}T_{\alpha\beta\gamma} \tag{41}$$

is the axial vector part of torsion, we obtain the Dirac equation,

$$i\hbar\gamma^{\mu}\tilde{D}_{\mu}\psi - m\psi = -\frac{3\hbar}{2}\breve{T}^{\lambda}\gamma_{\lambda}\gamma^{5}\psi\,, \tag{42}$$

for spinors. From this, energy level corrections due to torsion can be derived, depending on the alignment or anti-alignment between the spin and the spacetime torsion. For a constant background torsion $\breve{T}^3$, the two corresponding energy levels are

$$E^2 = p^2 + \left(m \mp \frac{3\hbar}{2}\breve{T}^3\right)^2\,, \tag{43}$$

for the spin down/up states, respectively.

Let us denote by $m_{\breve{T}}$ the mass correction due to the spin-torsion interaction, and consider the two possible energy levels E_1 and E_2, with $E_2 > E_1$. Then in the reference frame of the particle, the corresponding energy transition is given by

$$h\nu = \frac{1}{2}m_{\breve{T}} = \frac{3\hbar}{4}\breve{T}\,. \tag{44}$$

Reinserting the speed of light in vacuum, we get

$$\nu = \frac{3c}{8\pi}\breve{T}. \tag{45}$$

If we consider, for instance, $\breve{T} \sim 10^{-16}m^{-1}$, then we end up with the prediction of a transition in the $\nu \sim$nHz regime. In the case of a spherically symmetric torsion, using perturbation theory to first order, where

$$E \simeq E_{(0)} + < \psi_{(0)}|\hat{U}_{torsion-spin}|\psi_{(0)} >, \tag{46}$$

and $\psi_{(0)}$ are the eigen states of the unperturbed Hamiltonian associated to the eigen value $E_{(0)}$, we get a similar result with

$$\nu = \frac{\delta E}{h} = \frac{3E_{(0)}}{\pi}F(r)\,, \tag{47}$$

where $F(r)$ represents a geometrical term coming from the integration of the background spherical torsion over some volume.

To include parity breaking terms in the model we also consider the couplings $T \cdot a$ and $\breve{T} \cdot j$ in the Lagrangian

$$\mathcal{L}_{\text{fermions}} = \tilde{\mathcal{L}}_{\text{Dirac}} + (\alpha_1 T + \beta_2 \breve{T}) \cdot j + (\alpha_2 \breve{T} + \beta_1 T) \cdot a. \tag{48}$$

The terms $\beta_1 T^\lambda a_\lambda$ and $\beta_2 \breve{T}^\mu j_\mu$ break the parity invariance. Here j and a represent the Dirac vector and axial vectors, respectively, and T is the trace torsion vector. The corresponding extended Dirac equation is given by

$$i\hbar\gamma^\mu \tilde{D}_\mu \psi - m\psi = -\left(\alpha_1 T^\lambda + \beta_2 \breve{T}^\lambda\right) \gamma_\lambda \psi - \left(\alpha_2 \breve{T}^\lambda + \beta_1 T^\lambda\right) \gamma_\lambda \gamma^5 \psi \,. \tag{49}$$

In this case, and considering constant torsion quantities, and using the definitions

$$t^\nu \equiv \alpha_1 T^\nu + \beta_2 \breve{T}^\nu, \qquad \tau^\lambda \equiv \alpha_2 \breve{T}^\lambda + \beta_1 T^\lambda \,, \tag{50}$$

and taking $t^\mu = (0, t^1, t^2, t^3)$, and $\tau^\mu = (0, 0, 0, \tau)$, for simplicity, we obtain the following energy level corrections $E_2^2 = p_{\text{eff}}^2 + (m + \tau)^2$ and $E_1^2 = p_{\text{eff}}^2 + (m - \tau)^2$, corresponding to the energy transition

$$h\nu = E_2 - E_1 = \frac{4m\tau}{E_1 + E_2} \,, \tag{51}$$

which in the reference frame of the particle reads

$$h\nu = \frac{4m\tau}{\left[\vec{t}^2 + (m + \tau)^2\right]^{1/2} + \left[\vec{t}^2 + (m - \tau)^2\right]^{1/2}} \,, \tag{52}$$

and $p_{\text{eff}}^2 \equiv (p_1 + t^1)^2 + (p_2 + t^2)^2 + (p_3 + t^3)^2$. The parity symmetry breaking is one of the conditions usually considered in order to explain some early Universe particle physics that can provide a matter/anti-matter asymmetry. The torsion of the RC spacetime can induce parity breaking effects in the fermionic sector via the non-minimal couplings explored here. These effects include the prediction of well-defined frequencies that a free fermion can absorb or emit in order to make transitions between the predicted two energy levels that arise depending on the spin orientation with respect to external torsion quantities. The signature of parity breaking (chirality) might also be present in the radiated field itself, in the form of polarized light, and these type of parity-breaking spin-torsion interactions might be probed in the very early Universe with GW astronomy, where the signatures of chirality in the GW signals in principle require non-planar detectors and analysis with 3-point correlation functions.

4. Open questions and concluding remarks

In special and general relativity theories the metric is fundamental, providing the relevant spacetime geometry. In special relativity the metric provides a fixed background, while in GR it is described by a tensor field theory being one of the

fundamental dynamical fields together with the matter fields. In its essence GR is a background independent theory, where the metric (the local geometry) has to be derived by solving the Einstein field equations, for each particular physical/ astrophysical scenario. It is the fundamental geometrical field, solution to the Einstein gravity equations, from which all the aspects of pseudo-Riemannian geometry can be derived. It is therefore natural that due to epistemological historical reasons the metric has gained a fundamental importance in gravity and in the description of physical fields propagating in some spacetime geometry.

In spite of this, developments of geometrical methods in field theories led to the notion that the spacetime metric is no longer to be considered as a fundamental field. One can say that both the pre-metric foundations of electrodynamics and the gauge approach to gravity point in the same direction. The pre-metric approach to electrodynamics as expressed in differential forms give completely general, coordinate-free covariant inhomogeneous and homogeneous equations from charge conservation and magnetic flux conservation respectively. No metric is involved and therefore, electrodynamics is not linked to Minkowski spacetime at a fundamental level. Moreover, the spacetime metric up to a conformal factor, and therefore, the conformal-causal spacetime structure, can be derived from local and linear electrodynamics.[38] The resulting lightcone or causal-electromagnetic structure is a conformal geometry with local conformal symmetries associated to the lightcone at each spacetime point. The group of conformal transformations preserve the light-cone (causal) structure but the metric can change, with the set of all conformally related metrics associated to the local light-cone representing different equally valid metrics. There isn't a specific metric which is more fundamental or that can be considered to be more "physical" than the others. Moreover, in such geometry, under the assumption of locality, the parallel transport of a light cone from a given point to a neighbouring point gives rise to a deformation of the local causal/light-cone structure according to the non-metricity tensor. And since, as we saw, the tensor-valued non-metricity 1-form is linked to the existence of a non-Lorentzian linear connection, from a gauge point of view, this alone inevitably leads to Lorentz symmetry breaking. Therefore, on one hand, and in spite of the historical reasons relating Maxwell's theory with special relativity and Minkowski spacetime, electrodynamics is fundamentally connected to the conformal geometrical structure and the conformal group, and not to Minkowski spacetime, nor the Poincaré or Lorentz group. On the other hand, the notion of local symmetries, the basis of gauge theories, as applied to spacetime leads to gravitational theories with post-Riemann geometries, and non-metricity is directly related to non-Lorentzian connections, i.e, to Lorentz symmetry breaking. *If both the gauge theories of gravity and the premetric formulation of electrodynamics (with its spacetime constitutive relations) are jointly analysed, then we are led to consider that the conformal structure is more fundamental than the metric, post-Riemann geometries with non-metricity and to conformal gauge theories of gravity. Symmetry breaking mechanisms are plausible scenarios for bringing both gravity and electrodynamics into the phenomenological regime of Poincaré symmetries and related spacetime*

paradigm. It should be mentioned that the analogies between Yang-Mills fields and gauge theories of gravity in the exterior calculus of forms, clearly show that gravitational dynamics can also be described in a pre-metric way, just as electrodynamics, and its the gravitational spacetime constitutive relations that bring the conformal causal structure.

The exploration of the gauge theories of gravity, including its connection to spacetime symmetries and post-Riemann geometries, can lead to a vast number of predictions relevant for relativistic astrophysics, cosmology and GWs and also to interesting avenues towards unified gauge field theories. Moreover the connection between the gauge formalism, the Lagrangian and Hamiltonian formalisms, the pre-metric foundations, the constitutive relations (between the field strengths and its conjugate momenta, the excitations) and the causal structure of spacetime, might also contribute towards relevant non-perturbative, background-independent methods for quantum field theory and quantum gravity. The gauge approach can clarify which gravitational geometrical degrees of freedom should be taken as canonical conjugate variables for quantization. In its turn, this can relax the traditional emphasis that is usually put into the metric degrees of freedom, for historical reasons, within attempts at reconciling GR (or more general metric theories) with quantum theory.

The gauge theories of gravity are built upon a self-consistent approach that clarifies the fundamental connection between spacetime symmetries and spacetime geometries. In this context, the metric-affine formalism is clearly formulated within general spacetime geometries with curvature, torsion and non-metricity. In this work, the geometrical methods and symmetry principles in gravitation were explored motivating a new perspective into the spacetime paradigm. The effects of post-Riemann spacetime geometries with torsion were briefly exemplified in applications to fundamental fermionic and bosonic fields, cosmology and gravitational waves. Besides the brief exposition on some phenomenological considerations within PGTG, the fundamental ideas related to spacetime physics, motivated by geometrical methods and symmetry principles, have been discussed in the context of the possible routes towards a new spacetime paradigm in gravitation and unified field theories.

Thermodynamics of scalar-tensor gravity: A new approach

Valerio Faraoni
Dept. of Physics & Astronomy, Bishop's University
Sherbrooke, Québec, Canada J1M 1Z7
E-mail: vfaraoni@ubishops.ca

We propose a new approach to the thermodynamics of scalar-tensor gravity and its possible "diffusion" toward general relativity, previously regarded as an equilibrium state in spacetime thermodynamics. The main idea is describing scalar-tensor gravity as an effective dissipative fluid and applying Eckart's first order thermodynamics to it. This gives explicit effective quantities: heat current density, "temperature of gravity", viscosity coefficients, entropy density, plus an equation describing the "diffusion" to Einstein gravity. These quantities, otherwise missing in spacetime thermodynamics, pop out with minimal assumptions.

Keywords: Scalar-tensor gravity, temperature of gravity theories, limit to general relativity.

1. Introduction

The thermodynamics of spacetime proposal became the subject of great interest when Jacobson derived the Einstein equation as an equilibrium equation of state from the thermodynamical properties of vacuum[1] and, later, the field equation of (metric) $f(R)$ gravity was obtained in a non-equilibrium thermodynamical setting.[2] These works have generated a large literature and suggest that general relativity (GR) could be a sort of lowest energy state of gravity, while alternative theories of gravity correspond to excited states. Indeed, modifying gravity with respect to GR introduces extra degrees of freedom in addition to the usual massless spin two field of GR. Therefore, theories containing GR as a limit correspond to excitations of these extra degrees of freedom, which are quiescent or absent in GR. Ultimately, if modified gravity is an excited state of GR, one should quantify the distance of an excited state from the GR "ground state" and identify some order parameter and equations describing the relaxation of gravity to GR. This order parameter, a sort of "temperature of gravity theories", is a crucial piece missing from this picture. Here we restrict ourselves to scalar-tensor[3,4] and $f(R)$ gravity (the latter is a subclass of the former[5–7]) and we identify a possible "temperature of gravity" candidate. The identification should be made in some relativistic thermodynamical context. Here we start from a very simple fact: the field equations of scalar-tensor gravity can be rewritten as effective Einstein equations by grouping the terms generated by the extra scalar field in the right hand side and noticing that they assume the form of the stress-energy tensor of an *imperfect* effective fluid. Next, we ask ourselveves what we know about dissipative fluids. The simplest description of dissipation and

heat flux in GR is given by Eckart's first order thermodynamics.[8] This theory is notoriously plagued by non-causality and instabilities but is still widely used as an approximation. By describing scalar-tensor gravity as an effective imperfect fluid and using the constitutive equations of Eckart's theory (which are minimal assumptions and could be imposed in different models as well), we identify a "temperature of gravity" in the space of scalar-tensor theories,[3,4] which contain GR as the zero temperature limit.[9]

Let us recall the basics of scalar-tensor gravity, the prototypical alternative to Einstein's GR. The Jordan frame action is[a3]

$$S_{\rm ST} = \frac{1}{16\pi}\int d^4x\sqrt{-g}\left[\phi R - \frac{\omega(\phi)}{\phi}\,\nabla^c\phi\nabla_c\phi - V(\phi)\right] + S^{(\rm m)}\,, \tag{1}$$

where $\phi > 0$ is the Brans-Dicke scalar (approximately equivalent to the inverse of the effective gravitational coupling strength), $\omega(\phi)$ is the "Brans-Dicke coupling", $V(\phi)$ is a scalar field potential, and $S^{(\rm m)}$ is the matter action. Varying (1) produces the field equations

$$R_{ab} - \frac{1}{2}\,g_{ab}R = \frac{8\pi}{\phi}\,T^{(\rm m)}_{ab} + \frac{\omega}{\phi^2}\left(\nabla_a\phi\nabla_b\phi - \frac{1}{2}\,g_{ab}\nabla_c\phi\nabla^c\phi\right) + \frac{1}{\phi}\left(\nabla_a\nabla_b\phi - g_{ab}\Box\phi\right)$$
$$-\frac{V}{2\phi}\,g_{ab}\,, \tag{2}$$

$$\Box\phi = \frac{1}{2\omega+3}\quad\left(\frac{8\pi g^{ab}T^{(\rm m)}_{ab}}{\phi} + \phi\,\frac{dV}{d\phi} - 2V - \frac{d\omega}{d\phi}\nabla^c\phi\nabla_c\phi\right)\,, \tag{3}$$

where $T^{(\rm m)}_{ab}$ is the matter stress-energy tensor.

2. The temperature of scalar-tensor gravity

An effective fluid description of the field equations (2) has been proposed in[11] for non-minimally coupled scalar fields and in[12] for general scalar-tensor gravity, and completed in Ref. 13. The fluid 4-velocity is

$$u^a = \frac{\nabla^a\phi}{\sqrt{-\nabla^e\phi\nabla_e\phi}} \tag{4}$$

when the gradient $\nabla^c\phi$ is timelike. The $3+1$ splitting of spacetime into the 3-space "seen" by the comoving observers of the fluid and their time direction u^a follows, with $h_{ab} \equiv g_{ab} + u_a u_b$ and $h_{ab}u^a = h_{ab}u^b = 0$, $h^a{}_b\,h^b{}_c = h^a{}_c$. The fluid 4-acceleration is

$$\dot{u}_a = (-\nabla^e\phi\nabla_e\phi)^{-2}\,\nabla^b\phi\Big[(-\nabla^e\phi\nabla_e\phi)\nabla_a\nabla_b\phi + \nabla^c\phi\nabla_b\nabla_c\phi\nabla_a\phi\Big]\,, \tag{5}$$

[a]We follow the notation of Ref. 10, using units in which Newton's constant and the speed of light are unity.

and the effective stress-energy tensor of the Brans-Dicke-like field

$$8\pi T^{(\phi)}_{ab} = \frac{\omega}{\phi^2}\left(\nabla_a\phi\nabla_b\phi - \frac{1}{2}\,g_{ab}\nabla^c\phi\nabla_c\phi\right) + \frac{1}{\phi}\left(\nabla_a\nabla_b\phi - g_{ab}\Box\phi\right) - \frac{V}{2\phi}\,g_{ab} \tag{6}$$

can be written as the imperfect fluid stress-energy tensor

$$T_{ab} = \rho u_a u_b + q_a u_b + q_b u_a + \Pi_{ab}\,, \tag{7}$$

where[12,13]

$$\rho = T_{ab}u^a u^b\,, \qquad q_a = -T_{cd}\,u^c h_a{}^d\,, \qquad \Pi_{ab} \equiv P h_{ab} + \pi_{ab} = T_{cd}\,h_a{}^c\,h_b{}^d\,, \tag{8}$$

$$P = \frac{1}{3}\,g^{ab}\Pi_{ab} = \frac{1}{3}\,h^{ab}T_{ab}\,, \qquad \pi_{ab} = \Pi_{ab} - P h_{ab}\,, \tag{9}$$

are, respectively, the effective energy density, heat flux density, stress tensor, isotropic pressure, and anisotropic stresses in the comoving frame, while $q_c u^c = \Pi_{ab}u^b = \pi_{ab}u^b = \Pi_{ab}u^a = \pi_{ab}u^a = \pi^a{}_a = 0$. These comoving frame fluid quantities read[12,13]

$$8\pi\rho^{(\phi)} = -\frac{\omega}{2\phi^2}\,\nabla^e\phi\nabla_e\phi + \frac{V}{2\phi} + \frac{1}{\phi}\left(\Box\phi - \frac{\nabla^a\phi\nabla^b\phi\nabla_a\nabla_b\phi}{\nabla^e\phi\nabla_e\phi}\right), \tag{10}$$

$$8\pi q^{(\phi)}_a = \frac{\nabla^c\phi\nabla^d\phi}{\phi\left(-\nabla^e\phi\nabla_e\phi\right)^{3/2}}\left(\nabla_d\phi\nabla_c\nabla_a\phi - \nabla_a\phi\nabla_c\nabla_d\phi\right), \tag{11}$$

$$8\pi\Pi^{(\phi)}_{ab} = \left(-\frac{\omega}{2\phi^2}\,\nabla^c\phi\nabla_c\phi - \frac{\Box\phi}{\phi} - \frac{V}{2\phi}\right)h_{ab} + \frac{1}{\phi}\,h_a{}^c h_b{}^d\nabla_c\nabla_d\phi\,, \tag{12}$$

$$8\pi P^{(\phi)} = -\frac{\omega}{2\phi^2}\,\nabla^e\phi\nabla_e\phi - \frac{V}{2\phi} - \frac{1}{3\phi}\left(2\Box\phi + \frac{\nabla^a\phi\nabla^b\phi\nabla_b\nabla_a\phi}{\nabla^e\phi\nabla_e\phi}\right), \tag{13}$$

$$\begin{aligned} 8\pi\pi^{(\phi)}_{ab} = {} & \frac{1}{\phi\nabla^e\phi\nabla_e\phi}\left[\frac{1}{3}\left(\nabla_a\phi\nabla_b\phi - g_{ab}\nabla^c\phi\nabla_c\phi\right)\left(\Box\phi - \frac{\nabla^c\phi\nabla^d\phi\nabla_d\nabla_c\phi}{\nabla^e\phi\nabla_e\phi}\right)\right. \\ & \left. + \nabla^d\phi\left(\nabla_d\phi\nabla_a\nabla_b\phi - \nabla_b\phi\nabla_a\nabla_d\phi - \nabla_a\phi\nabla_d\nabla_b\phi + \frac{\nabla_a\phi\nabla_b\phi\nabla^c\phi\nabla_c\nabla_d\phi}{\nabla^e\phi\nabla_e\phi}\right)\right]. \end{aligned} \tag{14}$$

The comparison of Eqs. (11) and (5) yields

$$q^{(\phi)}_a = -\frac{\sqrt{-\nabla^c\phi\nabla_c\phi}}{8\pi\phi}\,\dot{u}_a\,, \tag{15}$$

which brings us to our main point. The relation (15) has a physical consequence in Eckart's first order thermodynamics,[8] in which the heat flux density is related to the temperature $\mathcal{T}$ by the generalized Fourier law (a constitutive relation)[8]

$$q_a = -K\left(h_{ab}\nabla^b\mathcal{T} + \mathcal{T}\dot{u}_a\right), \tag{16}$$

where K is the thermal conductivity. Comparing Eqs. (15) and (16) leads to the result that, in the comoving frame, the spatial temperature gradient vanishes and the heat flow is caused solely by the inertia of energy (the acceleration term in (16)). The positive-definite temperature of the effective fluid is[9, 13]

$$\mathcal{T} = \frac{\sqrt{-\nabla^c\phi\nabla_c\phi}}{8\pi K\phi}\,. \tag{17}$$

According to Eq. (17) GR, which is the limit $\phi = $ const. of scalar-tensor gravity,[3, 4] corresponds to zero temperature $\mathcal{T}$, while in scalar-tensor spacetimes the scalar degree of freedom ϕ is excited and $\mathcal{T} > 0$.[9] The "temperature of gravity" is higher when the gravitational coupling $G_{\rm eff} \sim \phi^{-1}$ is larger. In the space of scalar-tensor theories, gravity (viewed as a dissipative system) left to itself can "diffuse" toward GR, as described in.[9] Let us confront this idea with examples from gravitational physics.

3. Examples

3.1. *f(R) gravity*

Metric $f(R)$ gravity (see[5–7] for reviews) is the most popular alternative to Einstein theory to explain the current acceleration of the universe without invoking an *ad hoc* dark energy. This theory is equivalent to an $\omega = 0$ Brans-Dicke theory with dynamical[b] scalar field $\phi = f'(R)$ and potential $V(\phi) = \phi R - f(R)\Big|_{R=R(\phi)}$,[5–7] hence

$$\mathcal{T} = \frac{f''(R)\sqrt{-\nabla^c R\nabla_c R}}{8\pi K f'(R)}\,. \tag{18}$$

In order for the graviton to carry positive energy, it must be $f'(R) > 0$, while $f''(R) > 0$ is required for stability,[14] which guarantees that $K\mathcal{T} \geq 0$. This inequality is saturated by GR which, with $f(R) = R - 2\Lambda$, corresponds to $\mathcal{T} = 0$. It is significant that the requirement $\mathcal{T} > 0$ corresponds to local stability.

3.2. *Friedmann-Lemaître-Robertson-Walker universes*

In Friedmann-Lemaître-Robertson-Walker (FLRW) universes, spatial isotropy implies that the spatial heat flux of the effective fluid vanishes. For the same reason, the spatial temperature gradient $h_{ab}\nabla^b\mathcal{T} = 0$, while $\dot{a}_c \neq 0$ (in general, the ϕ-fluid does not obey the dust equation of state). Then, Eq. (16) implies that FLRW universes have "gravity temperature" $\mathcal{T} = 0$ in the comoving frame, whether they are solutions of scalar-tensor gravity or GR. Equivalently, in any FLRW space the imperfect effective fluid reduces to a perfect one for which heat flux and anisotropic

[b] In the Palatini version of $f(R)$ gravity, instead, ϕ is not dynamical and this theory is not an excitation of GR (cf.[23]).

stresses vanish identically (this property is valid also for Lovelock and $f(R,\mathcal{G})$ theories, where $\mathcal{G} \equiv R^2 - 4R_{ab}R^{ab} + R_{abcd}R^{abcd}$ is the Gauss-Bonnet term, in arbitrary dimension[15]). This conclusion goes against the idea (see, *e.g.*, Ref.[16]) that an attractor mechanism to GR operates in scalar-tensor cosmology. The situation of FLRW and Bianchi cosmologies with regard to the temperature of gravity is under examination and will be reported elsewhere.

3.3. *Vacuum, asymptotically flat, stationary black holes*

It is well known since an early theorem by Hawking that vacuum, asymptotically flat black holes in Brans-Dicke gravity are the same as in GR,[17] a result later generalized to scalar-tensor theories[18,19] provided that $V(\phi)$ has a minimum for the scalar ϕ to sit in stable equilibrium (the exceptions are maverick solutions with ϕ diverging on the horizon, *e.g.*,[20]). The key ingredient of Hawking's theorem consists of proving that ϕ is constant outside the horizon, in which case the theory reduces to GR in that region, corresponding to zero "theory temperature" $\mathcal{T}$. The interpretation is that these extreme objects "freeze" the extra dynamical degrees of freedom outside their horizons. Then, the no-hair theorems state that the GR black holes are the states of "lowest temperature" in the space of scalar-tensor black holes.

3.4. *Stealth scalar fields*

Clearly, Minkowski spacetime should correspond to zero temperature and, indeed, it is a constant ϕ solution of the field equations (2) and (3). However, Minkowski spaces with non-gravitating stealth scalar fields are also solutions of scalar-tensor gravity (*e.g.*,[21,22]). For example, the Ayon-Beato stealth solution $g_{ab} = \eta_{ab}$, $\phi = a_1 x^\mu x_\mu + p_\mu x^\mu + a_2$ (where $a_{1,2}$ and p_μ are constants)[21] correspond to "theory temperature"

$$\mathcal{T} = \frac{\sqrt{4a_1\left(\phi - a_2\right) + p_\alpha p^\alpha}}{8\pi K \phi}\,. \tag{19}$$

This interpretation makes sense where $\phi > 0$ and $a_1(\phi - a_2) + p_\mu p^\mu/4 > 0$. Even though the stress-energy tensor of the effective imperfect fluid disappears, the scalar degree of freedom is excited and the temperature of gravity is non-zero.

In another stealth solution due to Robinson,[22] $V \equiv 0$, $\omega = \text{const.}$, the geometry is Minkowskian, and the scalar is the wave

$$\phi = \begin{cases} \phi_0\, \mathrm{e}^{c_1 u + c_2} & \text{if} \quad \omega = -1\,, \\ \phi_0\left(c_1 u + c_1\right)^{\frac{1}{\omega+1}} & \text{if} \quad \omega \neq -1\,, \end{cases} \tag{20}$$

where u is the retarded time and $c_{1,2}$ are constants. In this case, a massless wave-like excitation of the scalar degree of freedom with $\nabla_c\phi\nabla^c\phi = 0$ gives $\mathcal{T} = 0$. A ϕ-wave as a dissipative system was regarded as a problem in[23] because classical gravitational theories are time-reversal invariant, but this state cannot decay, therefore this is not a truly dissipative system.

4. Conclusions

We have introduced a candidate to the role of "temperature of gravity" $\mathcal{T}$ using the effective imperfect fluid description of scalar-tensor gravity and Eckart's thermodynamics.[9,13] In this picture, the approach to GR is a diffusion-like process. Altough our proposal is intriguing at first sight, a deeper analysis is needed before it can be taken seriously. The specific examples discussed (plus those in[9]) corroborate the proposed Eq. (17), but our proposal remains preliminary. In any case, ultimately it will suffer from the same limitations of Eckart's theory. Nevertheless, the explicit expression of the "temperature of gravity" in the wide class of scalar-tensor theories (the prototypical alternative to GR, containing the $f(R)$ subclass extremely popular in cosmology) provides a working scheme to investigate the relaxation to GR.

Alternative approaches are possible: one can trade temperature with chemical potential, assigning to the effective ϕ-fluid zero temperature and entropy but nonzero chemical potential as done, *e.g.*, in.[24] These approaches and a more detailed analysis of our proposal for $\mathcal{T}$ are under study and will be reported elsewhere.

Two body dynamics in a quadratic modification of general relativity

Soham Bhattacharyya
Max Planck Institute for Gravitational Physics (Albert Einstein Institute)
Leibniz Universität Hannover

It is shown in this study that deviations from the Einstein-Hilbert action at the quadratic level using a proper analyses and suitable dynamical variables lead to a tiny modification to the post Newtonian equations of motion, and non-GR like behavior at very short length scales.

Keywords: Modified gravity; two-body dynamics; post-Newtonism formalism.

1. Introduction

General theory of Relativity (GR) is a field theory, one of the first of its kind, that is classified under classical physics. The validity of the theory ranges from solar system length scales to cosmological length scales. It has passed most of its predictions with flying colors, starting from the extra perihelion precession of Mercury in the inner solar system,[1] to gravitational lensing,[2] to the generation of gravitational waves (GW),[3–8] and finally to the existence of objects called black holes (BH).[9]

One of the first calculations that tested the predictive power of GR was the perihelion precession of Mercury, which is to say that GR gave predictions of all the possible orbital dynamics that was possible to be observed in the early 20th century, and its predictive power remains the same to this date. GR predicted that the *gravitational force* will not always be inverse squared of the distance from the source, and that at shorter length scales, the behavior changes. To be precise, a perturbative treatment of GR, also known as the post Newtonian (PN) formalism,[10–16] reveals that a series of shorter (than inverse squared) ranged velocity dependent forces can have a prominent effect on the dynamics of two objects trapped in their mutual gravitational field (like the Sun and Mercury system). Hence, the universality of Newtonian gravity stops being universal when one goes beyond the *Newtonian bubble*, broadly speaking.

However, an uncomfortable question pops up when one considers the PN forces of GR, and keeps on continuing the PN series to shorter and shorter length scales. Or when one considers the collapse of a self-gravitating mass of fluid at the extreme scenario. At every point along the collapse, the gravitational force, including the PN forces, are attractive in nature. Hence, if the fermionic pressure, or the force that makes matter solid, is unable to balance the increasingly powerful (but shorter ranged) forces of gravity, a singularity may occur. This is because in the tug of war of all the forces present in one or multiple gravitating systems, gravity seems to win

in some extreme conditions. Such conditions can occur in ultra dense self gravitating systems like the end stages of a star collapsing under its own gravity. If there is no other force that can stop the unyielding pull of gravity, matter eventually collapses fully in on itself. But long before such a full collapse, or singularity, can happen, a special surface forms around the eventual singularity. Such a surface is known as the event horizon, or the surface the forms the termination of all *events* in the Universe that lies outside of the surface. Here *event* refers to the special relativistic notation of space-time events, which are, in the sense of mathematical modelling, points in a four dimensional object known as the manifold, which in turn refers to the complete past, present, and future of the Universe that is being modelled.

However, the universality of attraction of gravity may not be the case when one goes beyond the Einstein-Hilbert (EH) action, referred to as GR in literature. In order to demonstrate that, a quadratic deviation to the EH action is considered, which is a subclass of post-Einsteinian theories known as $f(R)$ theories of gravity.[17,18] Such theories are characterized by an extra massive scalar degree of freedom,[19–21] in addition to the two massless tensor degrees of freedom.

A PN treatment of the densitized field equations of a quadratic extension to GR will be performed in this study that resembles the Landau-Lifshitz formulation of GR. It will be shown that the equations of motion have a rather good limit to GR (almost indistinguishable in fact), and only deviates from the predictions of GR at very high energy scales (where energy scales refer to really large velocities and very high spatial curvatures combined).

Geometrized units, $c = G = 1$ will be used in this study unless explicitly mentioned otherwise. The notations of[22] will be followed except a few changes in variable and index labeling. The mostly minus sign convention will be followed for the metric, that is $(+,-,-,-)$.

2. Layout

2.1. *The densitized formulation of GR*

The gothic metric/Landau-Lifshitz/densitized formulation of GR may be motivated from a particular observation regarding the structure of the second-most condensed form of the Einstein field equations in its covariant form (or the canonical form), that is

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R \propto T_{\mu\nu} \tag{1}$$

where the first tensor quantity on the LHS of the above is the Ricci tensor, and the scalar multiplied to the metric tensor in the second term of the LHS is the contraction of the Ricci tensor with the metric, known as the Ricci scalar. The RHS is the classical matter energy-momentum-stress density tensor, which contains certain information (although non-exhaustive) about the content that is separate from the space-time. One notices that the net content of the RHS of (1) is essentially a trace reversed form of the Ricci tensor. Trace reversal implies that the trace of

the new tensor that was introduced in the beginning of the 20th century has a trace that is negative of the trace of the Ricci tensor, and is known as the Einstein tensor, which leads to the most condensed form of the field equations of GR, or

$$G_{\mu\nu} \propto T_{\mu\nu} \tag{2}$$

where all components of the tensor $G_{\mu\nu}$ has a one-to-one relationship with all of the corresponding components of the matter energy-momentum-stress density tensor. However, the cost of condensation is the loss of information and usability. As it is, Eq. (2) does not tell one about how planets and stars move and how GWs are radiated. To be able to predict such phenomenon mathematically, one needs to 'dirty their hands'.

In classical GR, $T_{\mu\nu}$ can contain fluids (serving as a model for stars, dust, etc.), or it can contain the energy-momentum-stress density equivalent of electromagnetic fields and charges. The Ricci tensor/scalar are obtained from geometric principles governing the nature of surfaces, volumes, and higher dimensional generalization; which are in turn obtained by contracting the tensor quantity that serves as the model for the space-time 'fabric'[a], or the Riemann tensor $R_{\mu\sigma\rho\nu}$. The Riemann tensor in GR is a function of the metric and its derivatives (till second). It has certain symmetries that are given as follows

$$R_{\mu\sigma(\nu\rho)} = R_{(\mu\sigma)\nu\rho} = 0 \tag{3}$$

$$R_{\mu[\sigma\nu\rho]} = 0 \tag{4}$$

$$R_{\mu\rho\nu\sigma} = R_{\nu\sigma\mu\rho} \tag{5}$$

$$R_{\mu\rho[\nu\sigma;\alpha]} = 0. \tag{6}$$

The first, third of the identities, that is Eqs. (3) and (5), are called skew and interchange symmetries respectively. Whereas Eqs. (4) and (6) are known as the first and second Bianchi identities respectively. The second Bianchi identity is particularly useful since it leads to the following identity on the Einstein tensor $G_{\mu\nu}$

$$\nabla^{\mu} G_{\mu\nu} = 0, \tag{7}$$

where $\nabla^{\mu} \equiv g^{\mu\rho} \nabla_{\rho}$ is the index-raised covariant derivative associated with the metric $g_{\alpha\beta}$. The above, combined with the proportionality condition (2), lead to the following

$$\nabla^{\mu} T_{\mu\nu} = 0 \tag{8}$$

which is a covariant conservation law on the classical matter (or electromagnetic fields) energy-momentum-stress density tensor, and using which equation of motion of classical matter itself can be deduced. Hence the famous saying by J.A. Wheeler

[a] Although the term fabric is used, it is put under quotation to differentiate from an actual material object, which is something that the physics community thought of as 'Aether' before the famous Michelson-Morley experiment. In conventional notion, material or fabric can be torn or broken; however, a similar 'tearing' of space-time is something that does not seem to happen. Hence one must take the concept of 'fabric' with a pinch of salt.

about Eq. (2): *Spacetime tells matter how move; matter tells spacetime how to curve*, is incomplete without throwing in Eq. (8) into the fold.

With the above motivations one can define a new tensor given by[23–25]

$$\mathfrak{g}^{\mu\nu} = \sqrt{-g}\, g^{\mu\nu} \tag{9}$$

which utilizes the contravariant metric, or the 'dual' of the covariant metric, whose components actually define the space-time structure. Now the point of taking the dual is to simplify the equations that need to be solved, by replacing the problem at hand with another problem which relates to the original problem via transformation and/or reparametrizations. One also notices the presence of the determinant of the metric tensor through $\sqrt{-g}$ multiplying $g^{\mu\nu}$. Under the transformation (9), Eq. (1) or (2) can be framed as a slightly less condensed (but more useful) form given as follows

$$\frac{1}{2\,(-g)}\,\partial_{\alpha\,\beta} H^{\mu\alpha\nu\beta} \;-\; 8\,\pi\, t^{\mu\nu}_{LL} \;=\; 8\,\pi\, T^{\mu\nu}_{m} \tag{10}$$

$$H^{\mu\alpha\nu\beta} = \mathfrak{g}^{\alpha\beta}\mathfrak{g}^{\mu\nu} - \mathfrak{g}^{\alpha\nu}\mathfrak{g}^{\beta\mu} \tag{11}$$

$$\begin{aligned} 16\,\pi\,(-g)\,t^{\alpha\beta}_{\mathrm{LL}} = {} & \partial_\alpha \mathfrak{g}^{\mu\nu}\partial_\beta \mathfrak{g}^{\alpha\beta} - \tfrac{1}{4}\mathfrak{g}^{\alpha\beta}\mathfrak{g}_{\gamma\zeta}\mathfrak{g}_{\theta\iota}\mathfrak{g}^{\mu\nu}\partial_\alpha \mathfrak{g}^{\gamma\theta}\partial_\beta \mathfrak{g}^{\zeta\iota} \\ & + \tfrac{1}{2}\mathfrak{g}_{\gamma\zeta}\mathfrak{g}_{\theta\iota}\mathfrak{g}^{\mu\alpha}\mathfrak{g}^{\nu\beta}\partial_\alpha \mathfrak{g}^{\gamma\theta}\partial_\beta \mathfrak{g}^{\zeta\iota} + \tfrac{1}{8}\mathfrak{g}^{\alpha\beta}\mathfrak{g}_{\gamma\zeta}\mathfrak{g}_{\theta\iota}\mathfrak{g}^{\mu\nu}\partial_\alpha \mathfrak{g}^{\gamma\zeta}\partial_\beta \mathfrak{g}^{\theta\iota} \\ & - \tfrac{1}{4}\mathfrak{g}_{\gamma\zeta}\mathfrak{g}_{\theta\iota}\mathfrak{g}^{\mu\alpha}\mathfrak{g}^{\nu\beta}\partial_\alpha \mathfrak{g}^{\gamma\zeta}\partial_\beta \mathfrak{g}^{\theta\iota} - \partial_\alpha \mathfrak{g}^{\mu\alpha}\partial_\beta \mathfrak{g}^{\nu\beta} + \mathfrak{g}^{\alpha\beta}\mathfrak{g}_{\gamma\zeta}\partial_\alpha \mathfrak{g}^{\mu\gamma}\partial_\beta \mathfrak{g}^{\nu\zeta} \\ & + \tfrac{1}{2}\mathfrak{g}_{\alpha\beta}\mathfrak{g}^{\mu\nu}\partial_\gamma \mathfrak{g}^{\beta\zeta}\partial_\zeta \mathfrak{g}^{\alpha\gamma} - \mathfrak{g}_{\beta\gamma}\mathfrak{g}^{\nu\alpha}\partial_\alpha \mathfrak{g}^{\gamma\zeta}\partial_\zeta \mathfrak{g}^{\mu\beta} - \mathfrak{g}_{\beta\gamma}\mathfrak{g}^{\mu\alpha}\partial_\alpha \mathfrak{g}^{\gamma\zeta}\partial_\zeta \mathfrak{g}^{\nu\beta}. \end{aligned} \tag{12}$$

The definition of the Landau-Lifshitz pseudo-tensor $t^{\mu\nu}_{LL}$ deviates slightly from the usual definition found in literature since all the metrics that are used to raise or lower the indices have been transformed into the gothic metric. The covariant gothic metric is defined as

$$\mathfrak{g}_{\mu\nu} = \frac{g_{\mu\nu}}{\sqrt{-g}}. \tag{13}$$

One notices that the rank 4 tensor $H^{\mu\alpha\nu\beta}$ has the same symmetries as the Riemann tensor, and is proportional to the Riemann tensor corresponding to the maximally symmetric Riemann tensor. The maximally symmetric Riemann tensor is a solution of the field equations of GR when the space-time is homogeneous and isotropic everywhere. Deviation from such a space-time with the maximum number of symmetries is marked by the appearance of a coordinate or a gauge dependent tensor (or a pseudo-tensor) $t^{\mu\nu}_{LL}$, also known as the Landau-Lifshitz energy-momentum-stress density pseudo-tensor. $t^{\mu\nu}_{LL}$ is a quantification of the energy, momentum, and stress that is inherent in the space-time, and leads to a solutions that are less symmetric than the completely homogeneous and isotropic space-time one started off with. Such solutions are perturbative in nature and formed the early basis for the Post-Newtonian formalism in GR.[10–16] The perturbation is defined about the Minkowski space-time as

$$\mathfrak{h}^{\mu\nu} = \eta^{\mu\nu} \;-\; \mathfrak{g}^{\mu\nu}. \tag{14}$$

The above tensor is projected on a Cartesian coordinate frame of a freely falling observer by choosing the following gauge condition

$$\partial_\mu \mathfrak{h}^{\mu\nu} = 0 \tag{15}$$

which not only simplifies the field equations but also puts it in a form that offers a more intimate insight into the nature of space-time and its relationship to classical matter. They are given by the following

$$\Box \mathfrak{h}^{\mu\nu} = -16\,\pi\,\Lambda^{\mu\nu} \tag{16}$$

$$\Lambda^{\mu\nu} = \Theta^{\mu\nu} + \partial_{\alpha\,\beta}\chi^{\mu\nu\alpha\beta} \tag{17}$$

$$\Theta^{\mu\nu} = (-g)\,(T^{\mu\nu} + t^{\mu\nu}_{LL} - t^{\mu\nu}_{H}) \tag{18}$$

$$\chi^{\mu\nu\alpha\beta} = \frac{1}{16\,\pi}\left(\mathfrak{h}^{\alpha\nu}\,\mathfrak{h}^{\beta\mu} - \mathfrak{h}^{\alpha\beta}\,\mathfrak{h}^{\mu\nu}\right) \tag{19}$$

where a proportionality constant of $16\,\pi$ has now been used, which is the case when one uses geometrized units ($G = c = 1$). The rank 4 tensor $\chi^{\mu\alpha\nu\beta}$ with Riemann symmetry, being a total derivative term, can be turned into a boundary term using Gauss's law, and can be discarded as the source of the wave equation (16) when a particular choice of the Green's function is made for the flat-space Laplacian/wave operator $\Box$. One immediately notices that the dynamical variable now follows the well studied massless wave equation, which has standard solutions. It is also to be noted that if one chooses the effective energy-momentum-stress density tensor to be the sum of both the matter and the pseudo part, the dynamical variable has a one-to-one relationship with the matter density. The Landau-Lifshitz or the gothic metric formalism is hence often called as the densitized formalism, as it allows the introduction of a variable that can be taken as the space-time density itself, in contrast to the regular metric tensor which has a very complicated relationship with the energy-momentum-stress density tensor. The covariant conservation identity in Eq. (8) in this 'reduced' formalism, when added to the Landau-Lifshitz pseudo-tensor, along with the harmonic gauge condition (15), reduces to the following

$$\partial_\nu\,\Lambda^{\mu\nu} = 0. \tag{20}$$

Now to come back to the motivation for mentioning trace-reversal at the beginning of the section; one may choose to study perturbative GR by simply linearizing the metric tensor about the Minkowski space-time itself, that is

$$g^{\mu\nu} = \eta^{\mu\nu} - h^{\mu\nu} \tag{21}$$

At the linear order the gothic metric perturbation and the metric perturbation are related as follows (using Jacobi's identity)

$$\mathfrak{h}^{\mu\nu} = h^{\mu\nu} - \frac{1}{2}\,\eta^{\mu\nu}\,h \tag{22}$$

$$\mathfrak{h} = -h \tag{23}$$

where h and $\mathfrak{h}$ are the trace of the metric perturbation and the gothic metric perturbation respectively. Eq. (22) is used as a standard textbook solution for modeling the propagation of gravitational waves in empty space-times. Multiplying $\sqrt{-g}$ to the dual of the metric tensor is also similar to the multiplication of the same factor to the Ricci scalar (other than making the volume element covariant) to make the Einstein-Hilbert Lagrangian density, which has the same dimensions as any other matter Lagrangian density which may appear at the action level along with the Einstein-Hilbert Lagrangian density, that is

$$S = \int_{\mathscr{M}} \sqrt{-g}\, d^4x \left(\frac{R}{16\,\pi} + \mathscr{L}_{matter} + \mathscr{L}_{electromagnetism} + ... \right) \tag{24}$$

2.2. *The densitized formulation of $f(R)$ theories of gravity*

Like any other field theory, the class of theories known as $f(R)$ theories of gravity can be derived from the following action

$$S = \int_{\mathscr{M}} \sqrt{-g}\, d^4x \left(\frac{f(R)}{16\,\pi} + \mathscr{L}_{matter} + \mathscr{L}_{electromagnetism} + ... \right) \tag{25}$$

However, in the current study for simplicity, we will not be including electromagnetic fields or any other 'exotic' fields. The field equations can be derived by varying the action with respect to the metric, and its higher derivatives, and by enforcing all variations vanish at the boundaries of the integration, which is well suited to study the classical problem at hand. The field equations so obtained are as follows[21]

$$f'(R)\, R_{\mu\nu} - \frac{1}{2} f(R)\, g_{\mu\nu} - [\nabla_\mu \nabla_\nu - g_{\mu\nu} \Box]\, f'(R) = 8\,\pi\, T_{\mu\nu} \tag{26}$$

$$f'(R) = \frac{df(R)}{dR} \tag{27}$$

where ∇_μ, as usual, is the covariant derivative associated with the metric $g_{\mu\nu}$. The above field equations can be written in two different forms (if one intends to use the machinery of GR): one modifies the Newtonian constant (which has been put to unity in the current study), and the other preserves it. The former is written as[21]

$$G_{\mu\nu} = \frac{8\,\pi}{f'} \left(T_{\mu\nu} + T^{eff}_{\mu\nu} \right) \tag{28}$$

$$T^{eff}_{\mu\nu} \equiv \frac{1}{2} \left(f - R\, f' \right) g_{\mu\nu} + \left(\nabla_\mu \nabla_\nu - g_{\mu\nu} \Box \right) f' \tag{29}$$

where $\Box \equiv g^{\alpha\beta}\, \nabla_\alpha \nabla_\beta$. The latter version has the following form

$$G_{\mu\nu} = 8\,\pi\, T_{\mu\nu} + \tilde{T}^{eff}_{\mu\nu} \tag{30}$$

$$\tilde{T}^{eff}_{\mu\nu} = (1 - f')\, R_{\mu\nu} + \frac{1}{2} (R - f)\, g_{\mu\nu} + \left(\nabla_\mu \nabla_\nu - g_{\mu\nu} \Box \right) f'. \tag{31}$$

In this study, only the former, that is Eqs. (28)-(29) will be considered because of convenience, and the extra terms are less in number. There is also another differential equation that is satisfied by the scalar function f', which is independent of whatever form is chosen for the effective energy-momentum-stress density tensor, and is obtained by taking the trace of either Eqs. (28) or (30). It's given by

$$3\, g^{\mu\nu}\, \nabla_\mu\, \nabla_\nu\, f' \,+\, f'\, R \,-\, 2\, f = 8\, \pi\, T \tag{32}$$

and can be regarded as the dynamics of some effective scalar field. The transition of f' from an 'effective' to an actual scalar degree of freedom will be made clear in a few paragraphs.

Before trying to obtain an equivalent of Eq. (10) one must be made aware of a particular conformal property of $f\,(R)$ theories of gravity, that is under a general conformal transformation of the metric tensor

$$\tilde{g}_{\mu\nu} = \Omega^2\, g_{\mu\nu} \tag{33}$$

$f\,(R)$ theories can be written as an *Einstein + massive scalar* system. The $f\,(R)$ action without matter, for example transforms as[26–30]

$$S = \int_{\mathscr{M}} d^4x\, \sqrt{-g}\, \left(\frac{\tilde{R}}{16\, \pi} \,+\, \frac{1}{2}\, \tilde{g}^{\mu\nu}\, \phi_{,\mu}\, \phi_{,\nu} \,-\, V\,(\phi) \right) \tag{34}$$

$$\phi \equiv \sqrt{\frac{3}{16\, \pi}}\, \ln \Omega \tag{35}$$

$$V\,(\phi) \equiv \frac{1}{16\, \pi}\, \frac{f \,-\, R\, f'}{\left(f'\right)^2} \tag{36}$$

$$\Omega \equiv f' \tag{37}$$

Where $\tilde{R}$ is the Ricci scalar of the conformally transformed metric $\tilde{g}_{\mu\nu}$. This confirms the presence of an extra massive scalar degree of freedom in $f\,(R)$ theories of gravity. In the literature of $f\,(R)$ and scalar-tensor theories of gravity, the 'vanilla' metric $g_{\mu\nu}$ is known as the Jordan frame, whereas the conformally transformed metric $\tilde{g}_{\mu\nu}$ is called the Einstein frame. From this motivation, one can define a new gothic metric (in the Jordan frame) $\tilde{g}^{\mu\nu}$ given by

$$\tilde{\mathfrak{g}}^{\mu\nu} = f'\,(R)\, \sqrt{-g}\, g^{\mu\nu} \tag{38}$$

which frames the field equations (28) in the following form

$$\partial_{\alpha\,\beta} \tilde{H}^{\alpha\mu\beta\nu} = -16\, \pi\, (-g)\, f'\,(R)\, \left(T^{\mu\nu} \,+\, t^{\mu\nu}_{eff} \,+\, \tilde{t}^{\mu\nu}_{LL} \right), \tag{39}$$

$$\begin{aligned} 16\, \pi\, (-g)\, f'\, t^{\mu\nu}_{eff} = \sqrt{-g}\, \left(f \,-\, R\, f' \right)\, \tilde{\mathfrak{g}}^{\mu\nu} \,+\, \frac{3}{\left(f'\right)^2}\, \left(\tilde{\mathfrak{g}}^{\mu\alpha}\, \tilde{\mathfrak{g}}^{\nu\beta} \,-\, \frac{1}{2}\, \tilde{\mathfrak{g}}^{\mu\nu}\, \tilde{\mathfrak{g}}^{\alpha\beta} \right) \\ \times \quad \partial_\alpha f'\, \partial_\beta f' \end{aligned} \tag{40}$$

where $\tilde{H}^{\alpha\mu\beta\nu}$ and $\tilde{t}^{\mu\nu}_{LL}$ has the same form as that of $H^{\alpha\mu\beta\nu}$ and $t^{\mu\nu}_{LL}$, respectively, but with $\mathfrak{g}$ replaced by $\tilde{\mathfrak{g}}$. The newly appeared tensor $t^{\mu\nu}_{eff}$ contains products of only quadratic forms of first derivatives of f', as seen in Eq. (40). Owing to the conformal transformation, all the double derivatives of f' in the tensor field equations cancel away, making $t^{\mu\nu}_{eff}$ a perfectly usable source for the perturbative post Newtonian expansion. Curiously, the definition Eq. (38) appears as an identity of Palatini formalism of $f(R)$ theories of gravity as well, for example in Eq. (17) of.[31]

Now before a post Newtonian sequence of solutions can be found, one needs to choose a particular form of the function $f(R)$, which consequently fixes the form of the function $f'(R)$ as well, and can be taken for simplicity as

$$f(R) = R + \frac{f''(0)}{2} R^2 \tag{41}$$

$$f'(R) = 1 + f''(0)\, R \tag{42}$$

where the coefficients of expansion $f'(0)$ is taken to be unity to recover GR at the $R = 0$ limit, and $f''(0)$ will be taken to be negative for the course of this article, following.[32–35] One defines a tensor field $\tilde{\mathfrak{h}}^{\mu\nu}$, similar to Eq. (14), that propagates on the Minkowski background. One can define that as follows

$$\tilde{\mathfrak{h}}^{\mu\nu} = \eta^{\mu\nu} - \tilde{\mathfrak{g}}^{\mu\nu}. \tag{43}$$

In order to obtain wave like equations of motion where the coordinate variable functions comprising the coordinate 4-vectors follow the conditions

$$\Box\, x^{\mu} = 0, \tag{44}$$

one must choose the following gauge/coordinate condition similar to Eq. (15)

$$\partial_{\mu}\, \tilde{\mathfrak{h}}^{\mu\nu} = 0 \tag{45}$$

which will be called as the conformal harmonic gauge. Now similar to the conformally transformed new metric density $\tilde{\mathfrak{g}}^{\mu\nu}$, one must also define a scalar variable corresponding to a scalar density, say $\mathfrak{R}$, that follows a massive wave equation (to model the dynamics of the massive scalar degree of freedom), and maintains the $(-g)$ relationship with the trace of the net energy-momentum-stress density tensor $\tilde{\Lambda}^{\mu\nu}$ as well, as in Eq. (16). One may define that as follows

$$\mathfrak{R} = \sqrt{-g}\, R. \tag{46}$$

Substituting Eq. (43), (46), and (45) in the reduced field equations (39), one obtains the following

$$\Box\tilde{\mathfrak{h}}^{\mu\nu} = -16\,\pi\,\tilde{\Lambda}^{\mu\nu} \tag{47}$$

$$\tilde{\Lambda}^{\mu\nu} = (-g)\left[T^{\mu\nu}_{m}\left(1 - \frac{f''\,\mathfrak{R}}{\sqrt{-g}}\right) + t^{\mu\nu}_{LL} + t^{\mu\nu}_{H} + t^{\mu\nu}_{eff}\right]. \tag{48}$$

$t^{\mu\nu}_{eff}$ is comprised of various products of $\tilde{\mathfrak{h}}^{\mu\nu}$, $\mathfrak{R}$, and first derivatives of $\tilde{\mathfrak{h}}^{\mu\nu}$ and $\mathfrak{R}$; whose truncated form till the quadratic order of $f''(0)$ is given as follows

$$16\,\pi\,(-g)\,t^{\mu\nu}_{eff} = \frac{f''\,\mathfrak{R}^2}{\sqrt{-g}}\,\eta^{\mu\nu} + \frac{3\,(f'')^2}{4\,(-g)}\Big[2\,\big(\eta^{\mu\alpha}\,\eta^{\nu\beta} + \eta^{\mu\beta}\,\eta^{\nu\alpha} - \eta^{\mu\nu}\,\eta^{\alpha\beta}\big)\,\mathfrak{R}\,\partial_\alpha\mathfrak{R}\,\partial_\beta\tilde{\mathfrak{h}} + \Big(\eta^{\mu\alpha}\,\eta^{\nu\beta} - \frac{1}{2}\,\eta^{\mu\nu}\,\eta^{\alpha\beta}\Big)\Big(4\,\partial_\alpha\mathfrak{R}\,\partial_\beta\mathfrak{R} + \mathfrak{R}^2\,\partial_\alpha\tilde{\mathfrak{h}}\,\partial_\beta\tilde{\mathfrak{h}}\Big)\Big] + \mathscr{O}\left[\left(\frac{f''}{\sqrt{-g}}\right)^3\right] \tag{49}$$

$$\tilde{\mathfrak{h}} \equiv \eta_{\mu\nu}\,\tilde{\mathfrak{h}}^{\mu\nu} \tag{50}$$

with the following conservation law being satisfied by $\tilde{\Lambda}^{\mu\nu}$

$$\partial_\mu\,\tilde{\Lambda}^{\mu\nu} = 0\,, \tag{51}$$

whereas the new scalar dynamical variable $\mathfrak{R}$ satisfies the following, as obtained by substituting Eq. (43), (46), and (45) in Eq. (32)

$$\Box\mathfrak{R} + \sqrt{-g}\,\gamma^2\,\mathfrak{R} = -8\,\pi\,(-g)\,\gamma^2\,\tilde{\Lambda} \tag{52}$$

$$\gamma^2 \equiv -\frac{1}{3\,f''(0)} \tag{53}$$

$$\tilde{\Lambda} = T_m + f''(0)\left\{\frac{T_m\,\mathfrak{R}}{3\,\sqrt{-g}} + \frac{1}{8\,\pi\,(-g)}\left(\frac{\mathfrak{R}^2}{3} - \partial_\mu\mathfrak{R}\,\partial^\mu\tilde{\mathfrak{h}} - \frac{1}{2}\,\mathfrak{R}\,\partial_\mu\tilde{\mathfrak{h}}^{\alpha\beta}\,\partial^\mu\tilde{\mathfrak{h}}_{\alpha\beta} - \frac{1}{4}\,\mathfrak{R}\,\partial_\mu\tilde{\mathfrak{h}}\,\partial^\mu\tilde{\mathfrak{h}} - \frac{1}{2}\,\mathfrak{R}\,\Box\tilde{\mathfrak{h}}\right)\right\} + \mathscr{O}\left([f''(0)]^2\right) \tag{54}$$

$$\tag{55}$$

$$T_m = \eta_{\mu\nu}\,T^{\mu\nu}_m. \tag{56}$$

Before moving on to finding the equations of motion of compact objects, and to conclude this section one may take the LHS of Eq. (28) to be some modified Einstein tensor $\mathscr{G}_{\mu\nu}$, that is

$$\mathscr{G}_{\mu\nu} \equiv f'(R)\,R_{\mu\nu} - \frac{1}{2}\,f(R)\,g_{\mu\nu} - [\nabla_\mu\,\nabla_\nu - g_{\mu\nu}\,\Box]\,f'(R)\,, \tag{57}$$

it can be shown that[32] the modified tensor $\mathscr{G}_{\mu\nu}$ satisfies the same covariant conservation condition as the Einstein tensor $G_{\mu\nu}$, that is

$$\nabla^\mu\,\mathscr{G}_{\mu\nu} = 0 \tag{58}$$

which further implies

$$\nabla^\mu\,T_{\mu\nu} = 0. \tag{59}$$

The above leads to the conclusion that the covariant conservation law holds for $f(R)$ theories of gravity in general, and may help in finding a more generalized second Bianchi identity. However, from what is known in the literature (for example in[32,36])

about the consequence of the covariant conservation law is a peculiar identity on the function $f'(R)$, given by

$$(\Box \nabla_\nu - \nabla_\nu \Box)\, f' = R_{\mu\nu} \nabla^\mu f' \tag{60}$$

which is similar to the appearance of the Riemann curvature tensor due to covariant derivative of a vector field not commuting, implying curvature or non-flatness of the space-time. However, the above commuting relation is on a scalar field, implying that some unconventional geometry might be at large here.

3. Equations of motion from the covariant conservation law

References 22 and 37 showed that it is possible to obtain the post Newtonian sequence of solutions for beyond the weak field scenario, that is when the post Newtonian parameter squared ϵ^2 is proportional to the compactness (or equivalently, the potential at the surface of an ultra-compact object like Neutron stars and small black holes being proportional to the kinetic energy of either bodies). To be precise, in non-geometrized units when

$$\epsilon^2 \sim \frac{G\,M}{c^2\,a} \tag{61}$$

where M and a are the total mass and radius of the compact object. In order that strong surface gravity (post Minkowskian) can be incorporated within the post Newtonian (relativistic) framework, a series of coordinate transformations can be made that requires the integration of wave equations like (16) or (47) and (52) to be performed in the so-called *body-zone coordinate system*, while not worrying about the effects of strong internal gravity.

In order to maintain the compactness of the body to unity at all times, some temporal+spatial scalings are made, with the temporal scaling defining a proper time s (τ in[37]) given by

$$s = \epsilon\, t \tag{62}$$

where t is the coordinate time of the inertial observer. Under the above transformation, the Minkowski metric and the corresponding metric determinant scale as follows

$$\eta_{\mu\nu} = diag\left(\epsilon^{-2}, -1, -1, -1\right) \tag{63}$$

$$-\det\left(\eta_{\mu\nu}\right) = \epsilon^{-2} \tag{64}$$

which is singular for $\epsilon \to 0$. The spatial scalings that are going to be used for the integration in the body zone of Eq. (47) are given by

$$X^i_L \equiv \frac{x^i - z^i_L\,(s)}{\epsilon^2}. \tag{65}$$

The scalings in Eq. (62) and (65) lead to any rank two tensor, or in our case, the energy-momentum-stress density tensor, transforming as

$$T_L^{s\,s} = \epsilon^2\, T^{t\,t} \sim \mathscr{O}\left(\epsilon^{-2}\right) \tag{66}$$

$$T_L^{s\,i'} = \epsilon^{-1}\, T_L^{t\,i} \sim \mathscr{O}\left(\epsilon^{-5}\right) \tag{67}$$

$$T_L^{i'\,j'} = \epsilon^{-4}\, T_L^{i\,j} \sim \mathscr{O}\left(\epsilon^{-8}\right), \tag{68}$$

with the un-primed coordinates representing the unscaled coordinates. Now the above scalings, i.e. Eqs. (62)-(65), are made in a coordinate system that is stationary with respect to the origin or the center of mass of the $L-th$ compact body, denoted by an external observer with the position 3-vector $z_L^i\,(s)$, and the 3-velocity v_L^i defined as

$$v_L^i = \frac{d\, z_L^i\,(s)}{ds}. \tag{69}$$

Hence the next (and final) transformation requires the definition of a co-moving frame (but not co-rotating, since boost and rotation in the wrong order may lead to unnecessary Thomas precession), moving along an ultra compact object whose spin can be ignored. The energy-momentum-stress density tensor of just the matter content of the compact object transforms from an inertial frame to the near-zone or the co-moving frame as follows

$$T_L^{s\,s} = T_L^{s\,s} \tag{70}$$

$$T_L^{s\,i} = \epsilon^2 T_L^{s\,i'} + v_L^i T_L^{s\,s} \tag{71}$$

$$T_L^{i\,j} = \epsilon^4 T_L^{i'\,j'} + 2\epsilon^2 v_L^{(i}\, T_L^{j')s} + v_L^i\, v_L^j T_L^{s\,s}. \tag{72}$$

Then at the leading order the post Newtonian solutions for both GR and $f\,(R)$ theories of gravity, as seen by the inertial observer, are given by

$$\mathfrak{h}_{\mathscr{B}}^{s\,s} = 4\,\epsilon^4 \sum_{L=1,\,2} \left(\frac{P_L^s}{r_L} + \epsilon^2\, \frac{D_L^k\, r_L^k}{r_L^3} \right) + \mathscr{O}\left(\epsilon^8\right) \tag{73}$$

$$\mathfrak{h}_{\mathscr{B}}^{s\,i} = 4\,\epsilon^4 \sum_{L=1,\,2} \left(\frac{P_L^i}{r_L} + \epsilon^2\, \frac{J_L^{k\,i} r_L^k}{r_L^3} \right) + \mathscr{O}\left(\epsilon^8\right) \tag{74}$$

$$\mathfrak{h}_{\mathscr{B}}^{i\,j} = 4\,\epsilon^2 \sum_{L=1,\,2} \left(\frac{Z_L^{i\,j}}{r_L} + \epsilon^2\, \frac{Z_L^{k\,i\,j}\, r_L^k}{r_L^3} \right) + \mathscr{O}\left(\epsilon^6\right) \tag{75}$$

In the current formalism, the above components of the tensor potential are sufficient to obtain equations of motion of the two sources till the first PN order. The monopole and dipole moments, respectively, of various components of $\Lambda^{\mu\nu}$ (or $\tilde{\Lambda}^{\mu\nu}$) are defined

as follows

$$P_L^s = \lim_{\epsilon \to 0} \int_{\mathscr{B}_L} d^3 X_L \, \Lambda^{s\,s} \tag{76}$$

$$P_L^i = \lim_{\epsilon \to 0} \int_{\mathscr{B}_L} d^3 X_L \, \Lambda^{s\,i} \tag{77}$$

$$Z_L^{i\,j} = \lim_{\epsilon \to 0} \int_{\mathscr{B}_L} d^3 X_L \, \Lambda^{i\,j} \tag{78}$$

$$D_L^i = \lim_{\epsilon \to 0} \int_{\mathscr{B}_L} d^3 X_L \, \Lambda^{s\,s} \, X_L^i \tag{79}$$

$$J_L^{i\,j} = \lim_{\epsilon \to 0} \int_{\mathscr{B}_L} d^3 X_L \, \Lambda^{s\,i} X_L^j \tag{80}$$

$$Z_L^{i\,j\,k} = \lim_{\epsilon \to 0} \int_{\mathscr{B}_L} d^3 X_L \, \Lambda^{i\,j} \, X_L^k \tag{81}$$

where $\mathscr{B}_L$ implies the body zone/co-moving+scaled coordinate system of the $L-th$ body zone.

One defines a 4-momentum, by putting together the scalar in Eq. (76) and the 3-vector in Eq. (77), as[22,37–39]

$$P_L^\mu (s) = \epsilon^2 \int_{\mathscr{B}_L} d^3 X_L \, \Lambda^{s\,\mu} \tag{82}$$

which along with the conservation law (20) or (51), leads to the following 4-force or the 4-momentum evolution formula[22,37,38]

$$\frac{dP_L^\mu}{ds} = -\epsilon^{-4} \oint_{\partial \mathscr{B}_L} dS_k \, \Lambda^{k\,\mu} + \epsilon^{-4} \, v_L^k \oint_{\partial \mathscr{B}_L} dS_k \, \Lambda^{s\,\mu}. \tag{83}$$

When one defines the bare quasi-local mass of the body zone L to be Eq. (76), the 3-momentum to 3-velocity relation is given at the leading order by

$$P_L^i = P_L^s \, v_L^i + Q_L^i + \mathscr{O}\left(\epsilon^2\right) \tag{84}$$

$$Q_L^i = \epsilon^{-4} \oint_{\partial \mathscr{B}_L} dS_k \left(\Lambda^{s\,k} - v_L^k \, \Lambda^{s\,s}\right) X_L^i. \tag{85}$$

By choosing the origin of the coordinate system to be the center of mass of the body zone L (which is a choice that has already been made), Q_L^i can be shown to vanish at the leading (Newtonian) order, that is $\mathscr{O}(1)$. Therefore, one obtains the 3-velocity evolution relation (or the 3-force on the body zone L) as

$$\begin{aligned} P_L^s \, \frac{dv_L^i}{ds} = & -\epsilon^{-4} \oint_{\partial \mathscr{B}_L} dS_k \, \Lambda^{k\,i} + \epsilon^{-4} \, v_L^k \oint_{\partial \mathscr{B}_L} dS_k \, \Lambda^{s\,i} + \epsilon^{-4} \, v_L^i \left(\oint_{\partial \mathscr{B}_L} dS_k \, \Lambda^{k\,s} \right. \\ & \left. - v_L^k \oint_{\partial \mathscr{B}_L} dS_k \, \Lambda^{s\,s} \right) + \mathscr{O}\left(\epsilon^2\right). \end{aligned} \tag{86}$$

All of the relations in this section (as mentioned along the way) holds both for GR and $f(R)$ theories of gravity, and can be utilized to obtain the 2-body equations of motion of both theories, simply owing to the fact that the second Bianchi identity (or its generalization) holds for both theories of gravity. In GR for example, the equations of motion till 1 PN or $\mathscr{O}\left(\epsilon^2\right)$ of Eq. (86) for one of the bodies (say body zone 1) is given by

$$M_1 \frac{dv_1^i}{ds} = -\frac{M_1 M_2}{r_{1\,2}^2} n^i + \epsilon^2 \frac{M_1 M_2}{r_{1\,2}^2} \left[\left(-v_1^2 - 2\, v_2^2 + \frac{3}{2} \left(\hat{n} \cdot \mathbf{v}_2 \right)^2 + 4 \left(\mathbf{v}_1 \cdot \mathbf{v}_2 \right) \right.\right. \\ \left.\left. + \frac{5\, M_1}{r_{1\,2}} + \frac{4\, M_2}{r_{1\,2}} \right) n^i + \left\{ 4 \left(\hat{n} \cdot \mathbf{v}_1 \right) - 3 \left(\hat{n} \cdot \mathbf{v}_2 \right) \right\} \left(v_1^i - v_2^i \right) \right] + \mathscr{O}\left(\epsilon^4\right). \tag{87}$$

4. Post Newtonian sequence of solutions and equations of motion for the quadratic deviation to the Einstein-Hilbert action

4.1. *The curious case of the homogeneous solution*

One may be tempted to immediately go for the particular solution of the differential equation (52), that is by solving for the following inhomogeneous problem using the retarded Green's function $G_\gamma \left(x^\mu,\, x^{\mu'} \right)$

$$\left(\Box + \sqrt{-g}\, \gamma^2 \right) G_\gamma \left(x^\mu, x^{\mu'} \right) = \delta \left(x^\mu - x^{\mu'} \right). \tag{88}$$

The support of the corresponding integral problem (that is the limit for $x^{\mu'}$ in the Green's function integral) of the above lies in the past light-cone of the event x^μ. However, one must remember that the homogeneous solution of GR leads to the BH solutions. Hence, one must also consider the homogeneous solution of the Klein-Gordon equation, which must be solved simultaneously along with the homogeneous solution of GR.

The homogeneous Klein-Gordon equation of the current theory under study, under the transformation (62), has an ϵ dependence given as follows

$$\Box \mathfrak{R}_{hom} + \frac{\gamma^2}{\epsilon} \mathfrak{R}_{hom} = 0. \tag{89}$$

While the radiative solutions of the above, under the choice of no-incoming scalar radiation from past null infinity, can be put to zero, the time independent part of the homogeneous solution cannot be ignored. The time independent differential equation is given by

$$\nabla \mathfrak{R}_{hom} - \frac{\gamma^2}{\epsilon} \mathfrak{R}_{hom} = 0 \tag{90}$$

where ∇ is the Laplace operator in Minkowski space-time. In spherical symmetry, for example, the LHS of Eq. (90) is given by

$$\frac{1}{r^2}\left[r^2\,\left(\mathfrak{R}_{hom}\right)_{,r}\right]_{,r} - \frac{\gamma^2}{\epsilon}\,\mathfrak{R}_{hom} = 0 \tag{91}$$

which has a solution which is both regular at $r = 0$ and $r = \infty$, and is given by

$$\mathfrak{R}_{hom} = \frac{C\,e^{-\frac{\gamma\,r}{\sqrt{\epsilon}}}}{r} \tag{92}$$

where C is a real constant of integration yet to be fixed. It is to be noted that the homogeneous solution, which may be part of an extended homogeneous solution of the combined scalar+tensor theory under study (like the Schwarzschild and Kerr solutions of GR), for vanishing post Newtonian or post Minkowskian parameter ϵ, leads to an infinite mass of the scalar field. Which also implies for low energies, the Ricci scalar or the Ricci scalar density considered here is practically un-excitable.

However, it is interesting to look at the effect of $\mathfrak{R}$ on the tensor wave equation (39), and how it modifies the Newtonian order solution, or more specifically, the Newtonian potential. The time-time component of the conformally transformed metric density deviation satisfies the flat-space wave equation with a source, following Eq. (47)

$$\Box\tilde{\mathfrak{h}}^{t\,t} = 16\,\pi\,(-g)\,T^{t\,t}\,(1 - \epsilon\,f''\,\mathfrak{R}) \tag{93}$$

where the leading order, or only the terms in Eq. (48) that are proportional to the classical or matter energy-momentum-stress density tensor were used, along with Eq. (64). The above can be solved by using the retarded Green's function for the massless wave operator, with $\tilde{\mathfrak{h}}^{s\,s}$ given by the body zone integral

$$\tilde{\mathfrak{h}}^{s\,s} = 4\,\epsilon^4 \sum_{L=1,\,2}\int_{\mathscr{B}_L} d^3X_L\,\frac{T^{s\,s}\,(1 - \epsilon\,f''\,\mathfrak{R})}{\left|Z^i_L - \epsilon^2\,X^i_L\right|} \tag{94}$$

Eq. (64) and (66) was used to obtain the above from Eq. (93). The first integral, and its ϵ expansion of the series is given in Eq. (73), and is the usual Newtonian potential. However, a more curious thing occurs when one considers the extra term coming due to the quadratic modification to the gravitational action

$$\tilde{\mathfrak{h}}^{s\,s}_{extra} = -4\,\epsilon^5\,f'' \sum_{L=1,\,2}\int_{\mathscr{B}_L} d^3X_L\,\frac{T^{s\,s}\,\mathfrak{R}_{hom}}{\left|Z^i_L - \epsilon^2\,X^i_L\right|}. \tag{95}$$

Considering now the particular form of the homogeneous Ricci density (92), one obtains the following integral using the scaled coordinate (65)

$$\tilde{\mathfrak{h}}^{s\,s}_{extra} = -4\,\epsilon^3\,f'' \sum_{L=1,\,2} C_L\int_{\mathscr{B}_L} d^3X_L\,\frac{T^{s\,s}}{\left|Z^i_L\,(s) - \epsilon^2\,X^i_L\right|\,\left|X^i_L\right|}\,e^{-\gamma\,\epsilon^{\frac{3}{2}}\,\left|X^i_L\right|} \tag{96}$$

which seems to preceed the order at which the gothic metric deviation first appears, that is at $\mathscr{O}\left(\epsilon^3\right)$ compared to $\mathscr{O}\left(\epsilon^4\right)$. However, expanding the extra term about $\epsilon \to 0$ leads to the following

$$\tilde{\mathfrak{h}}^{s\,s}_{extra} = -4\,\epsilon^3\,f'' \sum_{L=1,\,2} \frac{C_L}{\left|Z^i_L\right|} \int_{\mathscr{B}_L} d^3X_L\,\frac{T^{s\,s}}{\left|X^i_L\right|} \tag{97}$$

$$\tilde{\mathfrak{h}}^{s\,s}_{extra} = -4\,\epsilon^3\,f'' \sum_{L=1,\,2} \frac{C_L\,N_L}{\left|X^i_L\right|} \tag{98}$$

which is a Newtonian potential like term with negative one multipole moment of the source, denoted by N_L. Therefore, the modified leading order metric deviation $\tilde{\mathfrak{h}}^{s\,s}$ can be written in the following form

$$\tilde{\mathfrak{h}}^{s\,s} = 4\,\epsilon^4 \sum_{L=1,\,2} \left[\frac{\tilde{P}^s_L}{\left|Z^i_L\right|} + \mathscr{O}\left(\epsilon^2\right)\right] \tag{99}$$

$$\tilde{P}^s_L = P^s_L - \lim_{\epsilon\,\to\,0} \frac{f''\,C_L}{\epsilon} \int_{\mathscr{B}_L} d^3X_L\,\frac{T^{s\,s}}{\left|X^i_L\right|} \tag{100}$$

where P^s_L was defined in Eq. (76). It is important to note that while the integral in the second term of the square bracket of the above has a well defined limit for $\epsilon \to 0$, the coefficient multiplying it does not. In fact, due to the ϵ^{-1} nature of the coefficient, the modified mass-energy definition blows up at the $\epsilon \to 0$ limit, leading to the following conclusion

$$C_L = 0, \tag{101}$$

implying that the homogeneous Ricci scalar does not modify the tensor deviation density at all.

4.2. *Deviation from the general relativistic equations of motion*

The leading order Ricci scalar density deviation occurs at $\mathscr{O}\left(\epsilon^4\right)$, and is given by the following

$${}_{(4)}\mathfrak{R}_{part} \equiv {}_{(4)}\mathfrak{R} = -8\,\pi\,\gamma^2\,\epsilon^4\,\frac{M_L\,e^{-\frac{\gamma\left|Z^i_L\right|}{\sqrt{\epsilon}}}}{\left|Z^i_L\right|} \tag{102}$$

whose form is the same as the now extinct homogeneous solution, but instead of the unknown constant, there is just the mass coming as a parameter, as in the definition of Eq. (76). The only unknown in the above equation is the inverse length scale γ, which was related to the coefficient of the quadratic deviation of the GR action in Eq. (53). Derivation of the above has been given in Appendix A.

In GR, the non-vanishing and body zone independent terms in the surface integrals of Eq. (86) lead to the 3-force at different PN orders, and has been well

documented in PN literature, for example.[40,41] However, in this study only the leading order modification to the general relativistic equations of motion due to the quadratic deviation to the GR action will be quoted. Such a modification can be found by using the modified conservation law (51) along with the definitions of (83) and (86) with $\Lambda^{\mu\nu}$ replaced by $\tilde{\Lambda}^{\mu\nu}$. In Eq. (86), various components of the modified net energy-momentum-stress density tensor $\tilde{\Lambda}^{\mu\nu}$ will appear as integrand of the surface integrals. However, the components that have a non-vanishing and *body zone boundary radius* independent contribution to the surface integrals of Eq. (86), was found to be coming from the space-space component of $t^{\mu\nu}_{eff}$, or

$$t^{i\,j}_{eff} = \frac{\epsilon^4}{192\,\pi\,\gamma^4}\,\Big[2\,\left(\eta^{i\,k}\,\eta^{j\,l}\,+\,\eta^{i\,l}\,\eta^{j\,k}\,-\,\eta^{i\,j}\,\eta^{k\,l}\right)\,\mathfrak{R}\,\partial_k\mathfrak{R}\,\partial_l\tilde{\mathfrak{h}} + \left(\eta^{i\,k}\,\eta^{j\,l}\,-\,\frac{1}{2}\,\eta^{i\,j}\,\eta^{k\,l}\right)\,\left(4\,\partial_k\mathfrak{R}\,\partial_l\mathfrak{R}\,+\,\mathfrak{R}^2\,\partial_k\tilde{\mathfrak{h}}\,\partial_l\tilde{\mathfrak{h}}\right)\Big] \tag{103}$$

where Eq. (64) was used to replace the metric determinant, or $\frac{1}{(-g)^2}$ multiplying the quadratic f'' part of $t^{\mu\nu}_{eff}$ in Eq. (49), which appear as ϵ^4 above.

Eq. (103) has three different ϵ orders worth of terms inside the square bracket. When one utilizes the scalings of the leading order deviation of either $\tilde{\mathfrak{h}}$ or $\mathfrak{R}$, one notices that $\tilde{\mathfrak{h}} \sim \epsilon^2$ and $\mathfrak{R} \sim \epsilon^4$, following Eqs. (63), (73)-(75), and (102). From the number of times either $\tilde{\mathfrak{h}}$ and $\mathfrak{R}$ appear inside the square bracket in each product of fields, the first term scale as ϵ^{10}, the second as ϵ^8, and the last one as ϵ^{12}. Since the overall factor of ϵ^4 cancels away due to ϵ^{-4} multiplying each surface integral of Eq. (86), the three terms inside the square brackets of Eq. (103) are 5th, 4th, and 6th PN effects on the two body equations of motion. However, not all of them survive the surface integral. Only the last term in the square bracket survives and is a 6th PN effect with the modification to the 3-force on the L^{th} body given as follows

$$M_L\,\frac{dv^i_L}{ds} = F^i_{N+PN,GR} \,-\, \epsilon^{12}\,\frac{32\,\pi\,M_L\,M^3_{L'}}{9\,r^4_{1\,2}}\,e^{-\frac{2\,\gamma\,r_{1\,2}}{\sqrt{\epsilon}}}\,n^i \tag{104}$$

where M_L is the quasi-local mass enclosed by the L^{th} body zone boundary, and $M_{L'}$ is the quasi-local mass enclosed by the partner object's body zone boundary in the two-body system. $r_{1\,2}$ is the distance between the origin of the two body zones, whereas n^i is a unit vector pointing from the origin of body zone L to the origin of body zone L'. The negative sign on the modified/extra force imply that the direction of the force is antiparallel to n^i, which is then a repulsive modification to the usual attractive Newtonian and PN forces indicated by the first term in the RHS of the above, that is $F^i_{N+PN,GR}$. Compared to other works in literature on $f\,(R)$ theories that calculate the conserved potential (or the force) from modifications to the time-time component of the metric tensor, the above has an inverse quartic distance falloff (along with the Yukawa exponential falloff) at 6 PN order, which is

an extremely tiny modification to the general relativistic PN equations of motion at the very high energy scales of ultra-compact two-body interactions.

5. Discussions and conclusion

In the current study a particular redefinition of the standard gothic metric was utilized to drastically simplify the field equations of general $f(R)$ theories of gravity. Once the identification was made that $f'(R)$ acts like a massive scalar field, a fourth order system was reduced to two second order system of differential equations. The field equations were framed in the densitized approach following the methods of Landau and Lifshitz, and their redefinition of the field equations of GR. The use of conformal densities to define Landau-Lifshitz like field equations were used in scalar-tensor theories, for example in.[42,43] In this study, it is shown that the redefinition to a conformal density greatly suppresses the actual effect of an extra massive scalar degree of freedom on orbital dynamics.

Following the definition of a tensor density, a scalar density $\mathfrak{R}$, corresponding to the massive scalar degree of freedom was defined, which relates to the trace of the energy-momentum-stress density tensor in the same manner as the conformal metric tensor density relates to the energy-momentum-stress density tensor in the Landau-Lifshitz like tensor field equations of $f(R)$ theories. The differential equation that is satisfied by $\mathfrak{R}$ throws up a static solution that makes the mass-energy definition at the Newtonian/leading order diverge, leading to its removal from further usage. At the leading order, the particular/inhomogeneous $\mathfrak{R}$ is seen to be static as well, and has the Yukawa potential form with a cutoff/inverse length scale that is related to the coefficient of the quadratic modification (with $(\text{length})^2$ dimensions) to the Einstein-Hilbert action.

However, just finding out the particular form of the leading order deviation of $\mathfrak{R}$ is quite useless, unless one finds its corresponding effect on the conformal tensor density field equations, and then, on the PN equations of motion. The leading order $\mathfrak{R}$ appears as an effective source tensor that drives the behavior of $\tilde{\mathfrak{h}}^{\mu\nu}$, as well as the evolutionary dynamics of the quasi-local four-momentum (83), and correspondingly, the velocity evolution equations (86) through surface integrals of various components of the energy-momentum-stress density tensor. It was found in Eq. (104) that the modification to the GR PN equations of motion, due to quadratic modification at the action level, appear at the sixth PN order. On top of that, the force has an inverse fourth powered dependence on the distance along with a Yukawa falloff, which is a very tiny modification to GR equations of motion. The modified force is dependent on the masses enclosed by the body zone boundaries, and the modification to the equations of motion of one of the objects is independent of the mass enclosed in that object's body zone boundary - implying that the equivalence principle (as far as it holds in the GR PN scheme) is not affected by the quadratic

modification to GR. The modified force is also conservative, and hence will not be adding to any extra dissipation (other than GR) of the orbital energy of the binary system, although it might lead to very tiny modifications to the phase evolution of the binary, as encoded in the gravitational waves. More importantly, the force is repulsive, compared to the PN forces that appear on perturbing GR about Minkowski space-times. So in the course of the binary evolution, at length scales comparable to γ^{-1}, if the two objects have not merged into a single object already, they will feel a repulsive force that will compete with the attractive GR PN forces coming out of the *superpotentials* of the PN expansion of GR, which are themselves progressively short ranged. Putting a constraint on the new length scale γ^{-1} is beyond the scope of this study, mostly because the author is not aware of sixth PN equations of motion appearing in the literature.

Appendix A

The net solution to the Klein-Gordon problem (52) with the boundary condition choice of no incoming scalar radiation from past null Minkowskian infinity is given as follows

$$\mathfrak{R}\left(x^{\mu}\right) = -8\,\pi\,\gamma^{2}\,\epsilon^{-2}\int d^{4}y\,G_{\tilde{\gamma}}\left(x^{\mu},\,y^{\mu}\right)\,T_{m}\left(y^{\mu}\right) \tag{A.1}$$

$$\tilde{\gamma}^{2} \equiv \frac{\gamma^{2}}{\epsilon} \tag{A.2}$$

where the factor of ϵ^{-2} arises because the metric determinant $(-g)$ multiplying the RHS of Eq. (52), under the transformation (62), scale as ϵ^{-2}, as seen after Eq. (63). $G_{\tilde{\gamma}}\left(x^{\mu},\,y^{\mu}\right)$ is the retarded Green's function of the Klein-Gordon equation, as was given in[32] with the $(+\,,-\,,-\,,-)$ metric signature as

$$\begin{aligned} G_{\tilde{\gamma}}\left(t,\,q;\,x^{i},\,y^{i}\right) = &\int_{-\infty,\,\tilde{\gamma}}^{-\tilde{\gamma},\,\infty}\frac{d\,\omega}{2\,\pi}\,e^{-i\,\omega(t-q)}\,\frac{e^{i\,\sqrt{\omega^{2}-\tilde{\gamma}^{2}}\,\left|x^{i}-y^{i}\right|}}{4\,\pi\,\left|x^{i}-y^{i}\right|} \\ &+\int_{-\tilde{\gamma}}^{\tilde{\gamma}}\frac{d\omega}{2\,\pi}\,e^{-i\,\omega\,(t-q)}\,\frac{e^{-\,\sqrt{\tilde{\gamma}^{2}-\omega^{2}}\,\left|x^{i}-y^{i}\right|}}{4\,\pi\,\left|x^{i}-y^{i}\right|}. \end{aligned} \tag{A.3}$$

The notation $\int_{-\infty,\,\tilde{\gamma}}^{-\tilde{\gamma},\,\infty}$ involve two integrals, one from $-\infty$ to $-\tilde{\gamma}$, and the other from $\tilde{\gamma}$ to ∞. It is to be noted that the three integrals whose domains encompass all of ω space must be evaluated simultaneously in order for the solution to converge. $T_{m}\left(q,\,y^{i}\right)$, the trace of the classical matter energy-momentum tensor, which being a scalar, does not transform under any of the coordinate scalings.

Due to the the coordinate scalings in Eq. (65), the infinitesimal 4-volume element $d^{4}y$ transform from the asymptotic observer's frame to either of the body zones $\mathscr{B}_{L}$ in the following manner

$$d^{4}y \equiv dt\,\wedge\,d^{3}y \tag{A.4}$$

$$\rightarrow \epsilon^{-1}\,ds\,\wedge\,\epsilon^{6}\,d^{3}X_{L} \tag{A.5}$$

where $\wedge$ denotes the wedge product between 1-form dt and 3-form d^3y. In the current operational context $\wedge$ is effectively scalar multiplication.

Substituting Eq. (A.3) in Eq. (A.1), and transforming into the body zone coordinates by substituting Eq. (A.5) as the infinitesimal covariant volume element in Eq. (A.1), one obtains the following integral for the particular solution $\mathfrak{R}_{part}$ for the inhomogeneous Klein-Gordon equation

$$\begin{aligned}
\mathfrak{R}_{part}\left(t,\, x^i\right) = -\epsilon^3\; 8\,\pi\,\gamma^2 \int_{-\infty}^{\infty} ds' \int_{\mathscr{B}_L} d^3X_L \int_{-\infty,\,\tilde{\gamma}}^{-\tilde{\gamma},\,\infty} \frac{d\omega}{2\,\pi}\, e^{-i\,\omega\left(t-s'/\epsilon\right)} \\
\times \quad \frac{e^{i\,\sqrt{\omega^2-\tilde{\gamma}^2}\left|Z_L^i-\epsilon^2\,X_L^i\right|}}{4\,\pi\,\left|Z_L^i-\epsilon^2\,X_L^i\right|}\,\left[\epsilon^4\,T_m\left(s'/\epsilon,\, X_L^i\right)\right] \\
-\epsilon^3 \quad 8\,\pi\,\gamma^2 \int_{-\infty}^{\infty} ds' \int_{\mathscr{B}_L} d^3X_L \int_{-\tilde{\gamma}}^{\tilde{\gamma}} \frac{d\omega}{2\,\pi}\, e^{-i\,\omega\left(t-s'/\epsilon\right)} \\
\times \quad \frac{e^{-\sqrt{\tilde{\gamma}^2-\omega^2}\left|Z_L^i-\epsilon^2\,X_L^i\right|}}{4\,\pi\,\left|Z_L^i-\epsilon^2\,X_L^i\right|}\,\left[\epsilon^4\,T_m\left(s'/\epsilon,\, X_L^i\right)\right]. \qquad \text{(A.6)}
\end{aligned}$$

In the body zones that surround each of the objects, the energy-momentum tensor of classical matter $\left(T_{\mathscr{B}_L} = \lim_{\epsilon\,\to\,0}\epsilon^4\,T_m\right)$ will be assumed to have a quasi-stationary/adiabatic initial condition for solving the relaxed system of equations, in the absence of any other time dependent driving force inside the compact object, and is given by

$$T_{\mathscr{B}_L}\left(X^i\right) = \sum_{n=-\infty}^{\infty} \mathfrak{T}_n\left(\left|X_L^i\right|, X_L^\theta\right)\, e^{i\,n\,\mathscr{X}} \qquad \text{(A.7)}$$

$$\mathscr{X}\left(s/\epsilon,\, X_L^\phi\right) \equiv \mathscr{X} = X_L^\phi - \Omega\, s/\epsilon + \phi_0 \qquad \text{(A.8)}$$

where an axial+time symmetry was assumed for the initial condition, such that the time dependence of the source body in the body zone coordinate system repeats after every $T = \frac{2\,\pi}{\Omega}$, with a constant phase parameter ϕ_0. The weighing factors $\mathfrak{T}_n$ are coefficients in the series expansion of the trace T_m (or $T_{\mathscr{B}_{\mathscr{L}}}$) using stationary functions $e^{i\,n\,\mathscr{X}}$, and are functions of the radial and azimuthal coordinates. Eq. (A.7) physically implies that the variations in the energy-momentum tensor sourcing $\mathfrak{R}$ in the body zone of the first object is purely generated by the effect of the motion of the second object around it. The body zone coordinates $\left(X_L^i\right)$ were defined in Eq. (65), in which $\left|X_L^i\right|$ is the distance from the center of mass of the body L to any point in the body zone coordinates, as viewed in the respective body zones. The choice in Eq. (A.7) has a simplifying effect on the subsequent calculations and is justified by the adiabatic and stationarity in the co-moving frame approximations, as found in the literature on PN expansions.

Assuming quasi-periodicity for the source tensor, as in Eq. (A.7), one can substitute it into Eq. (A.6), to obtain

$$\begin{aligned}\mathfrak{R}_{part}\left(t,\,x^i\right) = &-\epsilon^3\,\frac{8\,\pi\,\gamma^2}{2\,\pi}\sum_{n=-\infty}^{\infty}\int_{\mathscr{B}_L} d^3X_L\left(\int_{-\infty,\,\tilde{\gamma}}^{-\tilde{\gamma},\,\infty} d\omega\, e^{-i\,\omega\,t}\right) e^{i\,n\left(X_L^{\phi}+\phi_0\right)}\\ &\times\quad \frac{e^{i\,\sqrt{\omega^2-\tilde{\gamma}^2}\left|Z_L^i-\epsilon^2\,X_L^i\right|}}{4\,\pi\,\left|Z_L^i-\epsilon^2\,X_L^i\right|}\,\mathfrak{T}_n\left(\left|X_L^i\right|,X_L^{\theta}\right)\int_{-\infty}^{\infty} ds'\,e^{i\,(\omega-n\,\Omega)\,s'/\epsilon}\\ &-\epsilon^3\quad\frac{8\,\pi\,\gamma^2}{2\,\pi}\sum_{n=-\infty}^{\infty}\int_{\mathscr{B}_L} d^3X_L\left(\int_{-\tilde{\gamma}}^{\tilde{\gamma}} d\omega\, e^{-i\,\omega\,t}\right) e^{i\,n\left(X_L^{\phi}+\phi_0\right)}\\ &\times\quad \frac{e^{-\sqrt{\tilde{\gamma}^2-\omega^2}\left|Z_L^i-\epsilon^2\,X_L^i\right|}}{4\,\pi\,\left|Z_L^i-\epsilon^2\,X_L^i\right|}\,\mathfrak{T}_n\left(\left|X_L^i\right|,X_L^{\theta}\right)\int_{-\infty}^{\infty} ds'\,e^{i\,(\omega-n\,\Omega)\,s'/\epsilon}.\end{aligned} \tag{A.9}$$

Transforming

$$s' \to \epsilon\, s \tag{A.10}$$

and using the integral representation of the delta function,

$$\int_{-\infty}^{\infty} e^{i\,k\,(x-x')}\,dk = 2\,\pi\,\delta\,(x-x')\,, \tag{A.11}$$

one obtains

$$\begin{aligned}\mathfrak{R}_{part}\left(t,\,x^i\right) = &-\epsilon^4\;8\,\pi\,\gamma^2\sum_{n=-\infty}^{\infty}\int_{\mathscr{B}_L} d^3X_L\,\frac{e^{i\,\sqrt{n^2\,\Omega^2-\tilde{\gamma}^2}\left|Z_L^i-\epsilon^2\,X_L^i\right|}}{4\,\pi\,\left|Z_L^i-\epsilon^2\,X_L^i\right|}\\ &\times\quad \mathfrak{T}_n\left(\left|X_L^i\right|,X_L^{\theta}\right)\times e^{-i\,n\left(\Omega\,t-X_L^{\phi}-\phi_0\right)} \qquad\text{(A.12)}\\ &-\epsilon^4\;8\,\pi\,\gamma^2\sum_{n=-\infty}^{\infty}\int_{\mathscr{B}_L} d^3X_L\,\frac{e^{-\sqrt{\tilde{\gamma}^2-n^2\,\Omega^2}\left|Z_L^i-\epsilon^2\,X_L^i\right|}}{4\,\pi\,\left|Z_L^i-\epsilon^2\,X_L^i\right|}\\ &\times\quad \mathfrak{T}_n\left(\left|X_L^i\right|,X_L^{\theta}\right)\,e^{-i\,n\left(\Omega\,t-X_L^{\phi}-\phi_0\right)}. \qquad\text{(A.13)}\end{aligned}$$

The Green's function (A.3) can be written as an infinite sum of spherical harmonic functions, that are weighed by functions of the radial coordinates $\left|Z_L^i\right|$ and $\left|X_L^i\right|$, in the following way for $\left|Z_L^i\right| > \left|X_L^i\right|$

$$\frac{e^{i\,k\left|X^i-Z^i\right|}}{4\,\pi\,\left|X^i-Z^i\right|} = i\,k\sum_{\ell,\,m} j_{\ell}\left(k\,\left|X^i\right|\right)\,h_{\ell}^{(1)}\left(k\,\left|Z^i\right|\right)\,Y^*_{\ell\,m}\left(X^{\theta},\,X^{\phi}\right)\,Y_{\ell\,m}\left(Z^{\theta},\,Z^{\phi}\right) \tag{A.14}$$

$$\frac{e^{-\,k\left|X^i-Z^i\right|}}{4\,\pi\,\left|X^i-Z^i\right|} = \sum_{\ell,\,m}\frac{I_{\ell+\frac{1}{2}}\left(k\,\left|X^i\right|\right)\,K_{\ell+\frac{1}{2}}\,\left(k\,\left|Z^i\right|\right)}{\sqrt{\left|X^i\right|\,\left|Z^i\right|}}\,Y^*_{\ell\,m}\left(X^{\theta},\,X^{\phi}\right)\,Y_{\ell\,m}\left(Z^{\theta},\,Z^{\phi}\right)$$

$$Z_L^i \equiv \frac{x^i\,-\,z_L^i\,(s)}{\epsilon^2}\,;\quad L\,=\,1,\,2. \tag{A.15}$$

The various functions appearing above are as follows

- j_ℓ: Spherical Bessel function of first kind.
- $h^{(1)}_\ell$: Spherical Bessel function of third kind.
- $I_{\ell+\frac{1}{2}}$: Modified Bessel function of the first kind.
- $K_{\ell+\frac{1}{2}}$: Modified Bessel function of the second kind.
- $Y_{\ell\,m}$, $Y^*_{\ell\,m}$: Spherical harmonic functions and their complex conjugates.

After using Eqs. (A.14) and (A.15) in the above, one obtains for $\left|Z^i_L\right| > \left|X^i_L\right|$

$$\begin{aligned}
\mathfrak{R}_{part}\left(t,\, x^i\right) = -\epsilon^4\, 8\,\pi\, i\,\gamma^2 \sum_{n,\,\ell,\,m}^{|n|>\left\lfloor\frac{\tilde{\gamma}}{\Omega}\right\rfloor} \sqrt{n^2\,\Omega^2-\tilde{\gamma}^2} \int_{\mathscr{B}_L} d^3X_L\, e^{i\,n\left(X^\phi_L+\phi_0-\Omega\,t\right)} \\
\times \quad j_\ell\left(\epsilon^2\sqrt{n^2\,\Omega^2-\tilde{\gamma}^2}\,\left|X^i_L\right|\right)\, h^{(1)}_\ell\left(\sqrt{n^2\,\Omega^2-\tilde{\gamma}^2}\,\left|Z^i\right|\right) \\
\times \quad Y^*_{\ell\,m}\left(X^\theta_L,\, X^\phi_L\right)\, Y_{\ell\,m}\left(Z^\theta,\, Z^\phi\right)\, \mathfrak{T}_n\left(\left|X^i_L\right|,\, X^\theta_L\right) \\
-\epsilon^3 \quad 8\,\pi\,\gamma^2 \sum_{n,\,\ell,\,m}^{|n|<\left\lfloor\frac{\tilde{\gamma}}{\Omega}\right\rfloor} \int_{\mathscr{B}_L} d^3X_L\, e^{i\,n\left(X^\phi_L+\phi_0-\Omega\,t\right)} \\
\times \quad \frac{I_{\ell+\frac{1}{2}}\left(\epsilon^2\sqrt{\tilde{\gamma}^2-n^2\,\Omega^2}\,\left|X^i_L\right|\right)}{\sqrt{\left|X^i_L\right|}}\, \frac{K_{\ell+\frac{1}{2}}\left(\sqrt{\tilde{\gamma}^2-n^2\,\Omega^2}\,\left|Z^i\right|\right)}{\sqrt{|Z^i|}} \\
\times \quad Y^*_{\ell\,m}\left(X^\theta_L,\, X^\phi_L\right)\, Y_{\ell\,m}\left(Z^\theta,\, Z^\phi\right)\, \mathfrak{T}_n\left(\left|X^i_L\right|,\, X^\theta_L\right) \qquad \text{(A.16)}
\end{aligned}$$

one can substitute the following properties of spherical harmonic functions in Eq. (A.16)

$$Y^*_{\ell\,m} = (-1)^m\, Y_{\ell\,-m} \qquad \text{(A.17)}$$

$$Y_{\ell\,-m} = N_{\ell\,-m}\, P_{\ell\,-m}\left(\cos\, X^\theta_L\right)\, e^{-i\,m\,X^\phi} \qquad \text{(A.18)}$$

$$\int_0^{2\,\pi} dX^\phi_L\, Y^*_{\ell\,m}\, e^{i\,n\,X^\phi} = 2\,\pi\,(-1)^m\, N_{\ell\,-m}\, P_{\ell\,-m}\left(X^\theta_L\right)\, \delta_{m\,n} \qquad \text{(A.19)}$$

$$N_{\ell\,m} = (-1)^m \sqrt{\frac{(2\,\ell\,+\,1)}{4\,\pi}\,\frac{(\ell\,-\,m)!}{(\ell\,+\,m)!}} \qquad \text{(A.20)}$$

where $P_{\ell\,m}\left(X^\theta_L\right)$ are the associated Legendre polynomials and $\delta_{m\,n}$ is the Kronecker delta distribution. Since m takes values between $-\ell$ to ℓ, application of the Kronecker delta leads to the summation on ℓ in the first term of Eq. (A.16) going from the lower integral part of $\frac{\tilde{\gamma}}{\Omega}$ or $\left\lfloor\frac{\tilde{\gamma}}{\Omega}\right\rfloor$ to ∞, whereas the second terms' summation range takes ℓ from zero to $\left\lfloor\frac{\tilde{\gamma}}{\Omega}\right\rfloor$. The contributions to the particular solution from above the cutoff energy scale $\tilde{\gamma}$ is highly suppressed (especially at lower PN orders) because of the properties of j_ℓ and $h^{(1)}_\ell$ for asymptotically large values of ℓ, and

terms in $\mathfrak{R}$ series containing the same can be approximated to zero at the current orders of calculation. Hence one can safely set the first summation in RHS of Eq. (A.16) to zero and consider only the second summation. Hence it is to be noted that the factors that depend on ϵ in the above are only in the arguments of the Bessel function $I_{\ell+\frac{1}{2}}$.

Hence the only relevant factors that explicitly contain ϵ in both the sums in Eq. (A.16), can be expanded about $\epsilon \to 0$ as follows

$$I_{\ell+\frac{1}{2}}\left(\epsilon^2\,\Lambda\,|X_L|\right) \approx \epsilon^{2\,\ell+1}\,\frac{\Lambda^{\frac{2\,\ell+1}{2}}}{2^{\ell+\frac{1}{2}}\,\Gamma\left(\ell\,+\,\frac{3}{2}\right)}\,|X_L|^{\ell+\frac{1}{2}}\,. \tag{A.21}$$

The approximation of (A.21), when substituted in for the relevant factors of the RHS of Eq. (A.16), leads to the following polynomial series of ϵ about $\epsilon \to 0$

$$\begin{aligned}
\mathfrak{R}_{part}\left(t,\,x^i\right) \approx\, & -8\,\pi\,\gamma^2\sum_{L,\,\ell,\,m}^{\ell=\infty}\epsilon^{2\,\ell+4}\,\frac{\left(\tilde{\gamma}^2\,-\,m^2\,\Omega^2\right)^{\frac{2\,\ell+1}{4}}}{2^{\ell+\frac{1}{2}}\,\tilde{\gamma}\left(\ell\,+\,\frac{3}{2}\right)}\\
&\times e^{i\,m\,(\phi_0\,-\,\Omega\,t)}\,\frac{K_{\ell+\frac{1}{2}}\left(\sqrt{\tilde{\gamma}^2\,-\,m^2\,\Omega^2}\,\left|Z_L^i\right|\right)}{\sqrt{\left|Z_L^i\right|}}\,Y_{\ell\,m}\left(Z_L^\theta,\,Z_L^\phi\right)\\
&\times \mathfrak{M}_{L\,\ell\,m}
\end{aligned} \tag{A.22}$$

$$\begin{aligned}
\mathfrak{M}_{L\,\ell\,m} =\, & 2\,\pi\,(-1)^m\,N_{\ell\,-m}\int_{\mathscr{B}_L}\left|X_L^i\right|^{2+\ell}\sin\left(X_L^\theta\right)\\
&\times P_{\ell\,-m}\left(\cos X_L^\theta\right)\,\mathfrak{T}_m\left(\left|X_L^i\right|,\,X_L^\theta\right)\,d\left|X_L^i\right|\,dX_L^\theta.
\end{aligned} \tag{A.23}$$

From Eq. (A.22), one can immediately notice that the leading order deviation for the particular solution of the Ricci scalar for the L^{th} body zone comes at $\mathscr{O}\left(\epsilon^4\right)$ for $\ell = 0$ with $\mathfrak{M}_{L\,0\,0} \equiv M_L$ being the mass monopole, and was found to be

$${}_{(4)}\mathfrak{R}_{part} \equiv {}_{(4)}\mathfrak{R} \,=\, -8\,\pi\,\gamma^2\,\epsilon^4\,\frac{M_L\,e^{-\frac{\gamma\left|Z_L^i\right|}{\sqrt{\epsilon}}}}{\left|Z_L^i\right|}. \tag{A.24}$$

We present a comparative analysis of current observational constraints on three recently discussed alternative models for explaining the low-redshift acceleration of the universe: the so-called steady-state torsion model, the generalized coupling model, and the scale invariant model by Maeder (an example of a broader class which we also briefly study). These are compared to the traditional parameterization of Chevallier, Polarski and Linder. Each of the candidate models is studied under two different assumptions: as genuine alternatives to ΛCDM (where a new degree of freedom would be expected to explain the recent acceleration of the universe without any cosmological constant) and as parametric extensions of ΛCDM (where both a cosmological constant and the new mechanism can coexist, and the relative contributions of both are determined by the data). Our comparative analysis suggests that, from a phenomenological point of view, all such models neatly divide into two classes, with different observational consequences.

Keywords: Cosmology; Dark energy; Torsion; Generalized couplings; Scale invariance.

1. Introduction

The observational evidence for the acceleration of the universe shows that our canonical theories of cosmology and particle physics are at least incomplete, and possibly incorrect. Is dark energy a cosmological constant (i.e. vacuum energy)? If the answer is yes, it is ten to some large power times smaller than our Quantum Field Theory based expectations. If the answer is no, then the Einstein Equivalence Principle must be violated. Either way, new physics is out there, waiting to be discovered; we must search for, identify and characterize this new physics. The CosmoESPRESSO team uses the universe as a laboratory to characterize, with precision spectroscopy and other observational, computational and theoretical tools, the behaviour of the

gravitational interaction, with the goal of determining what makes the universe accelerate. In what follows we highlight recent contributions of the CosmoESPRESSO team to this fundamental quest.

The search for the physical mechanism underlying the observed low-redshift acceleration of the universe is the most compelling goal of modern fundamental cosmology, and several theoretical possibilities beyond a cosmological constant can be envisaged in principle, each with its specific observational consequences.

Our goal here is to present a comparative study of the observational constraints on three classes of alternative models: the so-called steady-state torsion model[1] of Kranas *et al.*, the generalized coupling model[2] of Feng and Carloni, and the scale invariant model[3] of Maeder; the latter is an example of a broader class of models[4,5] first proposed by Canuto *et al.*, which we also briefly study. As a benchmark we use the traditional phenomenological parameterization of Chevallier, Polarski and Linder (henceforth CPL).[6,7] All models have common parameters (specifically, the matter density parameter, Ω_m) but also some specific ones, and a comparative analysis using a common data set is therefore interesting.

We take three models at face value and phenomenologically constrain them through a standard likelihood analysis using low-redshift background cosmology data. Specifically, we use the recent Pantheon dataset,[8] including its covariance matrix. We also use a compilation of 38 Hubble parameter measurements.[9] Occasionally we will also use a Planck prior[10] on the matter density, $\Omega_m = 0.0315 \pm 0.007$. The value of the he Hubble constant is always marginalized analytically, following the procedure detailed in Ref. 11. The analysis is done on a grid (since we are only dealing with background cosmology, there is no computational need for a full MCMC analysis), and we have explicitly verified that the grid sizes that have been used are sufficiently large for the results presented in the following sections not to be affected by these sizes. Moreover, the following section will also present an explicit validation test of our code for the supernova data.We will work in units where the speed of light is set to $c = 1$.

2. Preamble: The CPL parameterization

In the CPL parameterization the dark energy equation of state parameter is assumed to have the form[6,7]

$$w(z) = \frac{p(z)}{\rho(z)} = w_0 + w_a \frac{z}{1+z}\,, \tag{1}$$

where w_0 is its present value while w_a quantifies its possible evolution. This is manifestly phenomenological: it is not intended to mimic a particular dark energy model, but aims to describe generic departures from the ΛCDM behaviour (which corresponds to $w_0 = -1$ and $w_a = 0$). In principle it allows for both canonical and phantom fields, since there is no restriction on the two model parameters, at least on purely mathematical grounds.

We assume a flat Friedmann-Lemaître-Robertson-Walker model, in which case the Friedmann equation has the form

$$\frac{H^2(z)}{H_0^2} = \Omega_m(1+z)^3 + (1-\Omega_m)(1+z)^{3(1+w_0+w_a)} \exp\left(-\frac{3w_a z}{1+z}\right), \qquad (2)$$

where the matter parameter is $\Omega_m \equiv \kappa\rho_0/3H_0^2$ and $\kappa = 8\pi G$. This can now be constrained using the aforementioned data.

The case of a constant equation of state parameter (i.e. $w_a = 0$), for the case of the supernova dataset, have been used in Ref. 12 as a validation test of our analysis code, against the results of Ref. 8. In this case the one-sigma constraints on the two model parameters from the combined data sets are

$$\Omega_m = 0.27 \pm 0.02 \qquad (3)$$

$$w_0 = -0.92 \pm 0.06\,, \qquad (4)$$

which are compatible with ΛCDM.

For the full three-parameter CPL model, the one-sigma constraints on the three model parameters from the combined data sets are

$$\Omega_m = 0.26^{+0.03}_{-0.05} \qquad (5)$$

$$w_0 = -0.92^{+0.09}_{-0.08} \qquad (6)$$

$$w_a = 0.86^{+0.14}_{-0.24}; \qquad (7)$$

the reduced chi-square at the best fit is $\chi^2_\nu \sim 0.9$, so the model is slightly overfitting the data (a behaviour which is mainly driven by the Hubble parameter data). The first two of these constraints are compatible with the values for the w_0CDM analysis (with naturally larger uncertainties), but there is a clear preference for a positive slope $w_a > 0$. However there are strong degeneracies between the parameters, and the constraints do depend on the choice of priors. In the above we used the uniform prior on the matter density $\Omega_m = [0.05, 0.5]$, the choice being motivated by the aforementioned validation of our code. As an illustration of the sensitivity of our results to this choice, if instead one uses the narrower uniform prior $\Omega_m = [0.15, 0.45]$, one find

$$\Omega_m = 0.26^{+0.03}_{-0.05} \qquad (8)$$

$$w_0 = -0.92^{+0.07}_{-0.08} \qquad (9)$$

$$w_a = 0.74^{+0.21}_{-0.48}; \qquad (10)$$

in other words, there is no impact on the matter density and w_0, but there is a significant impact on w_a. Breaking these degeneracies requires additional data, for example from cosmic microwave background observations. In any case, our purpose here is to set up a benchmark for the constraining power of these data sets, against which to compare the constraints on the alternative models to be discussed in what follows.

3. Steady-state torsion

A possible extension of General Relativity consists in allowing for the presence of spacetime torsion. In such theories there is a further degree of freedom (in addition to the usual metric), which also gravitates. Mathematically, the torsion tensor is defined as the antisymmetric part of the affine connection; the symmetric part of the connection are the usual Christoffel symbols. Physically, this defines relation between the intrinsic angular momentum (i.e., the spin) of matter with the geometric properties of the underlying spacetime. The only non-trivial contraction of the torsion tensor is a torsion vector, and the general field equations including torsion are known as the Einstein-Cartan equations. Nominally the Einstein equations retain the usual form, but the presence of torsion implies that the Ricci tensor and the energy-momentum tensor are not symmetric. The Cartan equations relate the torsion tensor to the spin tensor, and similarly for the torsion and spin vectors.

The form of the underlying torsion tensor can be chosen such that the homogeneity and isotropy of FLRW universes is preserved,[13] and in this case the remaining degree of freedom is a scalar function ϕ which must depend only on time (a spatial dependence would violate the homogeneity assumption), but is otherwise arbitrary. Making the standard assumption of treating the metric and the torsion as independent objects and furhter assuming a flat universe, one finds the following Friedmann, Raychaudhuri and continuity equations[1]

$$H^2 = \frac{1}{3}\kappa\rho\frac{1}{3}\Lambda - 4\phi^2 - 4H\phi \tag{11}$$

$$\frac{\ddot{a}}{a} = -\frac{\kappa}{6}(\rho + 3p) + \frac{1}{3}\Lambda - 2\dot{\phi} - 2H\phi \tag{12}$$

$$\dot{\rho} = -3H\left(1 + 2\frac{\phi}{H}\right)(\rho + p) + 4\phi\left(\rho + \frac{\Lambda}{\kappa}\right) . \tag{13}$$

Here the dot denotes a derivative with respect to physical time, $H = \dot{a}/a$ is the Hubble parameter, and ρ and p are the density and pressure. In what follows we will assume barotropic fluids with a constant equation of state $p = w\rho$. It has been recently suggested that such universes may undergo accelerating phases.[1] We can conveniently define a torsion contribution

$$\Omega_\phi = -4\left(\frac{\phi_0}{H_0}\right)\left[1 + \frac{\phi_0}{H_0}\right] . \tag{14}$$

In Ref. 14 these models were constrained under the so-called steady-state torsion assumption of a constant fractional contribution of torsion to the volume expansion, that is $\phi/H = \lambda = const.$.

It is easy to find, in agreement with other recent works, that models without a cosmological constant (where torsion itself would be expected to yield the current acceleration of the universe) are strongly disfavoured by the data. Indeed, in this case, for which the matter density would be given by $\Omega_m = (1 + 2\lambda)^2$, the best fit parameters would have a reduced chi-square of at least 2.7 for the datasets under consideration.

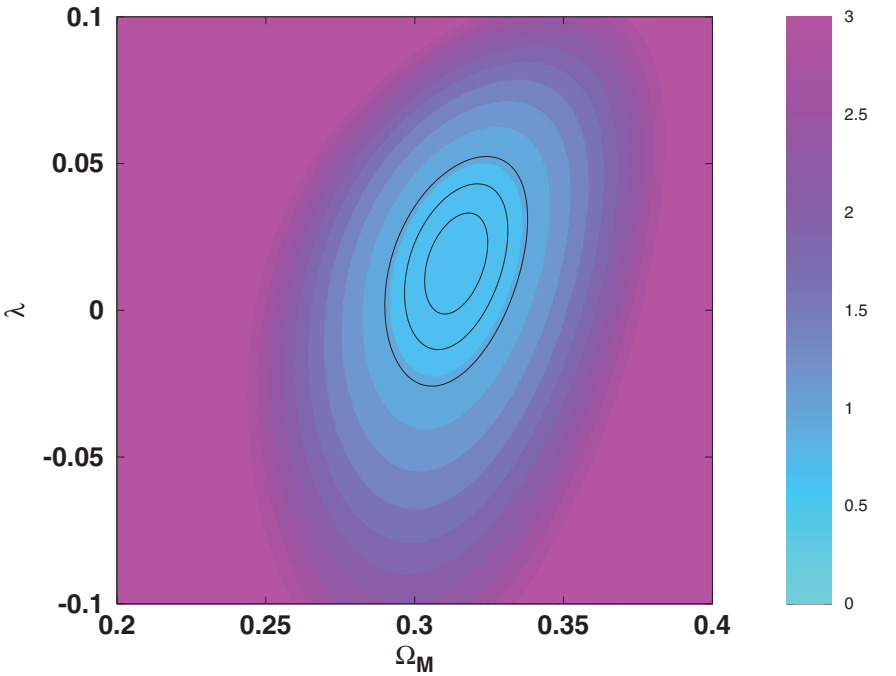

Fig. 1. Constraints on the λ–Ω_m parameter space for $w = 0$. The black lines represent the one, two and three sigma confidence levels, and the colormap depicts the reduced chi-square of the fit, with points with $\chi^2_\nu > 3$ shown in purple. Similar constraints can be found in Figure 2 of Ref. 14.

However, one can also treat these models as one-parameter extensions of ΛCDM, whereby one can constrain the relative contributions of the cosmological constant and of torsion. In this case, if one assumes that that matter has the standard equation of state, $w = 0$. As in the previous subsection will separately consider the cases without and with the aforementioned Planck prior on the matter density. Without the Planck prior, we find the following one-sigma posterior likelihoods for the two free parameters

$$\lambda_{w=0} = -0.07^{+0.05}_{-0.04} \tag{15}$$

$$\Omega_{m,w=0} = 0.18^{+0.06}_{-0.03}\,; \tag{16}$$

there is a clear degeneracy between the two parameters, and the preferred value of the matter density is lower. The inclusion of the Planck prior breaks the degeneracy and significantly improves the constraints, as shown in Fig. 1; the one-sigma posterior likelihood for the torsion parameter becomes

$$\lambda_{(w=0,Planck)} = 0.02^{+0.01}_{-0.02}\,, \tag{17}$$

which is consistent with the null result at just over one sigma.

Allowing for a non-zero (but still constant) equation of state, there is a weak degeneracy between w and the other model parameters, so although the constraints become weaker (as they must), both parameters are still well constrained by the data, provided the Planck prior is included. In this case we have

$$\lambda_{(w\neq 0,Planck)} = -0.01 \pm 0.02 \tag{18}$$

$$w_{Planck} = -0.05 \pm 0.03\,; \tag{19}$$

compared to the $w = 0$ case the best-fit value has changed sign, and the constraint is now consistent with the null result at one sigma.

Overall, we find no statistically significant preference for the presence of torsion. By itself it can't be responsible for the acceleration of the universe, and even if taken as an extension of the canonical ΛCDM paradigm the overall contribution to the Universe's energy budget is constrained to be no larger than a few percent. We also note that our constraints should be seen as conservative: an analysis including a full treatment of the cosmic microwave background should lead to stronger constraints.

4. Generalized couplings

The precise nature of the coupling between matter and the metric in the Einstein equations is at questionable assumption of the theory. One may therefore explore the possibility that this coupling is nontrivial. On such example is the Feng and Carloni's generalized coupling model,[2] which is equivalent to General Relativity in vacuum, but still allows for a different behaviour within a matter distribution.

In this case the Friedmann and Raychaudhuri equations, assuming a flat universe, can be written[2]

$$3qH^2 = \frac{256\kappa(1-pq)^3(q\rho+1)^2}{[4+q(\rho-3p)]^4} + q\Lambda - \kappa \tag{20}$$

$$6q(\dot{H}+H^2) = \frac{256\kappa(1-pq)^3(q\rho+1)[2-q(\rho+3p)]}{[4+q(\rho-3p)]^4} + 2(q\Lambda-\kappa)\,, \tag{21}$$

where q is a model-specific parameter defined as $q = \kappa/\lambda$ (where λ, not to be confused with the analogous torsion parameter, is interpreted as being akin to the vacuum energy density generated by matter fields) and p is the pressure of a fluid that is assumed to be barotropic, with an equation of state $p = w\rho$, where w is a constant equation of state parameter. The corresponding continuity equation takes the form

$$\dot{\rho} = -\frac{3H\rho(w+1)[q^2\rho^2 w(3w-1)+q\rho(1-7w)+4]}{q^2\rho^2 w(3w-1)-q\rho(3w^2+13w+2)+4}\,. \tag{22}$$

Note the model is effectively a bimetric theory.[2] In what follows we take the model as a phenomenological one and treat q (or a dimensionless version thereof) as a free parameter to be constrained by the data. It is convenient to define the dimensionless parameter $Q = q\rho_0$, where ρ_0 is the present-day critical density.

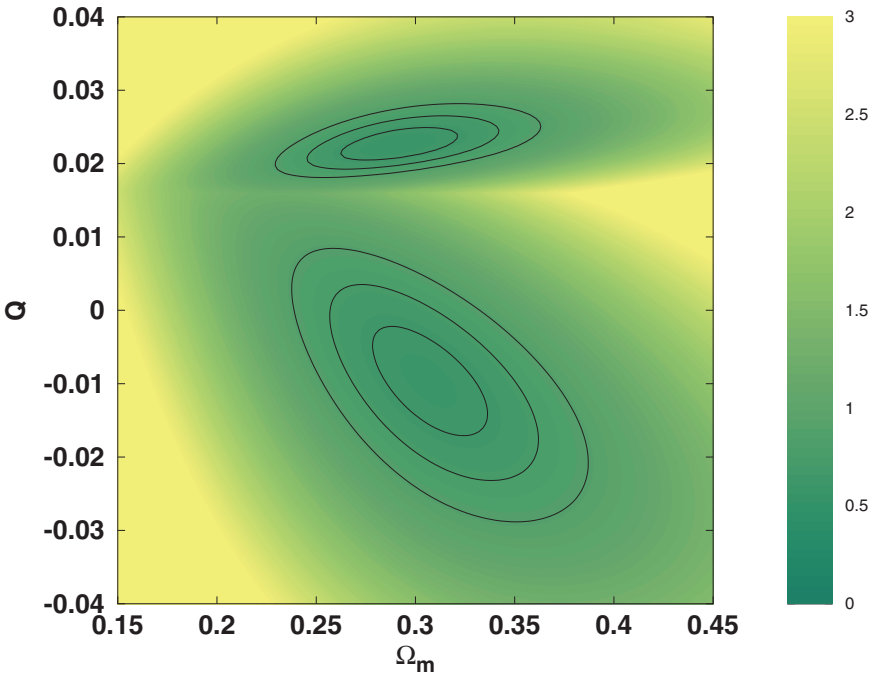

Fig. 2. Two-dimensional constraints on the $w = 0$ generalized coupling model. The $\Delta\chi^2 = 2.3$, $\Delta\chi^2 = 6.17$ and $\Delta\chi^2 = 11.8$ confidence levels are shown in black lines, and the color map depicts the reduced chi-square at each point in the parameter space, with points with $\chi^2_\nu > 3$ shown in yellow. Similar constraints can be found in Figure 3 of Ref. 12.

Since the model effectively has two types of vacuum energy, viz. the one generated by matter fields as well as the usual cosmological constant, one may wonder if the former is sufficient to yield an accelerating universe without invoking the latter. However, it is again simple to show that this can't be the case,[12] since in that case the minimum density would be $\Omega_m \sim 0.86$; clearly such high matter density universes would be incompatible with observations. Thus in what follows we treat this model as a phenomenological extension of ΛCDM, with the vacuum energy density of matter fields, Q, being an additional model parameter which we now constrain.

In the simpler case where the matter equation of state parameter has the standard value, $w = 0$, and agnostically allowing both positive and negative values of the model parameter Q, we find that while non-zero values of Q are preferred, the standard value is not significantly excluded, as shown in Fig. 2. We note the existence of two branches of the solution, one with $Q > 0$ and the other with $Q < 0$, with the former branch being slightly preferred. If we restrict the analysis to the

range $Q \leq 0$, the one-sigma constraints on the two model parameters are

$$\Omega_{m-} = 0.31 \pm 0.02 \tag{23}$$

$$Q_{-} = -0.010 \pm 0.006\,; \tag{24}$$

conversely, if we restrict the analysis to the range $Q \geq 0$ we find

$$\Omega_{m+} = 0.29 \pm 0.02 \tag{25}$$

$$Q_{+} = 0.023 \pm 0.003\,. \tag{26}$$

In all cases the reduced chi-square at the best fit is $\chi^2_\nu \sim 0.6$, so the model is clearly overfitting the data. All in all, there is no strong evidence for a non-zero Q.

In the general case, allowing the dark energy equation of state parameter w to become a further free parameter, one obtains the following one-sigma constraints on the parameters

$$\Omega_m = 0.29^{-0.09}_{+0.07} \tag{27}$$

$$Q = -0.018^{+0.005}_{-0.004} \tag{28}$$

$$w = -0.06^{+0.17}_{-0.08}\,. \tag{29}$$

The constraints on the matter density are now significantly weaker, but the two Q branches of the solution are still manifest, as are the degeneracies between the model parameters, as can be seen in Ref. 12. In this case the negative branch is also the preferred one. However, we should also point out that the matter equation of state parameter is already more tightly constrained than this (and this comment also applies to the above constraints on the torsion model). Recent analyses[15,16] constrain it, conservatively, to $|w| < 0.003$. Using this as a Gaussian prior and repeating the analysis, we recover the constraints on Q and Ω_m reported above for the $w = 0$ case, while the posterior for w itself simply recovers the prior.

5. Scale invariance: The specific Maeder model

Maeder's proposed scale invariant model[3] is a specific case of the scale-covariant theory of Canuto *et al.*[4,5] It is well known that the effects of scale invariance disappear upon the presence of matter; the assumption underlying scale invariant models is that at large (i.e., cosmological) scales empty space should still be scale invariant. This again leads to a bimetric theory, with a function λ (not to be confused with the parameters introduced in previous sections) playing the role of a scale transformation factor relating the ordinary matter frame to another frame which one assumes to still be scale invariant.

In this case, and with the further assumption of a flat homogeneous and isotropic universe, the Friedmann, Raychaudhuri, and continuity equations are[4,5]

$$\left(\frac{\dot{a}}{a}+\frac{\dot{\lambda}}{\lambda}\right)^2+\frac{k}{a^2}=\frac{1}{3}(\kappa\rho+\Lambda\lambda^2) \tag{30}$$

$$\frac{\ddot{a}}{a}+\frac{\ddot{\lambda}}{\lambda}+\frac{\dot{\lambda}}{\lambda}\frac{\dot{a}}{a}-\frac{\dot{\lambda}^2}{\lambda^2}=-\frac{\kappa}{6}(\rho+3p-2\Lambda\lambda^2) \tag{31}$$

$$\dot{\rho}+3(\rho+p)\frac{\dot{a}}{a}=-(\rho+3p)\frac{\dot{\lambda}}{\lambda}\,, \tag{32}$$

which match the standard equations if one chooses $\lambda = 1$. Note that for a homogeneous and isotropic model λ depends only on time, as does the scale factor.

The recent work of Maeder further postulates that the Minkowski metric is a solution of these Einstein equations, which leads to the following consistency conditions[3]

$$3\frac{\dot{\lambda}^2}{\lambda^2}=\Lambda\lambda^2 \tag{33}$$

$$2\frac{\ddot{\lambda}}{\lambda}-\frac{\dot{\lambda}^2}{\lambda^2}=\Lambda\lambda^2\,, \tag{34}$$

and further imply that

$$\lambda(t)=\sqrt{\frac{3}{\Lambda}}\,\frac{1}{t}\,. \tag{35}$$

We are again using $c = 1$, and constant equations of state, $p = w\rho$. Together with the solution for λ, the continuity equation yields

$$\rho\propto(1+z)^{3(1+w)}t^{1+3w}. \tag{36}$$

For a cosmological constant equation of state ($w = -1$) this becomes $\rho \propto t^{-2}$; in other words, this is effectively a model with a time-dependent cosmological constant, but no parametric ΛCDM limit. The author claims,[3] from a simple qualitative comparison, that with the choice $\Omega_m = 0.3$ the model is in good agreement with Hubble parameter data. In Ref. 12 this claim was assessed with a more thorough statistical analysis, and we summarize the results here.

With the aforementioned assumptions, the Friedmann equation for the Maeder model can be written

$$E^2(z,x)=\Omega_m(1+z)^{3(1+w)}x^{1+3w}+\frac{\Omega_\lambda}{x}E(z,x)\,, \tag{37}$$

where we have defined an effective parameter

$$\Omega_\lambda=\frac{2}{t_0H_0}\,, \tag{38}$$

which effectively quantifies the present age of the universe (in dimensionless units) and for convenience also introduced a dimensionless time $x = t/t_0$, with t_0 being

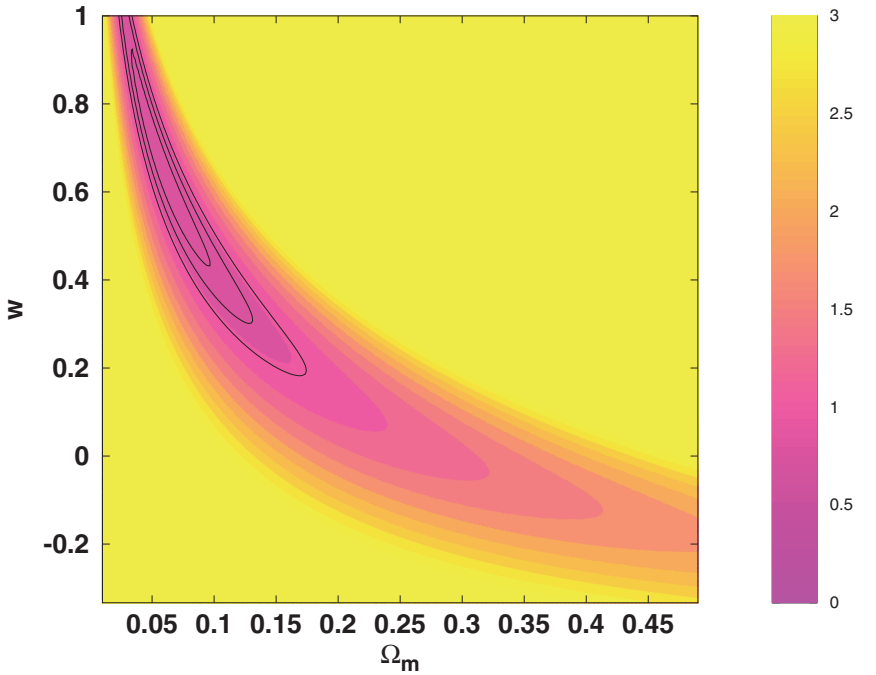

Fig. 3. Two-dimensional constraints on the Maeder model, with w as a free parameter. The black lines represent the one, two and three sigma confidence levels, and the color map depicts the reduced chi-square at each point in the parameter space, with points with $\chi^2_\nu > 3$ shown in yellow. Similar constraints can be found in Figure 6 of Ref. 12.

the current age of the universe. With these definitions the Friedmann equation can be re-written in the simpler form

$$E(z,x) = \frac{\Omega_\lambda}{2x}\left[1+\sqrt{1+M(z,x)}\right] \tag{39}$$

$$M(z,x) = \frac{4\Omega_m}{\Omega_\lambda^2}(1+z)^{3(1+w)}x^{3(1+w)}\,, \tag{40}$$

with the relation between redshift and (dimensionless) time being given by

$$\frac{dx}{dz} = -\frac{x}{1+z}\times\frac{1}{1+\sqrt{1+M(z,x)}} \tag{41}$$

and the initial condition $x = 1$ at $z = 0$.

In the $w = 0$ case we can write $\Omega_\lambda = 1 - \Omega_m$. and the one-sigma posterior constraint in the matter density is

$$\Omega_m = 0.26 \pm 0.02\,, \quad \chi^2_\nu = 1.3\,; \tag{42}$$

the inclusion of curvature as an additional parameter[12] slightly increases the preferred matter density but provides an equally poor fit. On the other hand, allowing

w as a further free parameter, one obtains the result shown in in Fig. 3. In this case the one sigma constraints are

$$\Omega_m = 0.06 \pm 0.02 \tag{43}$$

$$w = 0.60^{+0.16}_{-0.15}\,; \tag{44}$$

again the inclusion of curvature does not significantly change this.[12] In both cases the reduced chi-square is now $\chi^2_\nu = 0.8$, so the model is now slightly overfitting the data. Clearly there is a strong degeneracy between the matter density and the equation of state parameter (which are anticorrelated), and the best fit values of both parameters are very far from the standard ΛCDM ones.

6. Scale invariance: the general model

The previous section shows that the Maeder model is ruled out. One may therefore ask whether this conclusion extends to the more general model of Canute *et al.*, also introduced in the previous section. Here we present a very preliminary analysis of this issue. We will assume a generic power-law behaviour, $\lambda(t) \propto t^p$, choosing $\lambda_0 = 1$, and further assuming flat models[a]. This choice of λ also ensures that ΛCDM is recovered for $p = 0$.

Note that in the Maeder model there is no explicit cosmological constant Λ. In the general case it is still there, so we may again expect two classes of solutions. One has the usual Λ providing the acceleration, with the λ field providing a further contribution; in other words, this will be an extension of ΛCDM. The other has $\Lambda = 0$, meaning that the model will not have a ΛCDM limit, and the question is then whether the field λ can provide an alternative to acceleration in that case.

In this case the continuity equation gives

$$\rho \propto (1+z)^{3(1+w)} t^{-p(1+3w)}\,, \tag{45}$$

while the Friedmann equation gives

$$\left(E(z,x) + \frac{p}{2x}\Omega_\lambda\right)^2 = \Omega_m (1+z)^{3(1+w)} x^{-p(1+3w)} + \Omega_\Lambda x^{2p}\,. \tag{46}$$

For $p = -1$ the Maeder model is recovered with the further assumption that

$$\Omega_\Lambda = \frac{1}{4}\Omega_\lambda^2 = \frac{1}{(t_0 H_0)^2}\,. \tag{47}$$

In the general case the Friedmann equation can be re-written

$$E(z,x) = \frac{\Omega_\lambda}{2x}\left[-p + \sqrt{N(z,x)}\right] \tag{48}$$

$$N(z,x) = \frac{4}{\Omega_\lambda^2}\left[\Omega_m (1+z)^{3(1+w)} x^{2-p(1+3w)} + \Omega_\Lambda x^{2(1+p)}\right]\,, \tag{49}$$

[a] We will report on a more detailed analysis, relaxing some of these assumptions and exploring various scenarios, elsewhere.

and the relation between redshift and (dimensionless) time is now given by

$$\frac{dx}{dz} = -\frac{x}{1+z} \times \frac{1}{\sqrt{N(z,x) - p}}\,, \tag{50}$$

with the initial condition still being $x = 1$ at $z = 0$. One can easily check that the Maeder model equations are recovered in the appropriate limit. Note that Ω_λ is a dimensionless measure of the current age of the universe, and it must therefore be a positive quantity.

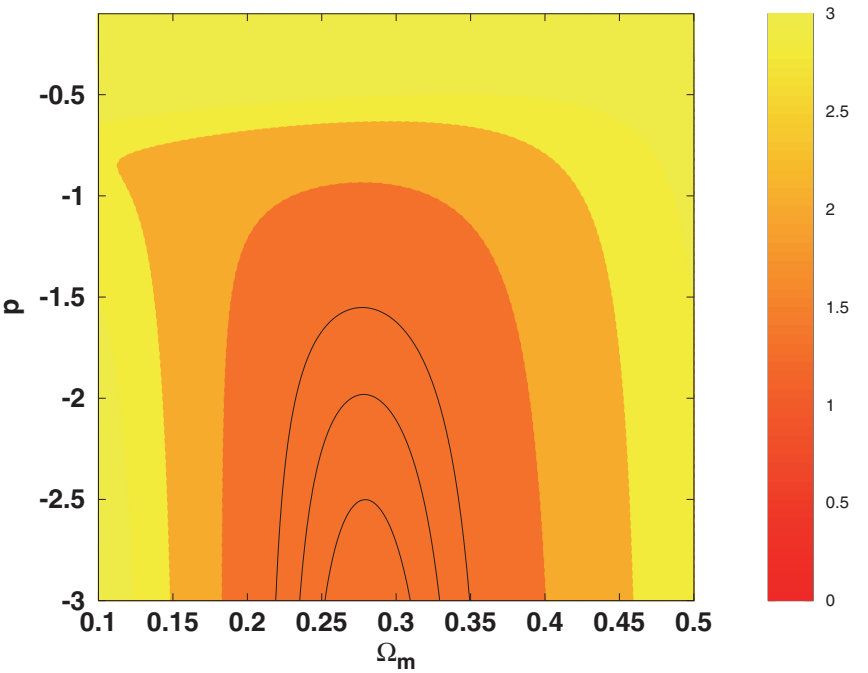

Fig. 4. Two-dimensional constraints on the Canuto *et al.* model, with $w = 0$ and $\Omega_\Lambda = 0$. The black lines represent the one, two and three sigma confidence levels, and the color map depicts the reduced chi-square at each point in the parameter space, with points with $\chi^2_\nu > 3$ shown in yellow.

Several different scenarios can now be considered. In what follows we only consider the simplest one. If we assume that $\Omega_\Lambda = 0$ and ordinary matter with an $w = 0$ equation of state we have two free parameters (Ω_m, p) and

$$-p\Omega_\lambda = 2(1 - \sqrt{\Omega_m})\,; \tag{51}$$

thus $p = 0$ corresponds to an $\Omega_m = 1$ universe, In this case we again find that this model does not provide a good fit to the data, cf. Fig. 4: while a matter density of around $\Omega_m \sim 0.28$ is preferred, the reduced chi-square of the best fit is quite poor,

being always larger than $\chi^2_\nu = 1.25$. An exploration of the wider parameter space, allowing for a cosmological constant, a non-zero equation of state, and curvature, will be reported elsewhere.

7. Outlook

We have briefly presented a comparison of three classes of models for the low-redshift acceleration of the universe against background low-redshift cosmological observations, further using the traditional CPL phenomenological parameterization as a benchmark. Each of these models contains, in principle, an additional mechanism, in addition to the cosmological constant, that could account for the recent acceleration of the universe.

We find that the steady-state torsion and generalized couplings have similar behaviours. The specific physical mechanism therein are ruled out as unique source of acceleration, but small (e.g. percent level) deviations from ΛCDM are still allowed by the data that we have considered. Constraints can of course be tightened by including further data. The scale invariant model provides an interesting contrast. Assuming the standard equation of state parameter, $w = 0$, the best-fit value is similar to the CPL one. However, these fits have a poor (specifically, high) reduced chi-square, indicating that the model does not provide a good fit to the data. An observationally viable model of this kind would require a highly non-standard 'matter' density (including a non-standard equation of state), which would conflict with other cosmological datasets. In passing, we also mention that another interesting phenomenological class is that of energy-momentum-powered models recently constrained in Ref. 17 and also discussed elsewhere in these proceedings.

Overall, we therefore conclude that ΛCDM is a remarkably robust paradigm. While it is clearly a phenomenological approximation to a still unknown more fundamental model, it is clearly a good one, and any plausible alternative model must be able to closely reproduce its behaviour in a broad range of cosmological settings.

Model-independent test of scalar-tensor gravity theory by reconstructing scalar mode of GW170817

Yuya Gushima* and Kazuhiro Hayama†

Department of Applied Physics, Fukuoka University, Fukuoka, 814-0180, Japan

† E-mail: hayama@fukuoka-u.ac.jp

Einstein's general relativity predicts that a gravitational wave is allowed to have two polarizations called tensor-modes: plus and cross modes. On the other hand, the general metric theory of gravity predicts that a gravitational wave is allowed to have up to six polarizations: two scalar and two vector modes in addition to the tensor-modes. In case the number of laser-interferometric gravitational wave telescopes is larger than the one of the polarizations the gravitational waves have, all the polarizations can be reconstructed separately. Since it depends on theories of gravity which polarizations the gravitational waves have, the investigation of polarizations is important for the test of theories of gravity. In this paper, in order to test the scalar-tensor gravity theory, one of important alternative theories of gravity, we search for the scalar-mode of GW170817 observed by LIGO Livingstone, Hanford and Virgo without prior information about any tensor-scalar gravity theories. As a result, we found the maximum SNR of the scalar-mode of GW170817 was 2.77, the p-value was 0.01, and the band-limited root sum square of h was $1.55 \times 10^{-21}[1/\sqrt{Hz}]$ with the time window of 2[s] and frequency window of 60∼120[Hz].

Keywords: Gravitational wave; polarization; scalar-mode; test of gravity theory; GW170817.

1. Introduction

Since the gravitational wave (GW) was observed in 2015, many gravitational waves have been detected.[1] The observation of GWs will provide an opportunity to unveil the mystery of the early universe,[2] black holes[1] and dark matter. Einstein's general relativity predicts that a GW is allowed to have two polarization modes, plus mode and cross mode, which are called tensor modes. On the other hand, the general metric theory of gravity predicts that a gravitational wave is allowed to have up to six polarizations, two scalar and two vector modes in addition to the tensor modes.[3,4] This suggests, if either the scalar or the vector modes are found, it is necessary to modify the general relativity.

E. Hubble observed that the universe was expanding,[5] and George Gamow proposed the big bang cosmology.[6] However, the proposed theory could not explain the flatness problem and the horizon problem. Inflation universe theories were proposed to solve these problems.[7] Direct evidence of inflation has not been found yet, but if inflation theories are correct, a scalar field may be necessary for inflation to occur.

Instead of the general relativity, the general metric theory of gravity has been proposed, and the theory of gravity has been tested using the GWs detected so far.[8,9] Among the proposed theories of gravity, the scalar-tensor gravity theory predicts the gravitation is given through not only the tensor field but also by the scalar field. It is possible to reconstruct the tensor and scalar modes from GW observations when the GW is observed by three or more laser-interferometric gravitational wave telescopes and the direction to the GW is known.[10] In this paper, in order to test the scalar-tensor gravity theory, we search for a scalar mode of GW170817[11] observed by LIGO-Livingston, LIGO-Hanford[12] and Virgo.[13] The direction to GW170817 is known by the multi-messenger observation.[14] Normally, when exploring GWs, the correlation between the predicted waveform and the observed data is examined, which is called the matched filter method. For this purpose, we must assume a specific theory model. In this paper, we take a different way to test the gravity theories. We reconstruct the polarizations without any prior information about waveform. Since our method of reconstruction does not rely on any specific gravity theory, it is possible to test theory of gravity with high generality. In Sec. 2, we describe how reconstruct each polarization. In Sec. 3, we show the analysis result. Section 4 is devoted to the summary of this paper.

2. Reconstruction of polarization modes

2.1. *Polarization modes of a gravitational wave*

The GW propagating in the z direction, the bases of the six polarizations are defined by following tensors in which time, x, y, z component from the left to the right or the top to the bottom,

$$
\begin{aligned}
e^{+}_{ij} &= \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \qquad e^{\times}_{ij} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \\
e^{b}_{ij} &= \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \qquad e^{l}_{ij} = \sqrt{2} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \\
e^{x}_{ij} &= \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix}, \qquad e^{y}_{ij} = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix},
\end{aligned}
\tag{1}
$$

where $+, \times, b, l, x$ and y denote plus, cross, breathing, longitudinal, vector-x, vector-y modes. Figure 1 shows that how each polarization affects test masses placed in

a circle. Using Eq. (1) and amplitude of each polarization $h_\alpha(\alpha = +, \times, b, l, x, y)$, the GW h_{ij} is given by

$$h_{ij} = h_+ e^+_{ij} + h_\times e^\times_{ij} + h_b e^b_{ij} + h_l e^l_{ij} + h_x e^x_{ij} + h_y e^y_{ij}. \tag{2}$$

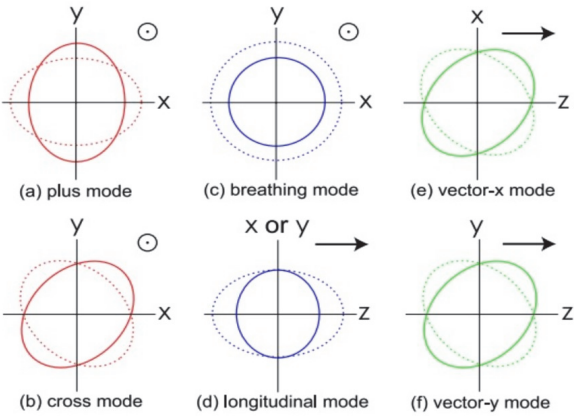

Fig. 1. Six gravitational wave polarizations in a general metric theory of gravity.[15]

2.2. *Antenna pattern function*

Suppose that a normal orthogonal system $(\hat{\mathbf{u}}, \hat{\mathbf{v}}, \hat{\mathbf{w}})$ in which the unit vector $\hat{\mathbf{u}}, \hat{\mathbf{v}}$ are directed to each detector arm. The coordination systems $(\hat{\mathbf{m}}, \hat{\mathbf{n}}, \hat{\mathbf{\Omega}})$ are given by the rotation angle(θ, ϕ, ψ) (Fig. 2). $\hat{\mathbf{\Omega}}$ is unit vector directed the direction to the GW, and the angle ψ around the $\hat{\mathbf{\Omega}}$ is an arbitrary angle. Using vector $\hat{\mathbf{m}}, \hat{\mathbf{n}}, \hat{\mathbf{\Omega}}$, the

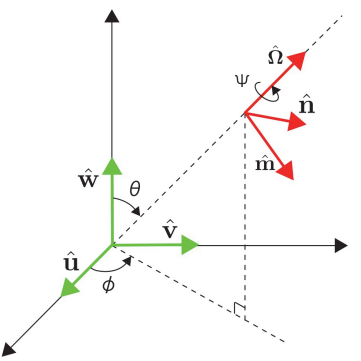

Fig. 2. Coordinate systems.[15]

polarization tensors are given by

$$\begin{aligned} \tilde{\mathbf{e}}_+ &= \hat{\mathbf{m}} \otimes \hat{\mathbf{m}} - \hat{\mathbf{n}} \otimes \hat{\mathbf{n}}, & \tilde{\mathbf{e}}_\times &= \hat{\mathbf{m}} \otimes \hat{\mathbf{n}} + \hat{\mathbf{n}} \otimes \hat{\mathbf{m}} \\ \tilde{\mathbf{e}}_b &= \hat{\mathbf{m}} \otimes \hat{\mathbf{m}} + \hat{\mathbf{n}} \otimes \hat{\mathbf{n}}, & \tilde{\mathbf{e}}_l &= \sqrt{2}\hat{\mathbf{\Omega}} \otimes \hat{\mathbf{\Omega}} \\ \tilde{\mathbf{e}}_x &= \hat{\mathbf{m}} \otimes \hat{\mathbf{\Omega}} + \hat{\mathbf{\Omega}} \otimes \hat{\mathbf{m}}, & \tilde{\mathbf{e}}_y &= \hat{\mathbf{n}} \otimes \hat{\mathbf{\Omega}} + \hat{\mathbf{\Omega}} \otimes \hat{\mathbf{n}} \end{aligned} \tag{3}$$

where the symbol $\otimes$ denotes a tensor product. The antenna pattern function $F_\alpha(\alpha = +, \times, b, l, x, y)$ of a detector is defined as

$$F_\alpha(\hat{\mathbf{\Omega}}) = \mathbf{D} : \tilde{\mathbf{e}}_\alpha(\hat{\mathbf{\Omega}}), \tag{4}$$

where the symbol : denotes contraction between tensors. $\mathbf{D}$ is a detector tensor and defined as

$$\mathbf{D} = \frac{1}{2}[\hat{\mathbf{u}} \otimes \hat{\mathbf{u}} - \hat{\mathbf{v}} \otimes \hat{\mathbf{v}}]. \tag{5}$$

The antenna pattern function depends on the position of detectors and the direction to the GW.

2.3. *Coherent network analysis*

Data from i-th detector are

$$x_i = h_i + \eta_i, \tag{6}$$

where h_i are the i-th detector response to the GW and η_i are the i-th detector noise. h_i is written as

$$h_i = F_{i+} h_+ + F_{i\times} h_\times + F_{is} h_s, \tag{7}$$

where $F_{i\alpha}(\alpha = +, \times, s)$ is the antenna pattern function of i-th detector. Here s denotes a scalar-mode. h_α are the amplitude of each polarization. As the antenna pattern function of the breathing-mode and the longitudinal-mode are degenerated, we can't decompose these scalar modes. In this paper, we suppose that the GW has two tensor modes and one scalar mode and the amplitude of vector modes is small enough to be ignored. If there are three detectors, from Eq. (6,7)

$$\begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} F_{1+} & F_{1\times} & F_{1s} \\ F_{2+} & F_{2\times} & F_{2s} \\ F_{3+} & F_{3\times} & F_{3s} \end{bmatrix} \begin{bmatrix} h_+ \\ h_\times \\ h_s \end{bmatrix} + \begin{bmatrix} \eta_1 \\ \eta_2 \\ \eta_3 \end{bmatrix}. \tag{8}$$

Equation (8) is written in a matrix as

$$\boldsymbol{x} = \boldsymbol{F}\boldsymbol{h} + \boldsymbol{\eta}. \tag{9}$$

$\boldsymbol{F}$ is not a square matrix and doesn't have its inverse matrix in general. But if we use Moore-Penrose pseudo-inverse matrix we can reconstruct each polarization. We consider the reconstruction without noise for simplicity. Multiplying Eq. (9) by transpose matrix $\boldsymbol{F^T}$, we get

$$\boldsymbol{F^T F h} = \boldsymbol{F^T x}. \tag{10}$$

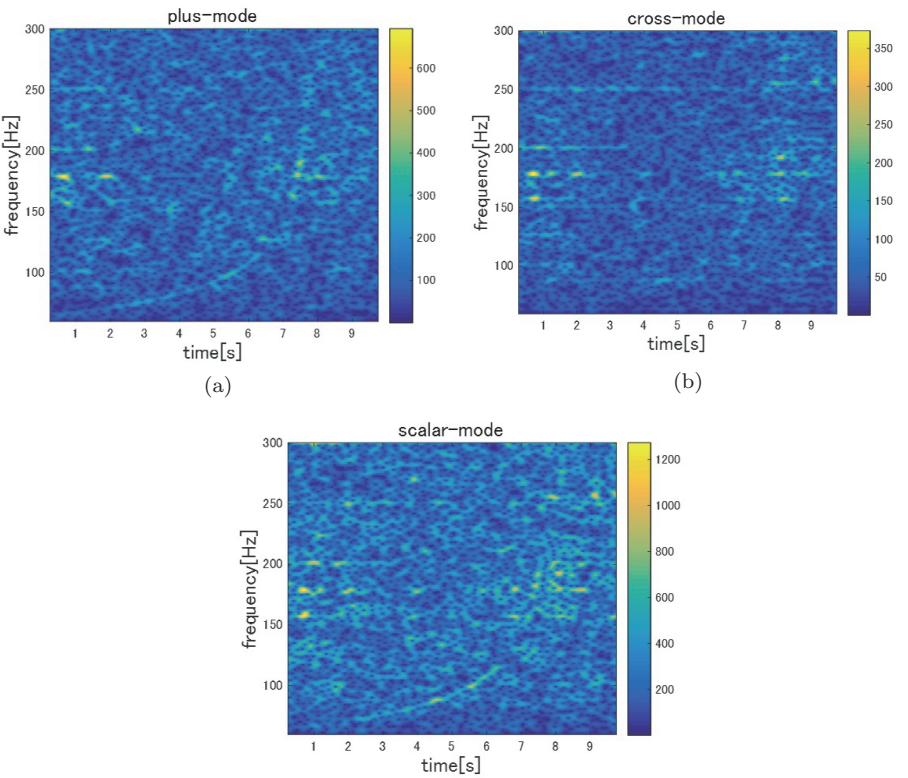
Since $\boldsymbol{F^T F}$ is a square matrix, we can find the inverse matrix. We finally get

$$\boldsymbol{h} = \boldsymbol{M^{-1} F^T x}, \qquad \boldsymbol{M} := \boldsymbol{F^T F}, \tag{11}$$

where $\boldsymbol{M^{-1} F^T}$ is the Moore-Penrose pseudo-inverse matrix.

3. Analysis method and results

Figure 3 shows spectrograms of three modes(plus, cross and scalar) reconstructed from GW170817.



(a) (b) (c)

Fig. 3. Spectrograms of the reconstructed plus-mode (a), cross-mode (b) and scalar-mode (c). The horizontal axis is time[s] since GPS time 1187008874[s]. The vertical axis is frequency [Hz].

Next, we describe the statistical evaluation method.

(1) Divide the data into 2, 3.5 or 5[s], and divide the frequency band of the data into 60[Hz] each from 60[Hz] to 300[Hz]. Figure 4 is the spectrogram on which red and black lines are drawn. The black lines are drawn at every 60[Hz] from 60[Hz]. The red lines are drawn at every 2[s] from 0[s].

(2) In each region, calculate the power of signal p, and create a histogram.

$$p = \Sigma {h_s}^2, \tag{12}$$

where h_s is the reconstructed scalar mode. Figure 5 is a histogram of the reconstructed scalar mode. The data used is divided into 2[s] and the frequency band is limited in 60∼120[Hz].

(3) Assuming that the probability distribution of p follows a normal distribution, find the mean μ and standard deviation σ from the distribution.

(4) Calculate the P-value and the signal-to-noise ratio(SNR).

$$\text{P-value} = \frac{n}{N}, \tag{13}$$

$$SNR = \frac{p_{gw} - \mu}{\sigma}, \tag{14}$$

where p_{GW} is the p in the region where GW170817 is in, n is the number of the p larger than p_{GW} and N is the total number of the p.

(5) Calculate the band limited root sum square of h_{rss} in the time-frequency domain with the highest SNR. The band limited root sum square of h, h_{rss}^{BL}, which we defined as follows

$$h_{rss}^{BL} = \sqrt{\sum_{t=t_1}^{t_2} \sum_{f=f_1}^{f_2} h_s(t,f)^2 dt}. \tag{15}$$

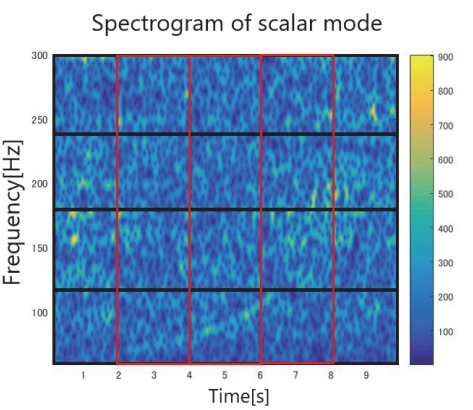


Fig. 4. Spectrogram of the reconstructed scalar-mode. The black lines are drawn at every 60[Hz] from 60[Hz]. The red lines are drawn at every 2[s] from 0[s].

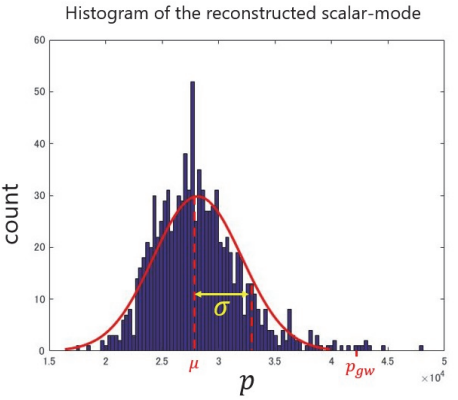

Fig. 5. Histogram of the reconstructed scalar-mode. The data used is divided into the 2[s] and the frequency band is limited in 60∼120[Hz]. μ is the mean value and σ is standard deviation of the p. p_{gw} is the p in the region where GW170817 is contained. n is the number of the p larger than p_{GW}.

Table 1. SNRs and P-values. The data used is divided into 2[s] and the frequency band is limited in 60∼120[Hz], 120∼180[Hz], 180∼240[Hz] and 240∼300[Hz].

frequency[Hz]	time[s]	2∼4	4∼6	6∼8
60∼120	P-value	0.13	0.01	0.60
	SNR	1.07	2.77	-0.308
120∼180	P-value	0.40	0.06	0.09
	SNR	0.0150	-0.453	1.39
180∼240	P-value	0.87	0.94	0.06
	SNR	-1.01	-1.33	1.59
240∼300	P-value	0.62	0.85	0.40
	SNR	-0.477	-0.897	0.0198

Figures 6, 7, 8, 9 shows spectrograms of the reconstructed scalar modes, and Tables 1, 2, 3 shows the SNRs and the P-values. In the Figs. 6, 7, 8, 9, the black lines are drawn at every 60[Hz] from 60[Hz], and the red lines are starting GPS time 1187008878∼1187008880[s], 1187008877∼1187008880.5[s], 1187008878∼1187008881.5[s], 1187008876∼1187008881[s], respectively.

The largest SNR was 2.77 with the time window of 2[s]. The P-value of the corresponding time-frequency region was 0.01. In the Fig. 6, the yellow frame is the region with the largest SNR. In case of the time window of 3.5[s], there are two regions where the SNR is larger than 2. The largest SNR was 2.54 with the time window of 3.5[s]. The P-value of the corresponding time-frequency region was 0.01. In the Fig. 7, the yellow frame is the region with the largest SNR. Also, The second

Table 3. SNRs and P-values. The data used is divided into 5[s] and the frequency band is limited in 60∼120[Hz], 120∼180[Hz], 180∼240[Hz] and 240∼300[Hz].

frequency[Hz]	time[s]	2∼7	3∼8
60∼120	P-value	0.02	0.06
	SNR	2.38	1.61
120∼180	P-value	0.44	0.27
	SNR	-0.0251	0.44
180∼240	P-value	0.96	0.58
	SNR	-1.50	-0.239
240∼300	P-value	0.81	0.71
	SNR	-0.860	-0.658

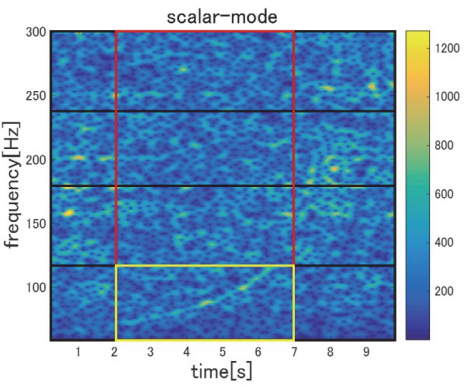

Fig. 9. Spectrogram of the reconstructed scalar-mode. The yellow frame is the region with highest SNR larger than 2.

largest SNR was 2.10. The P-value of the corresponding time-frequency region was 0.03. In the Fig. 8, the orange frame is the region with the second largest SNR. In case of the time window of 5[s], there is one region where the SNR is larger than 2. The largest SNR was 2.38 with the time window of 5[s]. The P-value of the corresponding time-frequency region was 0.02. In the Fig. 9, the yellow frame is the region with the largest SNR. Additionally, the h_{rss}^{BL} in the region with the maximum SNR was $1.55 \times 10^{-21}[1/\sqrt{Hz}]$.

4. Summary

We performed the model-independent test of the scalar-tensor gravity theory using GW170817 by reconstructing the tensor and scalar modes without any information about the waveform. We found the maximum SNR was 2.77 with the time window of 2[s] and the frequency band of 60∼120[Hz]. The P-value of the corresponding time-frequency region was 0.01, and the h_{rss}^{BL} of the same region was $1.55 \times 10^{-21}[1/\sqrt{Hz}]$. The SNR was small compared to threshold value of the GW detection by the matched filter analysis in recent years. In order to claim the detection of the scalar-mode, it is necessary to further increase the sensitivity of GW telescope and/or detect larger GWs. There are some future issues. First, we need evaluate the error that occurs in the process of the waveform reconstruction. Next, the method of reconstruction needs to be optimal for the scalar-mode. Our recent studies have shown that different locations have different amounts of leakage from the tensor mode. Therefore, by investigating it in detail, it will be possible to test the scalar-tensor gravity theory with high generality.

We apply cosmological reconstruction methods to the $f(R,T)$ modified gravity, in its recently developed scalar-tensor representation. We do this analysis assuming a perfect fluid in a Friedmann-Lemaître-Robsertson-Walker (FLRW) universe. In this contribution we show the equations of motion obtained and we present the solutions found for one of the particular cases we analysed: an exponential evolution of the cosmological scale factor.

Keywords: Cosmology; modified gravity; scalar-tensor theories; accelerated expansion.

1. Introduction

The late-time universe is observed to be expanding in an accelerated way.[1,2] This behaviour can be modelled by introducing a dark energy component, often identified as a cosmological constant. However, we still lack the understanding for the dark energy mechanism at the fundamental level. Alternatively, it is possible to explain the accelerated expansion by modifying the theory of gravity. Many such modifications have been proposed to extend Einstein's General Relativity (GR) (e.g. see Refs. 3–9). For instance, one can modify the gravitational Lagrangian, which depends linearly on the Ricci curvature scalar R, to instead depend on a *general function* of R – thus, referred to as $f(R)$ gravity.[10] Resulting in modified Friedmann equations, $f(R)$ gravity can allow for the accelerated expansion without the need for dark energy.[11]

It is natural, then, to explore further extensions, such as $f(R,T)$ gravity[12] where the action depends on a general function of the curvature scalar R *and* of the trace of the stress-energy tensor T. Because of this explicit coupling between curvature and matter, the stress-energy tensor is not necessarily conserved, allowing the

appearance of a fifth force. Since its proposal, the $f(R,T)$ gravity has sparked a lot of interest leading, in some cases, to the study of its cosmological applications (e.g. see Refs. 13–19).

Recently, the original geometrical representation of the $f(R,T)$ gravity was reformulated into an equivalent scalar-tensor representation,[20] where the two extra degrees of freedom of the theory are expressed by means of two scalar fields. So far, this scalar-tensor theory was used to find thin shells' junction conditions[20] and thick brane solutions.[21] Since in scalar-tensor theories it is often easier to find analytical solutions, it calls for further study also of cosmological models in this representation of the $f(R,T)$ gravity. This study is undertaken in our work, modelling a Friedmann-Lemaître-Robsertson-Walker (FLRW) universe. We used reconstruction methods,[13–15,23,24] whereby the function $f(R,T)$ is not defined *a priori*, and instead we start from known cosmological solutions such as the time evolution of the spatial scale factor which seem to model well the observations. Here we give simply a preview of this work and some of its preliminary results. A more complete analysis is being incorporated into a paper under preparation.

2. The theory of the $f(R,T)$ gravity

We first introduce briefly the theory of $f(R,T)$ gravity, showing the main equations without detailing all of the steps. For further details we point to the main references. In its original geometrical formulation (see Ref. 12), the action of the $f(R,T)$ gravity is

$$S = \frac{1}{2\kappa^2}\int \sqrt{-g}\, f(R,T) d^4x + \int \sqrt{-g}\, \mathcal{L}_m d^4x, \tag{1}$$

where $\kappa^2 = 8\pi G/c^4$, G is the gravitational constant and c is the speed of light, g is the determinant of the metric $g_{\mu\nu}$, $f\,(R,T)$ is an arbitrary well-behaved function of the Ricci curvature scalar R and the trace of the stress-energy tensor T, and $\mathcal{L}_m$ is the matter Lagrangian. More explicitly, $R = g^{\mu\nu}R_{\mu\nu}$, where $R_{\mu\nu}$ is the Ricci tensor, and $T = g^{\mu\nu}T_{\mu\nu}$, where the stress-energy tensor $T_{\mu\nu}$ is defined in terms of the variation of the matter Lagrangian $\mathcal{L}_m$ as

$$T_{\mu\nu} = -\frac{2}{\sqrt{-g}}\frac{\delta\left(\sqrt{-g}\mathcal{L}_m\right)}{\delta g^{\mu\nu}}. \tag{2}$$

When reformulating into the dynamically equivalent scalar tensor representation (see Ref. 20 for further details), one defines two scalar fields

$$\varphi \equiv \frac{\partial f}{\partial R}, \qquad \psi \equiv \frac{\partial f}{\partial T}, \tag{3}$$

with the associated potential

$$V(\varphi,\psi) \equiv -f(R,T) + \varphi R + \psi T. \tag{4}$$

With these definitions, the action (1) can equivalently be written as

$$S = \frac{1}{2\kappa^2}\int_\Omega \sqrt{-g}\left[\varphi R + \psi T - V(\varphi,\psi)\right] d^4x + \int_\Omega \sqrt{-g}\mathcal{L}_m d^4x. \tag{5}$$

The variation of this action with respect to the metric $g_{\mu\nu}$ yields the modified field equations

$$\varphi R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} \left(\varphi R + \psi T - V\right) - \left(\nabla_\mu \nabla_\nu - g_{\mu\nu} \Box\right) \varphi = \kappa^2 T_{\mu\nu} - \psi (T_{\mu\nu} + \Theta_{\mu\nu}), \quad (6)$$

where ∇_μ is the covariant derivative and $\Box \equiv \nabla^\sigma \nabla_\sigma$ is the D'Alembert operator, both defined in terms of the metric $g_{\mu\nu}$, and the tensor $\Theta_{\mu\nu}$ is defined as

$$\Theta_{\mu\nu} \equiv g^{\rho\sigma} \frac{\delta T_{\rho\sigma}}{\delta g^{\mu\nu}}. \quad (7)$$

On the other hand, the variation of the action (5) with respect to the scalar fields φ and ψ gives, respectively,

$$V_\varphi = R, \quad (8)$$

$$V_\psi = T, \quad (9)$$

where the subscripts in V_φ and V_ψ denote the partial derivatives of the potential $V(\varphi, \psi)$ with respect to the variables φ and ψ, respectively.

A general conservation equation can be found by taking the divergence of Eq. (6),

$$(\kappa^2 - \psi) \nabla^\mu T_{\mu\nu} = \left(T_{\mu\nu} + \Theta_{\mu\nu}\right) \nabla^\mu \psi + \psi \nabla^\mu \Theta_{\mu\nu} - \frac{1}{2} g_{\mu\nu} \left[R \nabla^\mu \varphi + \nabla^\mu \left(\psi T - V\right)\right]. \quad (10)$$

Even though it is not a requirement of the theory, in this work we will impose the conservation of the stress-energy tensor, i.e. $\nabla^\mu T_{\mu\nu} = 0$, a condition that is automatically assured in GR. As detailed in the following section, for our cosmological model we use a FLRW metric and a perfect fluid approach in order to find the modified equations of motion.

In the following, we adopt a system of geometrized units in such a way that $G = c = 1$, and thus $\kappa^2 = 8\pi$.

3. Cosmology in the scalar-tensor representation

3.1. *Assumptions and equations of motion*

Let us first state the assumptions of our cosmological model with which we derived the equations of motion that are the focus of our study. We take the metric to be of the FLRW form, i.e., in spherical coordinates (t, r, θ, ϕ),

$$ds^2 = -dt^2 + a^2(t) \left[\frac{dr^2}{1 - kr^2} + r^2 \left(d\theta^2 + \sin^2 \theta d\phi^2\right)\right], \quad (11)$$

where $a(t)$ is the scale factor and k is the curvature parameter which can take the values $k = \{-1, 0, 1\}$ corresponding to a hyperbolic, spatially flat, or hyperspherical universe, respectively.

We assume the stress-energy tensor $T_{\mu\nu}$ to be well described by that of an isotropic perfect fluid,

$$T_{\mu\nu} = (\rho + p)u_\mu u_\nu + p g_{\mu\nu}, \tag{12}$$

where ρ is the energy density, p is the isotropic pressure, and u^μ is the fluid 4-velocity satisfying the normalization condition $u_\mu u^\mu = -1$. We take the matter Lagrangian to be $\mathcal{L}_m = p$.[22] Under these considerations, the tensor $\Theta_{\mu\nu}$ takes the form

$$\Theta_{\mu\nu} = -2T_{\mu\nu} + p g_{\mu\nu}. \tag{13}$$

With these assumptions, and with all physical quantities depending only on the time coordinate t (which guarantees the homogeneity and isotropy of the solutions $\rho(t)$, $p(t)$, $\varphi(t)$, $\psi(t)$, etc.), the following equations of motion were obtained. From the two independent components of Eq. (6), we obtained the modified Friedmann equation and the modified Raychaudhuri equation,

$$\dot{\varphi}\left(\frac{\dot{a}}{a}\right) + \varphi\left(\frac{\dot{a}^2 + k}{a^2}\right) = \frac{8\pi}{3}\rho + \frac{\psi}{2}\left(\rho - \frac{1}{3}p\right) + \frac{1}{6}V, \tag{14}$$

$$\ddot{\varphi} + 2\dot{\varphi}\left(\frac{\dot{a}}{a}\right) + \varphi\left(\frac{2\ddot{a}}{a} + \frac{\dot{a}^2 + k}{a^2}\right) = -8\pi p + \frac{\psi}{2}(\rho - 3p) + \frac{1}{2}V, \tag{15}$$

respectively, where overdots denote derivatives with respect to time. From Eqs. (8) and (9) we obtained

$$V_\varphi = 6\left(\frac{\ddot{a}}{a} + \frac{\dot{a}^2 + k}{a^2}\right), \tag{16}$$

$$V_\psi = 3p - \rho, \tag{17}$$

respectively. By our choice, we imposed $\nabla_\mu T^{\mu\nu} = 0$ that leads to the usual continuity equation,

$$\dot{\rho} = -3\frac{\dot{a}}{a}(\rho + p). \tag{18}$$

Consequently, from the general conservation equation (Eq. (10)) we obtained

$$2\dot{\psi}(\rho + p) = -\psi(\dot{\rho} - \dot{p}). \tag{19}$$

Finally, we impose an equation of state of the form

$$p = w\rho, \tag{20}$$

where w is a dimensionless parameter.

These equations of motion are the framework with which we searched for cosmological solutions in the $f(R,T)$ gravity. There is a redundancy in the equations obtained, since they are not all linearly independent, and one can be discarded without loss of generality. We chose to work with Eqs. (14), (16), (17), (18), (19), and (20) which form a system of six independent equations. This system is still

underdetermined since we have nine degrees of freedom: a, k, w, ρ, p, φ, ψ and V which contributes with two degrees of freedom (because it is a function of two variables, φ and ψ). In a first instance, we solved as much as it was possible without further constraining the system, obtaining some general solutions for $\rho(t)$, $p(t)$, $\psi(t)$, and the $V(\varphi, \psi)$ dependence on ψ. Only subsequently, did we provide further constraints to close the system and analyse particular cases.

3.2. *General solutions*

Taking the system of equations we have derived, Eqs. (14), (16), (17), (18), (19), and (20), we first found some general results. Beginning in a similar way that we would in GR, we used the equation of state (20) in the continuity equation (18) to find the general forms of the energy density and pressure as a function of a,

$$\rho = \rho_0 \left(\frac{a}{a_0}\right)^{-3(1+w)}, \tag{21}$$

$$p = w\rho_0 \left(\frac{a}{a_0}\right)^{-3(1+w)}, \tag{22}$$

respectively, where ρ_0 and a_0 are arbitrary constants from integration, and usually the subscript 0 denotes the value of the quantity today, at $t = t_0$. These solutions are identical to those in GR. This is only so because we required $\nabla_\mu T^{\mu\nu} = 0$ which, again, does not have to be generally true in modified gravity. Yet, it seems sensible to assume the validity of the continuity equation, at least on a first analysis.

Equipped with the results in Eqs. (21) and (22), we then solved Eq. (19) by integration and obtained

$$\psi = \psi_0 \left(\frac{a}{a_0}\right)^{\frac{3}{2}(1-w)}, \tag{23}$$

where ψ_0 is an integration constant. At this point, we were able to make the following considerations. The partial derivative V_ψ in Eq. (17) depends on ρ and p. We have the forms of $\rho(a)$ and $p(a)$ in Eqs. (21) and (22), and we can find a function $a(\psi)$ by inverting Eq. (23) (which we can do for $w \neq 1$, so, in what follows we will not be considering stiff matter). Thus, we combined these results to write the partial derivative V_ψ in Eq. (17) as depending only on ψ. We integrated the partial derivative to obtain a separable potential $V(\varphi, \psi) = V_0 + V_1(\varphi) + V_2(\psi)$, where V_0 is an arbitrary constant, $V_1(\varphi)$ is an arbitrary function of φ, and $V_2(\psi)$ is a function of ψ given by

$$V_2(\psi) = \frac{(1-3w)(1-w)}{(1+3w)} \rho_0 \psi_0^{\frac{2(1+w)}{(1-w)}} \psi^{-\frac{(1+3w)}{(1-w)}}, \tag{24}$$

which is undefined when $w = \{-1/3, 1\}$ and vanishes when $w = 1/3$ (corresponding to the case when the stress-energy tensor is traceless $T = 0$, such as for radiation).

This is as far as we were able to go without imposing further constraints. Up to this point, from the system of equations we are considering we have already used Eqs. (17), (18), (19), and (20), so we have only Eqs. (14) and (16) remaining . In balance, there are still five degrees of freedom at the moment: a, k, w, φ and $V_1(\varphi)$. Hence, we have to impose three further constraints in order to fully determine the system. We note that, as it stands, making a choice of the curvature and equation of state parameters, k and w, is not sufficient to determine the evolution of the universe modelled by $a(t)$. This is in contrast with GR where to each equation of state corresponds a unique evolution of the scale factor $a(t)$. Therefore, in this work we took the approach of first specifying the form of the scale factor, and then explored the parameter space of k and w in each particular case. The forms of the scale factor we chose are those known to model well different epochs of the universe: $a(t)$ given by an exponential or by a power law. By way of example, we present here only the particular case with an exponential scale factor, which can model the accelerated expansion observed in the present era.

3.3. *The particular case of an exponential expansion*

The universe is seen to be undergoing a phase of accelerated expansion. So, one of the particular cases we analysed was the de-Sitter solution that one obtains in GR, i.e., we impose in our system of equations an exponentially evolving scale factor of the form

$$a(t) = a_0 e^{\sqrt{\Lambda}(t-t_0)}, \tag{25}$$

where a_0, t_0 and Λ are constants. Once again, this particular choice does not require a unique value of w in $f(R,T)$ gravity and the solutions for ρ and ψ from Eqs. (21) and (23) become

$$\rho(t) = \rho_0 e^{-3\sqrt{\Lambda}(t-t_0)(1+w)}, \tag{26}$$

$$\psi(t) = \psi_0 e^{\frac{3}{2}\sqrt{\Lambda}(t-t_0)(1-w)}, \tag{27}$$

respectively. The pressure is simply given by $p\,(t) = w\rho\,(t)$.

To make further progress in order to find analytical solutions for $\varphi(t)$ and $V_1(\varphi)$, we set $k = 0$ (flat geometry) and left w arbitrary. With this choice of the curvature parameter and with the scale factor given by Eq. (25) the computation of Eq. (16) yields simply $V_\varphi = 12\Lambda$. Given that this is equivalent to having $dV_1/d\varphi = 12\Lambda$, we integrated it to obtain $V_1\,(\varphi) = 12\Lambda\varphi$. By doing so, we absorbed the arbitrary integration constant into V_0 in the full expression of the potential, which in this case reads as

$$V(\varphi,\psi) = V_0 + 12\Lambda\varphi + \frac{(1-3w)(1-w)}{(1+3w)}\rho_0\psi_0^{\frac{2(1+w)}{(1-w)}}\psi^{-\frac{(1+3w)}{(1-w)}}. \tag{28}$$

Having determined the form of the potential, we solved Eq. (14) to obtain $\varphi(t)$,

$$\varphi(t) = \varphi_0 e^{\sqrt{\Lambda}(t-t_0)} - \frac{V_0}{6\Lambda} - \frac{\rho_0}{3\Lambda}\left[\frac{8\pi e^{-3(1+w)\sqrt{\Lambda}(t-t_0)}}{(4+3w)} + \frac{4\,(1+w)\,\psi_0 e^{-\frac{3}{2}(1+3w)\sqrt{\Lambda}(t-t_0)}}{(1+3w)\,(5+9w)}\right], \tag{29}$$

where φ_0 is an integration constant. This solution $\varphi\,(t)$ is undefined at $w = \{-4/3, -5/9, -1/3\}$, and, from before, we were already not considering the $w = 1$ case. Apart from these discontinuities, the system does not pose further constraints to the equation of state. In the paper under preparation, we include a more complete analysis of this parameter space. However, here we show the solutions only for three particular choices of w.

A natural choice was to take $w = -1$, which in GR is the equation of state of constant dark energy density that drives an exponential expansion, corresponding to a cosmological constant. Given that we have the freedom to do so, we also set $w = 0$, i.e. the case in which pressureless (or dust-like) matter dominates. Alternatively, we also set $w = 1/3$ to model the case in which the energy density is dominated by radiation (remembering, for instance, that the stress-energy tensor of the electromagnetic field is traceless, i.e. $T = 3p - \rho = 0$ in the case of isotropic perfect fluid considered, corresponding to $w = 1/3$). That we tried different values for the equation of state, e.g. for matter and radiation, may be confusing at first given that we are considering an exponential growth of the universe, but we need only to remember that due to the extra degrees of freedom in $f(R, T)$ gravity, this cases can still be consistent within the system of equations we derived.

For each of these three values of the equation of state, $w = \{-1, 0, 1/3\}$, the energy density as given by Eq. (26) is plotted in Fig. 1. When space expands exponentially, the energy density is constant for $w = -1$ (cosmological constant), and undergoes exponential decay for $w = 0$ (dust) and $w = 1/3$ (radiation) — the decay is faster for radiation than for dust (due to the redshift of radiation). For each of the same three values of w, the scalar field $\psi(t)$ as given by Eq. (27) is plotted in Fig. 2. In the three cases, the field ψ grows exponentially with time — in descending order, it grows faster with the cosmological constant than with dust and than with radiation. Likewise, we plot the scalar field $\varphi\,(t)$ as given by Eq. (29) in Fig. 3. When $t \gg t_0$, all of the plotted $\varphi\,(t)$ solutions grow exponentially (in fact, they can all be approximated by $\varphi\,(t) \sim \varphi_0 \exp(\sqrt{\Lambda}t)$ in this limit). On the other hand, when $t < t_0$ the $\varphi\,(t)$ solutions show different behaviour between them. The two scalar fields do not have a straightforward physical interpretation; as a reminder, they were defined as the partial derivatives of the function $f\,(R, T)$, i.e. $\varphi = \partial f/\partial R$ and $\psi = \partial f/\partial T$. Finally, to each value of the equation of state corresponds a different form of the potential $V\,(\varphi, \psi)$ as given by Eq. (28),

$$w = -1: \qquad V(\varphi, \psi) = V_0 + 12\Lambda\varphi - 4\rho_0\psi, \tag{30}$$

$$w = 0: \qquad V(\varphi, \psi) = V_0 + 12\Lambda\varphi + \frac{\rho_0\psi_0^2}{\psi}, \tag{31}$$

$$w = 1/3: \qquad V(\varphi, \psi) = V_0 + 12\Lambda\varphi. \tag{32}$$

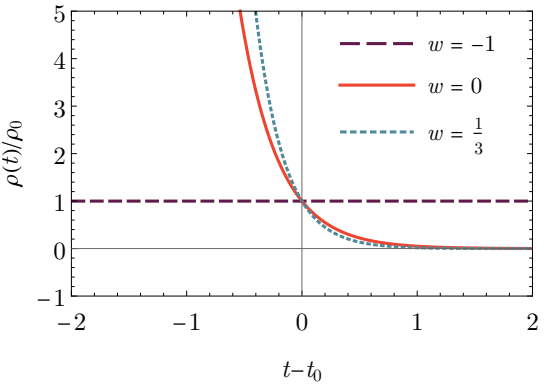

Fig. 1. Energy density $\rho(t)/\rho_0$ from Eq. (26) in the particular case where $a(t)$ is given by Eq. (25), setting $\Lambda = 1$, with the equation of state forced to be each of these values $w = \{-1, 0, 1/3\}$.

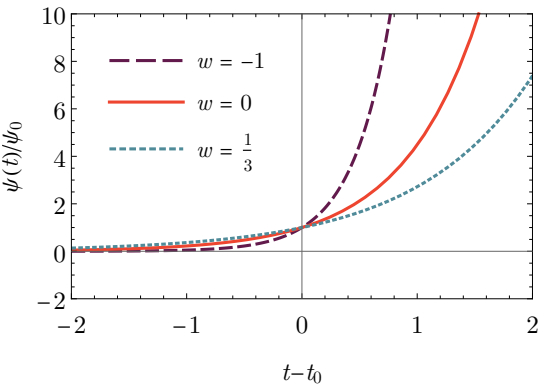

Fig. 2. Scalar field $\psi(t)/\psi_0$ from Eq. (27) in the particular case where $a(t)$ is given by Eq. (25), setting $\Lambda = 1$, with the equation of state forced to be each of these values $w = \{-1, 0, 1/3\}$.

As exemplified here, we were able to find solutions for all the variables in our system: $\rho(t)$, $p(t)$, $\varphi(t)$, $\psi(t)$ and $V(\varphi, \psi)$, for particular choices of $a(t)$, k and w. The next question we addressed in our work was: what form(s) of the function $f(R, T)$ generate these cosmologies?

3.4. *Reconstructing the function $f(R, T)$*

Given that we were able to obtain consistent solutions, one may hope that it is possible to reconstruct the explicit form of the function $f(R, T)$ that can lead to those solutions. For instance, we have found the form of the potential $V(\varphi, \psi)$ and, by definition, the potential is related to the function $f(R, T)$, as per Eq. (4) which

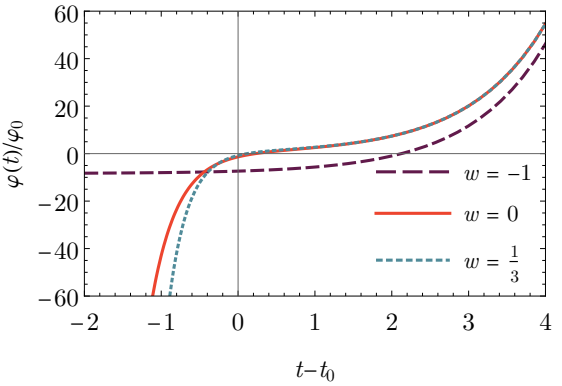

Fig. 3. Scalar field $\varphi(t)/\varphi_0$ from Eq. (29), setting $\varphi_0 = \rho_0 = \psi_0 = 1$, in the particular case where $a(t)$ is given by Eq. (25), setting $\Lambda = 1$, with the equation of state forced to be each of these values $w = \{-1, 0, 1/3\}$.

can be rewritten as

$$f(R,T) = -V(f_R, f_T) + f_R R + f_T T, \tag{33}$$

where we have changed the notation using $\varphi = f_R$ and $\psi = f_T$, with the subscripts R and T denoting the partial derivatives. Taking the partial derivatives of this equation with respect to R and T, we obtained a system of two PDEs which are satisfied for an arbitrary $f(R,T)$ if $V_\varphi = R$ and $V_\psi = T$. These two conditions are the equations of motion we obtained for the fields φ and ψ, in Eqs. (8) and (9), and so are always satisfied. It can be seen, e.g. from Eq. (28), that

$$V_\psi = T = (3w-1)\rho_0 \left(\frac{f_T}{\psi_0}\right)^{-\frac{2(1+w)}{(1-w)}}, \tag{34}$$

which is not defined for $w = 1$. If $w = \{-1, 1/3\}$, this equation does not give a relation between f_T and T. On the other hand, if $w = 0$, for instance, then $T = -\rho_0 \psi_0^2 / f_T^2$. This relation can be inverted and integrated to give

$$f(R,T) = g(R) \pm 2\psi_0 \sqrt{-\rho_0 T}, \tag{35}$$

where $g(R)$ is an arbitrary function of R. In the case of a flat universe ($k = 0$) with an exponentially evolving scale factor as given by Eq. (25), $V_\varphi = R = 12\Lambda$ which does not provide a direct relation between f_R and R, and so it does constrain the form of $g(R)$. Other particular cases are studied in our work and will be presented in the upcoming paper.

4. Summary and concluding remarks

Modified gravity has the potential to solve some of the remaining questions in cosmology, such as the current accelerated expansion. With this motivation, we

took the recently developed scalar-tensor representation of the $f(R,T)$ gravity to explore allowed FLRW cosmologies. To keep our contribution short, we presented here only one particular case: that of an exponential expansion. As opposed to GR, in $f(R,T)$ gravity there is not a one-to-one relation between the evolution of the scale factor and the equation of state. For instance, we were able to find a solution by choosing a flat, dust dominated, exponentially expanding universe, which would not have been possible in GR. The extra degrees of freedom in modified gravity may contribute to an effective dark energy, thus allowing an exponential expansion to occur even when the equation of state is that of matter or radiation. In the paper under preparation, we include other particular cases, such as power law evolution of the scale factor, non flat geometries, and other equations of state. We are also already working on testing whether finite time singularities can appear in $f(R,T)$ gravity.

On the interaction between electromagnetic, gravitational, and plasma related perturbations on LRS class II spacetimes

P. Semrén

E-mail: philip.semren@umu.se

We consider first order perturbations on locally rotationally symmetric (LRS) class II spacetimes. In particular, we investigate the interactions between electromagnetic, gravitational, and plasma related perturbations when allowing for a non-zero magnetic field on the background spacetime. In doing so we focus on mechanisms for generating and magnifying the magnetic fields, as these kinds of mechanisms may have some relevance when trying to explain the origin of the observed large scale cosmic magnetic fields. The equations governing the behavior of the perturbations are gathered from the Ricci identities for certain preferred vector fields, the Bianchi identities, Maxwell's equations, and from relations describing energy-momentum conservation and particle conservation for the cosmological plasma. After employing a simplified cold magnetohydrodynamic (MHD) description, and harmonically decomposing the spatial dependencies, we arrive at a closed set of ordinary differential equations in time. On analyzing this system, which decouples into an even and an odd subsector, we indeed observe possible mechanisms for generating magnetic field perturbations to first order.

Keywords: Cosmological perturbations; LRS Class II; plasma; MHD.

1. Introduction

Using the standard ΛCDM model of cosmology, assumed to be homogeneous and isotropic on average, most of our current observations can be explained. However, as the bounds on a possible anisotropy in our universe still remains quite unrestrictive,[1,2] it is still interesting to study more general anisotropic models. These models have a special relevance when considering electromagnetic perturbations in a cosmological context. When using the standard models as background spacetimes in a perturbative approach, the isotropy of these models make it is essentially impossible to have a non-zero magnetic field on the zeroth order level, since such a field would define a preferred spatial direction. Therefore, when considering electromagnetic perturbations on a FLRW background, previous works have often found it necessary to employ a non-linear perturbation theory to maintain gauge invariance and to be able to see any interesting interactions between the electromagnetic fields and the variables related to gravitational effects.[3–5] However, using an anisotropic model as background spacetime, there is no fundamental problem of having a non-zero magnetic field to zeroth order.

In this work, we take a first step towards a more general anisotropic model by using a $1 + 1 + 2$ covariant split of spacetime to investigate linear perturbations

on homogenous and hypersurface orthogonal locally rotationally symmetric (LRS) class II spacetimes. Since these spacetimes have a preferred spatial direction around which they are locally rotationally symmetric, we are able to include a magnetic field to zeroth order in a perturbative approach. The aim is then to investigate if this allows for interesting interactions between the electromagnetic fields and the gravitational variables already to first order in the perturbations.

As for linear perturbations on LRS class II cosmologies, these have been studied extensively before for perfect fluids, with and without vorticity.[6–8] A study of more general and dissipative perturbations can be found in Ref. 9 and in a forthcoming paper. Regarding electromagnetic perturbations, these have also been considered before, but, as far as we know, only when treating these perturbations as test fields or in rather restrictive cases.[10,11] This work therefore seeks to present a more general treatment of electromagnetic perturbations on LRS class II cosmologies when using a cold magnetohydrodynamic (MHD) approximation to describe the details of the cosmological plasma. However, in doing so, we will only outline the main steps and results. For more details, the reader is referred to Ref. 12 or a forthcoming paper to be published elsewhere.

2. Governing Equations

The studied LRS spacetimes are assumed to have two preferred directions, specified by a time-like vector field, u^a, and a space-like vector field n^a. These vector fields are assumed to be normalized as $u^a u_a = -1$ and $n^a n_a = 1$. The time-like direction could represent the 4-velocity of the cosmological fluid or some congruence of fundamental observers, whilst the spatial direction is the direction around which the spacetimes are locally rotationally symmetric.

2.1. *Spacetime Dynamics*

The characteristic directions u^a and n^a play a crucial role when describing the spacetime dynamics, as we will get many of our equations from the Ricci identities for these vector fields, namely

$$2\nabla_{[a}\nabla_{b]}u_c - R_{abcd}u^d = 0, \tag{1}$$

$$2\nabla_{[a}\nabla_{b]}n_c - R_{abcd}n^d = 0. \tag{2}$$

In addition to these equations, we will also make use of the contracted Bianchi identities

$$2\nabla_{[e}R_{d]b} + \nabla_a R^a{}_{bde} = 0, \tag{3}$$

$$\nabla^a G_{ab} = 0, \tag{4}$$

where $G_{ab} \equiv R_{ab} - g_{ab}R/2$ is the Einstein tensor. We will also implicitly enforce Einstein's field equations

$$G_{ab} = T_{ab} - \Lambda g_{ab}, \tag{5}$$

by using them to write the Ricci tensor and Ricci scalar in terms of the energy momentum tensor T_{ab} and the cosmological constant Λ.

Although the relations stated above will give us many of the equations that we need, they will in general not result in a closed set. To get the remaning relations, we also need to specify the detailed properties of the energy-momentum tensor.

2.2. *Plasma Dynamics*

In our case, where we want to describe a cosmological plasma together with its associated electromagnetic fields, we can divide the energy-momentum tensor as

$$T^{ab} = {T_{(F)}}^{ab} + {T_{(EM)}}^{ab}, \tag{6}$$

where ${T_{(F)}}^{ab}$ is due to the fluid whilst ${T_{(EM)}}^{ab}$ is due to the electromagnetic fields. The electromagnetic part can be written as

$${T_{(EM)}}^{ab} = {F^a}_c F^{bc} - \frac{1}{4} g^{ab} F^{cd} F_{cd}\,, \tag{7}$$

in terms of the Faraday tensor F_{ab}, which in turn is assumed to satisfy Maxwell's equations

$$\nabla_{[a} F_{bc]} = 0, \tag{8}$$

$$\nabla_b F^{ab} = j^a. \tag{9}$$

Here j^a is the 4-current density, which can be written as $j^a = \rho u^a + J^a$ in terms of the charge density ρ and the 3-current density J^a, where $u^a J_a = 0$.

Following the formalism in Ref. 13, the behavior of the fluid contribution can be deduced by first treating the cosmological plasma as a charged multi-component fluid, where the ith component is assumed to have the 4-velocity

$${u_{(i)}}^a = \gamma_{(i)} \left(u^a + {v_{(i)}}^a \right), \tag{10}$$

with the properties

$$u^a {v_{(i)}}_a = 0, \quad \gamma_{(i)} = \frac{1}{\sqrt{1 - {v_{(i)}}^2}}, \quad {v_{(i)}}^2 \equiv {v_{(i)}}_a {v_{(i)}}^a. \tag{11}$$

The dynamics of the ith component is then determined by imposing the following equations, describing conservation of energy-momentum and particles

$$\nabla_b {T_{(i)}}^{ab} = F^{ab} {j_{(i)}}_b + {I_{(i)}}^a, \tag{12}$$

$$\nabla_a \left(\mathcal{N}_{(i)} {u_{(i)}}^a \right) = 0. \tag{13}$$

Here, $\mathcal{N}_{(i)}$ is the number density for the ith component relative to its own rest frame, whilst ${T_{(i)}}^{ab}$ is the energy-momentum contribution from this component, so that

$${T_{(F)}}^{ab} = \sum_{(i)} {T_{(i)}}^{ab}. \tag{14}$$

As for the right hand side in Eq. (12), ${I_{(i)}}^a$ includes interactions, such as collisions, between the fluid components, whilst ${j_{(i)}}^a$ is the 4-current density of the ith component, which satisfies the relations

$$ {j_{(i)}}^a = q_{c(i)} \mathcal{N}_{(i)} {u_{(i)}}^a, \tag{15} $$

$$ j^a = \sum_{(i)} {j_{(i)}}^a. \tag{16} $$

Here $q_{c(i)}$ is the charge of the ith species. Furthermore, we will also assume that the ith component is a perfect fluid, so that

$$ {T_{(i)}}^{ab} = \left(\mu_{(i)} + p_{(i)}\right) {u_{(i)}}^a {u_{(i)}}^b + p_{(i)} g^{ab}, \tag{17} $$

where $\mu_{(i)}$ is the energy density and $p_{(i)}$ is the isotropic pressure relative to the rest frame of the fluid component. After specifying some reasonable equations of state $p_{(i)} = p_{(i)}(\mu_{(i)}, \mathcal{N}_{(i)})$, Eqs. (1)-(17) are enough to be able to get a closed system in the end. To simplify this system, we will in the following employ a cold MHD description. Instead of working directly with the individual fluid components, we then want to rewrite the system in terms of some collective variables. For this purpose, we will first assume that the plasma is sufficiently cold, so that the components can be seen as dust-like fluids with negligible pressures $p_{(i)}$. We will then, after having linearized the equations as described later on, rewrite the equations in terms of the following collective variables

$$ \mu_{(F)} \equiv \sum_i \mu_{(i)}, $$

$$ \mu_{(F)} {v_{(F)}}^a \equiv \sum_i \mu_{(i)} {v_{(i)}}^a, $$

where $\mu_{(F)}$ is the total energy density of the fluid and ${v_{(F)}}^a$ is an average plasma 3-velocity. In the following we will assume that the plasma consists of an electron component and a much more massive ion counterpart. Then, on following the usual approximations of the resistive MHD description, it is possible to derive an Ohm's law of the form[a]

$$ J^a = \frac{1}{\eta} \left(E^a + \epsilon^{abc} {v_{(F)}}_b B_c\right), $$

which will be used to describe the 3-current density. Here, η is the electrical resistivity whilst E^a and B^a are the electric and magnetic fields as defined by the relation

$$ F_{ab} = \epsilon_{abc} B^c + 2 u_{[a} E_{b]}, $$

where $\epsilon_{abc} \equiv \eta_{dabc} u^d \equiv 4! \sqrt{-g} \delta^0{}_{[d} \delta^1{}_a \delta^2{}_b \delta^3{}_{c]} u^d$ is the 3-dimensional Levi-Civita volume element. As for the charge density, total charge neutrality is assumed on

[a] A simplified derivation starting from the linearized and harmonically decomposed multi-component equations can be found in Ref. 12.

the background spacetime, where the plasma velocities ${u_{(i)}}^a$ are assumed to coincide with the fundamental observers u^a. To first order, however, the charge density will be allowed to be non-zero, and is determined by the electromagnetic fields through Maxwell's equations in the MHD description.

Before delving deeper into the perturbations, however, we first break the relevant equations down into smaller pieces by using covariant splits of spacetime.

3. Covariant Splits of Spacetime

Since the studied background spacetimes are equipped with two preferred directions, it is natural to decompose our variables with respect to the vector fields u^a and n^a. We start by performing a $1+3$ split with respect to u^a, after which the 3-dimensional hypersurfaces orthogonal to u^a are decomposed with respect to n^a, yielding a $1+1+2$ covariant split of spacetime.[14]

3.1. 1 + 3

Starting with the $1+3$ split, we first write the metric as

$$g_{ab} = U_{ab} + h_{ab}, \tag{18}$$

where $U_{ab} = -u_a u_b$ is a projection tensor along u^a, whilst h_{ab} projects onto the 3-dimensional hypersurfaces orthogonal to u^a. Using Eq. (18) we may then decompose every other quantity with respect to u^a. This has already been done for the electromagnetic and plasma-related variables in the previous section, but we note the following new variables which emerge as projections of the total energy-momentum tensor and the Weyl tensor

$$\begin{aligned}
\mu &\equiv T^{cd} u_c u_d, \\
q_a &\equiv -T^{cd} u_c h_{da}, \\
p &\equiv \frac{1}{3} T^{cd} h_{cd}, \\
\pi_{ab} &\equiv \left(h_{(a}{}^c h_{b)}{}^d - \frac{1}{3} h^{cd} h_{ab} \right) T_{cd} \equiv T_{\langle ab \rangle}, \\
E_{ab} &\equiv C_{acbd} u^c u^d, \\
H_{ab} &\equiv \frac{1}{2} \epsilon_a{}^{ef} C_{efbd} u^d.
\end{aligned}$$

Here μ is the total energy density, q_a is the total energy flow relative to u^a, p is the total isotropic pressure, and π_{ab} is the total anisotropic pressure, whilst E_{ab} and H_{ab} are the electric and magnetic parts of the Weyl tensor C_{abcd}. When defining the anisotropic pressure, we have introduced a notation with angular brackets to denote the Projected Symmetric and Trace-Free (PSTF) part of a tensor with respect to h_{ab}.

To describe the spacetime dynamics, we also have to decompose the covariant derivatives. For this purpose we define a time derivative

$$\dot{T}^{ab\ldots}{}_{cd\ldots} \equiv u^e \nabla_e T^{ab\ldots}{}_{cd\ldots},$$

and a spatial derivative that is fully projected onto the 3-dimensional hypersurfaces

$$D_e T^{ab\ldots}{}_{cd\ldots} \equiv h^a{}_f h^b{}_g \cdots h_c{}^h h_d{}^i \cdots h_e{}^j \nabla_j T^{fg\ldots}{}_{hi\ldots}.$$

Using these definitions, we may write the covariant derivative of u^a as

$$\nabla_a u_b = -u_a \dot{u}_b + \frac{1}{3}\Theta h_{ab} + \omega_{ab} + \sigma_{ab},$$

where $\Theta \equiv D^a u_a$ is the expansion rate, $\omega_{ab} \equiv D_{[a} u_{b]}$ is the vorticity, and $\sigma_{ab} \equiv D_{\langle a} u_{b\rangle}$ is the shear. When dealing with the vorticity we will in the following use the vorticity 3-vector

$$\omega^a \equiv \frac{1}{2}\epsilon^{abc}\omega_{bc},$$

rather than the vorticity tensor.

3.2. 1 + 1 + 2

Having decomposed the relevant quantities with respect to u^a, we perform an additional decomposition with respect to n^a. After writing the projection tensor h_{ab} as

$$h_{ab} = N_{ab} + n_a n_b,$$

we may then write the relevant 3-vectors as

$$\begin{aligned} q^a &= Q n^a + Q^a, & B^a &= \mathfrak{B} n^a + \mathfrak{B}^a, \\ \omega^a &= \Omega n^a + \Omega^a, & E^a &= \mathfrak{E} n^a + \mathfrak{E}^a, \\ \dot{u}^a &= \mathcal{A} n^a + \mathcal{A}^a, & J^a &= \mathfrak{J} n^a + \mathfrak{J}^a, \\ \dot{n}^a &= \mathcal{A} u^a + \alpha^a, & v_{(F)}{}^a &= \mathcal{V}_{(F)} n^a + \mathcal{V}_{(F)}{}^a, \end{aligned}$$

where the rightmost vectors in each relation are orthogonal to both u^a and n^b. As for PSTF 3-tensors ψ_{ab}, we decompose these as

$$\psi_{ab} = \Psi\left(n_a n_b - \frac{1}{2}N_{ab}\right) + 2n_{(a}\Psi_{b)} + \Psi_{ab},$$

where $n^a \Psi_a = 0$ and

$$\Psi_{ab} = \left(N_{(a}{}^c N_{b)}{}^d - \frac{1}{2}N_{ab}N^{cd}\right)\psi_{cd} \equiv \psi_{\{ab\}}.$$

Here we have introduced a notation with curly brackets to denote the PSTF part of a tensor with respect to N_{ab}. For the tensors relevant to us, we can therefore write

$$\pi_{ab} = \Pi\left(n_a n_b - \frac{1}{2}N_{ab}\right) + 2n_{(a}\Pi_{b)} + \Pi_{ab},$$

$$E_{ab} = \mathcal{E}\left(n_a n_b - \frac{1}{2}N_{ab}\right) + 2n_{(a}\mathcal{E}_{b)} + \mathcal{E}_{ab},$$
$$H_{ab} = \mathcal{H}\left(n_a n_b - \frac{1}{2}N_{ab}\right) + 2n_{(a}\mathcal{H}_{b)} + \mathcal{H}_{ab},$$
$$\sigma_{ab} = \Sigma\left(n_a n_b - \frac{1}{2}N_{ab}\right) + 2n_{(a}\Sigma_{b)} + \Sigma_{ab}.$$

Finally, we also need to decompose the spatial derivatives. For this purpose we define a spatial derivative along n^a

$$\hat{T}^{ab\ldots}{}_{cd\ldots} \equiv n^e D_e T^{ab\ldots}{}_{cd\ldots},$$

and a spatial derivative fully projected onto the 2-sheets orthogonal to both u^a and n^a

$$\delta_e T^{ab\ldots}{}_{cd\ldots} \equiv N^a{}_f\, N^b{}_g \cdots N_c{}^h N_d{}^i \cdots N_e{}^j D_j T^{fg\ldots}{}_{hi\ldots}.$$

With these definitions, we may write the spatial derivative of n^a as

$$D_a n_b = n_a a_b + \frac{1}{2}\phi N_{ab} + \xi\epsilon_{ab} + \zeta_{ab},$$

where $\epsilon_{ab} \equiv \epsilon_{abc}n^c$, $\phi \equiv \delta^c n_c$ describes an expansion of the 2-sheets, $\xi\epsilon_{ab} \equiv \delta_{[a}n_{b]}$ describes a twist of these sheets, $\zeta_{ab} \equiv \delta_{\{a}n_{b\}}$ is the distortion, and $a_a \equiv \hat{n}_a$.

4. Background Spacetimes

Having decomposed the equations using the $1+1+2$ covariant split of spacetime, we move on to consider these equations perturbatively, starting with the zeroth order background spacetime. We will assume that this spacetime is a homogeneous and hypersurface orthogonal member of LRS class II, which is characterized by that H_{ab}, ω_{ab} and ξ are all identically zero. To be able to use the same type of harmonics for all of the studied spacetimes, we will also assume that $\phi = 0$. These spacetimes can be described with the line element

$$ds^2 = -dt^2 + a_1^2(t)\,dz^2 + a_2^2(t)\left(d\vartheta^2 + f_\kappa(\vartheta)d\varphi^2\right),$$

where the scale factors a_1 and a_2 satisfy the relations

$$\Theta = \frac{\dot{a}_1}{a_1} + 2\frac{\dot{a}_2}{a_2},$$
$$\Sigma = \frac{2}{3}\left(\frac{\dot{a}_1}{a_1} - \frac{\dot{a}_2}{a_2}\right).$$

The function $f_\kappa(\vartheta)$ is determined by the 2D-curvature scalar

$$\mathcal{R} = \frac{2\kappa}{a_2^2} = 2(\mu + \Lambda) + \frac{3\Sigma^2}{2} - \frac{2\Theta^2}{3}.$$

When $\kappa = 1$, the sheets are 2-spheres with $f_1(\vartheta) = \sin^2\vartheta$. If $\kappa = 0$ the 2-sheets are flat and $f_0(\vartheta) = 1$ (or ϑ^2). Lastly, if $\kappa = -1$, the 2-sheets are pseudo-spheres with $f_{-1}(\vartheta) = \sinh^2\vartheta$.

As previously mentioned, we will to zeroth order assume charge neutrality and that the plasma velocities coincide with the fundamental observers. We will also assume that interactions between the plasma components, as described by the last term in Eq. (12), vanish to zeroth order. With these assumptions, our choice of background spacetimes implies that the only relevant non-zero dynamical quantities to zeroth order are

$$S^{(0)} = \left\{\Theta, \Sigma, \mu_{(F)}, \mathfrak{B}, \mathcal{E}, \mu, p, \Pi\right\},$$

which are found to satisfy the equations

$$\begin{aligned}
\dot{\Theta} &= -\frac{\Theta^2}{3} - \frac{3\Sigma^2}{2} - \frac{1}{2}(\mu + 3p) + \Lambda,\\
\dot{\Sigma} &= \frac{2}{3}(\mu + \Lambda) + \frac{\Sigma^2}{2} - \Sigma\Theta - \frac{2\Theta^2}{9} + \Pi,\\
\dot{\mu}_{(F)} &= -\mu_{(F)}\Theta,\\
\dot{\mathfrak{B}} &= \left(\Sigma - \frac{2\Theta}{3}\right)\mathfrak{B},
\end{aligned}$$

where

$$\begin{aligned}
3\mathcal{E} &= -2(\mu + \Lambda) - 3\Sigma^2 + \frac{2\Theta^2}{3} + \Sigma\Theta - \frac{3\Pi}{2},\\
\mu &= \mu_{(F)} + \frac{\mathfrak{B}^2}{2},\\
p &= \frac{\mathfrak{B}^2}{6},\\
\Pi &= -\frac{2\mathfrak{B}^2}{3}.
\end{aligned}$$

5. Perturbations

With the behavior of the background determined, we now move on to consider first order perturbations in the gravitational, electromagnetic and plasma-related variables. To ensure gauge invariance, we will use quantities which are zero on the background spacetime to describe the perturbations, as these are gauge invariant in accordance with the Stewart–Walker lemma.[15] However, since there are some non-zero variables on the background, we have to define some new variables to describe the perturbations in these quantities. For this purpose we take advantage of the background homogeneity and let the perturbations of the non-zero background variables be described by spatial gradients of these variables. Therefore, we define

the following first order quantities[b]

$$X_a \equiv \delta_a \mathcal{E}, \quad V_a \equiv \delta_a \Sigma, \quad W_a \equiv \delta_a \Theta, \quad \mu_{(F)_a} \equiv \delta_a \mu_{(F)},$$
$$Y_a \equiv \delta_a \Pi, \quad \mu_a \equiv \delta_a \mu, \quad p_a \equiv \delta_a p, \quad \mathcal{B}_a \equiv \delta_a \mathfrak{B}.$$

Collecting these variables with those that are naturally zero on the background, the complete set of gauge invariant first order quantities are

$$S^{(1)} \equiv \{X_a, V_a, W_a, \mu_a, p_a, Y_a, \mathcal{A}, \mathcal{A}_a, \Sigma_a, \Sigma_{ab}, \mathcal{E}_a, \mathcal{E}_{ab},$$
$$\mathcal{H}, \mathcal{H}_a . \mathcal{H}_{ab}, \alpha_a, a_a, \xi, \phi, \zeta_{ab}, \Omega, \Omega_a, Q, Q_a, \Pi_a,$$
$$\mu_{(F)_a}, \mathcal{V}_{(F)}, \mathcal{V}_{(F)_a}, \mathfrak{E}, \mathfrak{E}_a, \mathfrak{B}_a, \mathcal{B}_a, \rho, \mathfrak{J}, \mathfrak{J}_a\}.$$

To obtain the equations governing these variables to first order, we first rewrite the equations from Sec. 2 in terms of the variables in $S^{(1)}$ by using some commutation relations between the derivatives in the $1+1+2$ formalism. After removing terms which are of second order or higher in the variables in $S^{(1)}$, we arrive at a large set of coupled linear partial differential equations. To simplify the analysis of this system, we now perform a harmonic decomposition, whereby the system can be reduced to a closed set of ordinary differential equations in time.

6. Harmonic Decomposition

When performing the aforementioned harmonic decomposition, we will follow Ref. 7 and make use of the eigenfunctions $P^{k_\parallel}$ and $Q^{k_\perp}$, which are defined as functions satisfying

$$\hat{\Delta} P^{k_\parallel} = -\frac{k_\parallel^2}{a_1^2} P^{k_\parallel}, \quad \delta_a P^{k_\parallel} = 0, \quad \dot{P}^{k_\parallel} = 0,$$
$$\delta^2 Q^{k_\perp} = -\frac{k_\perp^2}{a_2^2} Q^{k_\perp}, \quad \hat{Q}^{k_\perp} = 0, \quad \dot{Q}^{k_\perp} = 0,$$

where $\hat{\Delta} \equiv n^a \nabla_a n^b \nabla_b$, and $\delta^2 = \delta_a \delta^a$, whilst $k_\parallel$ and $k_\perp$ are comoving dimensionless wave numbers along n^a and in the 2-sheets respectively. Using these harmonics, we may also define even and odd vector and tensor harmonics

$$Q^{k_\perp}{}_a = a_2 \delta_a Q^{k_\perp}, \qquad Q^{k_\perp}{}_{ab} = a_2^2 \delta_{\{a} \delta_{b\}} Q^{k_\perp},$$
$$\overline{Q}^{k_\perp}{}_a = a_2 \epsilon_{ab} \delta^b Q^{k_\perp}, \quad \overline{Q}^{k_\perp}{}_{ab} = a_2^2 \epsilon_{c\{a} \delta^c \delta_{b\}} Q^{k_\perp},$$

where the odd harmonics are denoted with bars. Equipped with these harmonics, we decompose scalars Ψ, 2-vectors Ψ_a, and PSTF 2-tensors Ψ_{ab} as

$$\Psi = \sum_{k_\parallel, k_\perp} \Psi^S_{k_\parallel k_\perp} P^{k_\parallel} Q^{k_\perp},$$

[b]Instead of using the $\delta_a G$ gradients to describe perturbations of a variable G that is non-zero on the background, we could have defined our perturbations using the spatial $\hat{G}$ derivatives. However, after performing a harmonic decomposition, it can be shown that $\hat{G}$ can be written in terms of $\delta_a G$ and the vorticity.[8]

$$\Psi_a = \sum_{k_\parallel, k_\perp} P^{k_\parallel} \left(\Psi^V_{k_\parallel k_\perp} Q^{k_\perp}{}_a + \overline{\Psi}^V_{k_\parallel k_\perp} \overline{Q}^{k_\perp}{}_a \right),$$

$$\Psi_{ab} = \sum_{k_\parallel, k_\perp} P^{k_\parallel} \left(\Psi^T_{k_\parallel k_\perp} Q^{k_\perp}{}_{ab} + \overline{\Psi}^T_{k_\parallel k_\perp} \overline{Q}^{k_\perp}{}_{ab} \right),$$

where the coefficients $\{\Psi^{S,V,T}_{k_\parallel k_\perp}, \overline{\Psi}^{V,T}_{k_\parallel k_\perp}\}$ now only depend on time. In the following we will omit the wave number indices on these coefficients when there is no risk of ambiguity.

7. Final System

After performing the harmonic decompositions described in the previous section, the first order linearized partial differential equations reduce to a set of constraints and ordinary differential equations in time for the harmonic coefficients. On using the constraints to solve for some of the coefficients in terms of the others, the system can be reduced significantly. In doing so, we also use the remaining freedom of specifying the dyad $\{u^a, n^a\}$ to first order to set a_a, $\mathcal{A}_a$, and $\mathcal{A}$ to zero. We are then left with two separate sectors, one so-called odd sector and one even sector, which decouple from each other. The odd sector consists of the coefficients

$$\{\Omega^S, \overline{\mathcal{E}}^T, \mathcal{H}^T, \overline{\mathcal{V}}_{(F)}{}^V, \mathfrak{E}^S, \mathfrak{E}^V, \overline{\mathfrak{B}}^V\},$$

whilst the even sector contains the coefficients

$$\{\overline{\Omega}^V, \overline{\mathcal{H}}^T, \mathcal{E}^T, \Sigma^T, \mu_{(F)}{}^V, \mathcal{V}_{(F)}{}^S, \mathcal{V}_{(F)}{}^V, \mathcal{B}^V, \overline{\mathfrak{E}}^V\}.$$

These sectors form closed sets in the sense that we have evolution equations for all of the coefficients above. As for the remaining coefficients, these can be given algebraically in terms of the ones above.

7.1. *Odd Sector*

The coefficients in the odd sector are found to satisfy the equations

$$\begin{aligned}
\dot{\Omega}^S &= \tilde{F}\Omega^S, \\
\dot{\overline{\mathcal{E}}}^T &= -\frac{3}{2}(F + \Sigma D)\,\overline{\mathcal{E}}^T + \frac{ik_\parallel}{a_1}(1 - D)\,\mathcal{H}^T \\
&\quad + P\Omega^S + \frac{1}{a_2}(1 + D)\left(\mu_{(F)}\overline{\mathcal{V}}_{(F)}{}^V + \mathfrak{B}\mathfrak{E}^V\right), \\
\dot{\mathcal{H}}^T &= \left(\frac{3ia_1\Pi}{k_\parallel k_\perp^2}\left(\Sigma + \frac{\Theta}{3}\right) + S\right)\Omega^S + \frac{1}{a_2}\mathfrak{B}\overline{\mathfrak{B}}^V \\
&\quad + \frac{ia_1}{a_2 k_\parallel B}\left(\left(\Sigma + \frac{\Theta}{3}\right)\left(3\Pi + \frac{k_\perp^2}{a_2^2}\right) - \frac{k_\parallel^2}{a_1^2}\tilde{F}\right)\left(\mu_{(F)}\overline{\mathcal{V}}_{(F)}{}^V + \mathfrak{B}\mathfrak{E}^V\right) \\
&\quad + \frac{ia_1}{2k_\parallel}\left(\frac{2k_\parallel^2}{a_1^2} - CB + 9\Sigma E + 3\Pi\right)\overline{\mathcal{E}}^T - \frac{3}{2}(2E + F)\,\mathcal{H}^T,
\end{aligned}$$

$$
\begin{aligned}
\dot{\overline{\mathcal{V}}}^{V}_{(F)} &= \frac{\mathfrak{B}}{\eta\mu_{(F)}}\left(\mathfrak{E}^{V} - \mathfrak{B}\overline{\mathcal{V}}_{(F)}{}^{V}\right) + \frac{1}{2}\left(\Sigma - \frac{2\Theta}{3}\right)\overline{\mathcal{V}}_{(F)}{}^{V},\\
\dot{\mathfrak{E}}^{S} &= \frac{k_{\perp}^{2}}{a_2}\overline{\mathfrak{B}}^{V} - \frac{2ia_1}{k_{\parallel}}\mathfrak{B}\left(\Sigma + \frac{\Theta}{3}\right)\Omega^{S} + \left(\Sigma - \frac{2\Theta}{3} - \frac{1}{\eta}\right)\mathfrak{E}^{S}, \qquad (19)\\
\dot{\mathfrak{E}}^{V} &= \frac{ik_{\parallel}}{a_1}\overline{\mathfrak{B}}^{V} - \frac{1}{2}\left(\Sigma + \frac{4\Theta}{3}\right)\mathfrak{E}^{V} - \frac{1}{\eta}\left(\mathfrak{E}^{V} - \mathfrak{B}\overline{\mathcal{V}}_{(F)}{}^{V}\right) - \frac{2a_2\dot{\mathfrak{B}}}{k_{\perp}^{2}}\Omega^{S}, \qquad (20)\\
\dot{\overline{\mathfrak{B}}}^{V} &= \left(\frac{ik_{\parallel}}{a_1}\mathfrak{E}^{V} - \frac{1}{a_2}\mathfrak{E}^{S}\right) - \frac{1}{2}\left(\Sigma + \frac{4\Theta}{3}\right)\overline{\mathfrak{B}}^{V}\\
&\quad - \frac{ia_1}{k_{\parallel}}\mathfrak{B}\left[\frac{2\left(\mathcal{R}a_2^{2} - k_{\perp}^{2}\right)}{a_2 B}\left(\frac{3\Sigma}{2}\overline{\mathcal{E}}^{T} + \frac{ik_{\parallel}}{a_1}\mathcal{H}^{T}\right)\right.\\
&\quad - \frac{2}{B}\left(3\Sigma\left(\Sigma + \frac{\Theta}{3}\right) + \frac{2k_{\parallel}^{2}}{a_1^{2}}\right)\left(\mu_{(F)}\overline{\mathcal{V}}_{(F)}{}^{V} + \mathfrak{B}\mathfrak{E}^{V}\right)\\
&\quad \left. - \frac{a_2}{k_{\perp}^{2}}\left(\mu + p - \frac{\Pi}{2} - 3\mathcal{E} + 2N + 3\Sigma\left(\Sigma + \frac{\Theta}{3}\right) + \frac{2k_{\parallel}^{2}}{a_1^{2}}\right)\Omega^{S}\right], \qquad (21)
\end{aligned}
$$

where we have defined the following auxiliary variables

$$
\begin{aligned}
\tilde{k}^{2} &= \frac{k_{\perp}^{2}}{a_2^{2}} + \frac{2k_{\parallel}^{2}}{a_1^{2}},\\
B &= \tilde{k}^{2} + \frac{9}{2}\Sigma^{2} + 3\left(\mathcal{E} + \frac{1}{2}\Pi\right),\\
CB &= \Sigma\left(\Theta - \frac{3\Sigma}{2}\right) - \frac{k_{\perp}^{2}}{a_2^{2}},\\
F &= \Sigma + \frac{2\Theta}{3},\\
\tilde{F} &= \Sigma - \frac{2\Theta}{3},\\
D &= C + \frac{\mu + p - 2\Pi}{B},\\
P &= \frac{2}{k_{\perp}^{2}B}\left(\mu + p - \frac{1}{2}\Pi\right)\left(B + 3\mathcal{E} + \mu + p - \frac{1}{2}\Pi + \mathcal{R} - \frac{k_{\perp}^{2}}{a_2^{2}}\right),\\
S &= \frac{2ia_1}{3k_{\parallel}k_{\perp}^{2}B}\left(\mu + p - \frac{1}{2}\Pi\right)\left(3\Sigma\left(\frac{k_{\perp}^{2}}{a_2^{2}} - \frac{k_{\parallel}^{2}}{a_1^{2}} + 3\Pi\right) + \Theta\left(\tilde{k}^{2} + 3\Pi\right)\right),\\
EB &= \frac{\Sigma}{2}\left(CB - \mathcal{E} - \frac{5}{2}\Pi\right) + \frac{\Theta}{3}\left(\mathcal{E} - \frac{1}{2}\Pi\right),\\
N &= \left(\mu + p - \frac{1}{2}\Pi\right)\left(1 + \frac{2}{a_2^{2}B}\left(\mathcal{R}a_2^{2} - k_{\perp}^{2}\right)\right).
\end{aligned}
$$

7.2. *Even Sector*

As for the even sector, its coefficients satisfy the equations

$$
\begin{aligned}
\dot{\mu}^V_{(F)} =& \left(\frac{\Sigma}{2} - \frac{4\Theta}{3} - \frac{3\Sigma\mu_{(F)}}{2B}\right){\mu_{(F)}}^V - \frac{3\Sigma\mu_{(F)}\mathfrak{B}}{2B}\mathcal{B}^V \\
&+ \frac{ia_1\mu_{(F)}}{2a_2k_\parallel}\left(\left(1 - \frac{3\Sigma}{B}\left(\Sigma + \frac{\Theta}{3}\right)\right)\mu_{(F)} - \frac{2k_\parallel^2}{a_1^2}\right){\mathcal{V}_{(F)}}^S \\
&- \mu_{(F)}\left(\left(1 + \frac{3\Sigma}{2B}\left(\Sigma - \frac{2\Theta}{3}\right)\right)\mu_{(F)} - \frac{k_\perp^2}{a_2^2}\right){\mathcal{V}_{(F)}}^V \\
&+ \frac{3a_2\Sigma\mu_{(F)}}{2}(C-1)\mathcal{E}^T - \frac{a_2B\mu_{(F)}}{2}(C-1)\Sigma^T \\
&- \frac{ia_2k_\parallel\mu_{(F)}}{2a_1}(J-2)\overline{\mathcal{H}}^T - \frac{ia_1\mu_{(F)}}{k_\parallel}\left(\frac{G}{B} + \frac{2k_\parallel^2}{a_1^2}\right)\overline{\Omega}^V \\
&+ \frac{\mathfrak{B}\mu_{(F)}}{2B}\left(2B + 3\Sigma\left(\Sigma - \frac{2\Theta}{3}\right)\right)\overline{\mathfrak{E}}^V, \\
\dot{\mathcal{B}}^V =& \frac{ia_1\mathfrak{B}\mu_{(F)}}{a_2k_\parallel B}\left(B - 3\Sigma\left(\Sigma + \frac{\Theta}{3}\right)\right){\mathcal{V}_{(F)}}^S \\
&- \frac{3\mathfrak{B}\Sigma}{B}{\mu_{(F)}}^V + 3a_2\mathfrak{B}\Sigma C\mathcal{E}^T - a_2\mathfrak{B}BC\Sigma^T - \frac{ia_2k_\parallel\mathfrak{B}J}{a_1}\overline{\mathcal{H}}^T \\
&- \frac{2ia_1\mathfrak{B}G}{k_\parallel B}\overline{\Omega}^V + \left(\frac{3\Sigma\mathfrak{B}^2}{B}\left(\Sigma - \frac{2\Theta}{3}\right) - \frac{k_\perp^2}{a_2^2}\right)\overline{\mathfrak{E}}^V \\
&+ \frac{3}{2}\left(\Sigma - \frac{2\Theta}{3} - \frac{2\Sigma\mathfrak{B}^2}{B}\right)\mathcal{B}^V - \frac{3\mathfrak{B}\Sigma\mu_{(F)}}{B}\left(\Sigma - \frac{2\Theta}{3}\right){\mathcal{V}_{(F)}}^V, \\
\dot{\overline{\mathfrak{E}}}^V =& \frac{2a_2^2k_\parallel^2\mathfrak{B}}{a_1^2k_\perp^2B}{\mu_{(F)}}^V + \frac{2ia_2k_\parallel\mathfrak{B}\mu_{(F)}}{a_1k_\perp^2B}\left(\Sigma + \frac{\Theta}{3}\right){\mathcal{V}_{(F)}}^S \\
&+ \left(\frac{2a_2^2k_\parallel^2\mu_{(F)}}{a_1^2k_\perp^2B}\left(\Sigma - \frac{2\Theta}{3}\right) - \frac{1}{\eta}\right)\mathfrak{B}{\mathcal{V}_{(F)}}^V \\
&+ \left(\frac{\mathcal{R}a_2^2 - k_\perp^2}{a_2B} - \frac{a_2^3\Sigma L}{k_\perp^2}\right)\mathfrak{B}\mathcal{E}^T + \frac{a_2^3\mathfrak{B}BL}{3k_\perp^2}\Sigma^T + \frac{2ia_2^3k_\parallel\mathfrak{B}L}{3a_1k_\perp^2}\overline{\mathcal{H}}^T \\
&+ \frac{4ia_2^2k_\parallel\mathfrak{B}}{a_1k_\perp^2B}(\mu + p + \Pi)\left(\Sigma + \frac{\Theta}{3}\right)\overline{\Omega}^V \\
&- \left(\frac{\Sigma}{2} + \frac{2\Theta}{3} + \frac{1}{\eta} + \frac{2a_2^2k_\parallel^2\mathfrak{B}^2}{a_1^2k_\perp^2B}\left(\Sigma - \frac{2\Theta}{3}\right)\right)\overline{\mathfrak{E}}^V \\

8. Discussion and Outlook

From Eqs. (19)-(23), which describe the evolution of the electromagnetic fields, we see that mechanisms for generating magnetic fields from perturbations in variables related to gravitational effects, such as the magnetic part of the Weyl tensor, indeed seem to exist. These mechanisms can be explicitly seen when solving the system numerically.[12] However, the mechanisms depend fundamentally on $\mathfrak{B}$ being non-zero, since the electromagnetic evolution equations decouple completely from the other first order equations when $\mathfrak{B} = 0$. Since a background anisotropy is needed to have a non-zero B-field, these mechanisms are therefore crucially dependent on the LRS nature of the zeroth order solution, at least to first order in the perturbations.

As we were, in the end, able to observe mechanisms for generating magnetic field perturbations, an interesting question is whether or not these results can be used to shed some light on the origin of the observed large scale cosmic magnetic fields. However, determining the viability of these mechanisms as candidates for amplifying primordial magnetic seeds would require a deeper investigation regarding the initial conditions and the primordial seed spectra, and is therefore left for future work.

Quintessence fields, or scalar fields minimally coupled to gravity, are considered to be viable candidates for dark energy. It is well-known that some classes of modified theories of gravity can be recast as Einstein's general relativity with a minimally coupled scalar field, through conformal transformation. The 'universe' described by the initial and the final actions are referred to as the Jordan and Einstein frames, respectively. Although these conformally connected frames are mathematically equivalent, the equations of motion in these two frames may describe drastically different physical scenarios. Depending upon the choice of the Jordan frame action (or equivalently the scalar field potential in Einstein frame) it is possible that while the Einstein frame expands, the Jordan frame collapses. We classify quintessence models in the Einstein frame that are dual to $f(R)$ gravity theories in the Jordan frame, based on whether they possess such expansion-collapse duality. We derive a general condition for expansion-collapse duality, applicable to quintessence models with arbitrary time-dependent equations of state. The condition also takes into account the presence of other components in the Einstein frame universe. Such expansion-collapse duality between these conformally connected frames can lead to an effective description of a collapsing universe in terms of an expanding one, which is a topic of further exploration.

Keywords: $f(R)$ theories; quintessence; dark energy; Einstein and Jordan frames

1. Introduction

The quintessence model, or scalar fields minimally coupled to gravity, is a widely used implementation of dark energy in Einstein's gravity.[1–5] As an alternative to the cosmological constant model, quintessence fields (φ) can provide a simple dynamical description of the late-time acceleration of the universe. The equation of state of quintessence (w_φ) can violate the strong energy condition if the potential term ($V(\varphi)$) is set to be sufficiently flat. In general, w_φ can vary with time. One can introduce the time-dependence in w_φ by postulating a parameterization of the form $w_\varphi(a; w_0, w_1, \ldots)$,[6–10] where a is the scale factor and $w_0, w_1 \ldots$ are constant parameters of the model, usually constrained from different cosmological observations.

It is also well-known that some classes of modified theories of gravity can provide a dual description of minimally coupled scalar fields in Einstein gravity, in a conformally connected frame.[11–14] $f(R)$ theory is a simple modification of Einstein gravity, where the Ricci scalar (R) in the Einstein–Hilbert action is replaced with an arbitrary function of the Ricci scalar ($f(R)$) (for reviews, see [11, 12]). The

'universe' governed by the $f(R)$ theory is referred to as the *Jordan frame universe*. A conformal transformation allows for the Jordan frame action to be written as the Einstein–Hilbert action with a quintessence field (for reviews, see [11, 14, 15]). The 'universe' described by the latter action is referred to as the *Einstein frame universe*. Thus, one may consider that dark energy, as implemented by a quintessence field in Einstein gravity, has an equivalent description in terms of a pure $f(R)$ gravity theory in the conformally connected Jordan frame.

Although Einstein and Jordan frames are mathematically equivalent, the field equations in these two frames may describe drastically different universes. In this paper, we are interested in quintessence–$f(R)$ pairs for which, while the Einstein frame universe expands, the Jordan frame universe collapses. We derive a simple condition for such expansion-collapse duality for quintessence models with arbitrary, time-varying equation of state parameters. The condition is general enough to accommodate any other components in the Einstein frame, such as dust or radiation. As an example, we study the quintessence model with logarithmic equation of state[6, 10, 16] ($w_\varphi(a) = w_0 - w' \ln a$) and discuss the possibility of the expansion-collapse duality in the presence of non-relativistic matter and spatial curvature component.

A quintessence model–$f(R)$ theory pair with the expansion-collapse duality essentially provides a description of an expanding universe in terms of a collapsing one. This map between expanding and collapsing geometries may lead to potentially interesting results; for example, introducing perturbation in the background of FRW metric one can study how the evolution of perturbations in the expanding frame corresponds to the perturbations in the collapsing one. This will be pursued elsewhere.

This paper is organized as follows. In Sec. 2 we start with a brief review of the Jordan frame–Einstein frame correspondence in the context of $f(R)$ gravity. Our main result, the expansion-collapse duality condition is presented in Sec. 3. In Sec. 4 we conclude with a summary and discussion.

2. $f(R)$ gravity and quintessence: Einstein and Jordan frames

Let us consider that the Jordan frame universe is governed by the action of an $f(R)$ theory,

$$\mathcal{S}_J = \frac{1}{2\kappa^2} \int \mathrm{d}^4x \sqrt{-g} f(R), \tag{1}$$

where $\kappa = 8\pi G$, R is the Ricci scalar in Jordan frame, $f(R)$ is an arbitrary function of R. The Jordan frame metric $g_{\mu\nu}$ is the spatially flat FRW metric, i.e., $g_{\mu\nu} \equiv \mathrm{diag}(-1, a^2, a^2, a^2)$, and $a(t)$ is the scale factor in the Jordan frame (see [11, 12] for general reviews on $f(R)$ theories). One can then define a new metric using a conformal transformation,

$$\tilde{g}_{\mu\nu} = \Omega^2(x) g_{\mu\nu}. \tag{2}$$

If the conformal parameter Ω^2 is taken to be $\Omega^2 = \partial f/\partial R = F(R)$, then the same Jordan frame action can be recast in terms of the new metric $\tilde{g}_{\mu\nu}$ as,

$$\mathcal{S}_E = \int \mathrm{d}^4x\sqrt{-\tilde{g}}\frac{1}{2\kappa^2}\tilde{R} - \int \mathrm{d}^4x\sqrt{-\tilde{g}}\left[\frac{1}{2}\tilde{g}^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi + V(\varphi)\right], \tag{3}$$

where $\tilde{R}$ is the Ricci scalar in Einstein frame[17] and

$$\varphi = \frac{\sqrt{6}}{2\kappa}\ln F, \tag{4a}$$

$$V = \frac{1}{2\kappa^2}\frac{FR - f}{F^2}. \tag{4b}$$

The first part of the action in (3) is the Einstein–Hilbert action with respect to the metric $\tilde{g}_{\mu\nu}$, the second part is the action of a minimally coupled scalar field φ, with potential V. Equation (3) is the action in the Einstein frame universe.

On the other hand, if we consider the Einstein frame to be the physical frame, then the scalar field action in (3) can play the role of the quintessence model of dark energy. The equation of state parameter of φ can be computed as[5,9]

$$w_\varphi = \frac{P_\varphi}{\rho_\varphi} = \frac{\frac{1}{2}\dot{\varphi}^2 - V}{\frac{1}{2}\dot{\varphi}^2 + V}, \tag{5}$$

where P_φ and ρ_φ are the pressure and energy density associated with the quintessence field φ. As we can see from (5), for sufficiently flat potential ($V \gg \dot{\varphi}^2$) w_φ can become $w_\varphi < -1/3$, allowing for the scalar field to drive the acceleration in the Einstein frame.

As a simple example, let us consider a quintessence model with constant equation of state parameter w_φ. The quintessence potential in this case takes the form[16]

$$V(\varphi) = \frac{1}{2}(1-w)\rho_0 \exp\left(-\sqrt{3\kappa^2(1+w)}(\varphi)\right). \tag{6}$$

One can then solve the differential equation (4b), using (4a) and (6), and reconstruct the correspond $f(R)$ action in the Jordan frame as (see [18] for details)

$$f(R) = C_1R - A_1C_1^b \text{ or} \tag{7a}$$

$$f(R) = \frac{b-1}{b(A_1b)^{\frac{1}{b-1}}}R^{\frac{b}{b-1}}, \tag{7b}$$

where, $A_1 = \kappa^2\rho_0(1-w)$, $b = -\frac{3}{\sqrt{2}}\sqrt{1+w} + 2$.

In general, the equation of state of the quintessence field can be a function of time. One usually starts with a parameterized time-dependent ansatz for w_φ and then constrains the parameters of the model from cosmological observations (for different parameterizations of equation of state see [6–10]). In this work, we consider the logarithmic parameterization as an example of time-dependent equation of state ([6, 16]), given by

$$w_\varphi(\tilde{a}) = w_0 - w'\ln\tilde{a}, \tag{8}$$

where $\tilde{a}$ is the scale factor in Einstein frame, (w_0, w') are two constant parameters of the model. The values of (w_0, w') are constrained from different cosmological observations in [10, 16]. The quintessence field Φ for this model can be solved as a function of the scale factor as,[16]

$$\varphi(\tilde{a}) = \Phi(\tilde{a}) - \Phi_0 = \frac{2}{\sqrt{3}} \frac{1}{\kappa w'} \left[(1 + w_0)^{\frac{3}{2}} - (1 + w_0 - w' \ln \tilde{a})^{\frac{3}{2}} \right], \tag{9}$$

where Φ_0 is the value of the scalar field at current Einstein frame, i.e. at $\tilde{a} = 1$. We take $w' < 0$ to ensure that the field remains real valued in the late time limit of the Einstein frame $\tilde{a} \to \infty$. In the paper,[18] we used analytical approximations to reconstruct $F(R)$ corresponding to this quintessence model in two parts. First, we derived a perturbative solution in the small R limit, which is applicable in the near future of the Einstein frame. Second, we also obtained a non-perturbative, asymptotic form of $F(R)$ in the late time limit of the Einstein frame. However, as we will see later, the condition for the expansion-collapse duality does not directly depend on the form of the $f(R)$ function. We will hence not discuss the reconstruction of the Jordan frame action here. More details in this regard can be found in [18].

Having summarized the key features of the Einstein-Jordan frame correspondence, we now discuss the main results in the following section.

3. Expansion-collapse duality

A pure $f(R)$ action in the Jordan frame (1) gives rise to only a quintessence field in Einstein gravity in the Einstein frame (3). In order to incorporate the presence of any other matter components in the Einstein frame, the Jordan frame action (3) must be modified. Moreover, since we consider the Einstein frame to be the physical frame, we want the field equations in the Einstein frame to lead to the usual Friedmann equations. Essentially, we want the Einstein frame action to have the form

$$\begin{aligned} \mathcal{S}_E = & \int d^4x \sqrt{-\tilde{g}} \frac{1}{2\kappa^2} \tilde{R} - \int d^4x \sqrt{-\tilde{g}} \left[\frac{1}{2} \tilde{g}^{\mu\nu} \partial_\mu \varphi \partial_\nu \varphi + V(\varphi) \right] \\ & + \int d^4x \sqrt{-\tilde{g}} \mathcal{L}_{\mathrm{M}}(\psi_{\mathrm{M}}; \tilde{g}_{\mu\nu}), \end{aligned} \tag{10}$$

where $\mathcal{L}_{\mathrm{M}}(\psi_{\mathrm{M}}; \tilde{g}_{\mu\nu})$ is the Lagrangian density of some matter field ψ_{M}, which is independent of the quintessence field φ. In order to arrive at the Einstein frame action (10), we postulate the following Jordan frame action in the presence of matter,

$$\mathcal{S}_J = \frac{1}{2\kappa^2} \int \mathrm{d}^4x \sqrt{-g} f(R) + \int \mathrm{d}^4x \sqrt{-g} F^2(R) \mathcal{L}_{\mathrm{M}}(\psi_{\mathrm{M}}; F(R) g_{\mu\nu}). \tag{11}$$

It can be easily verified that the conformal transformation $\tilde{g}_{\mu\nu} = F g_{\mu\nu}$ gives back the desired Einstein frame action (10). It is to be noted that in the modified Jordan frame action (11), the matter field ψ_{M} is now non-minimally coupled to gravity

through the term $F(R)$. However, as we will see now, the exact form of the Jordan frame action is not required in order to predict the expansion-collapse duality.

The Einstein frame action of the form (10) leads to the Friedmann equation

$$\tilde{H}^2 = \frac{\kappa^2}{3}\left(\rho_\varphi + \sum \rho_I\right), \tag{12}$$

where $\tilde{H} = (\mathrm{d}\tilde{a}/\mathrm{d}\tilde{t})/\tilde{a}$ is the Einstein frame Hubble parameter, $\tilde{t}$ is the coordinate time in the Einstein frame, $\sum \rho_I$ denotes the summation of energy densities of all the component in the Einstein frame apart from φ. Noting that the Einstein frame metric is also a spatially flat FRW metric, $\tilde{g}_{\mu\nu} \equiv \mathrm{diag}(-1, \tilde{a}^2, \tilde{a}^2, \tilde{a}^2)$, one can relate the scale factors in the Jordan frame (a) and Einstein frame ($\tilde{a}$) as (see, for example, [11])

$$a = \frac{\tilde{a}}{\Omega} = \frac{\tilde{a}}{\sqrt{F}}. \tag{13}$$

Using (12) in (13), we find derivative of a with respect to $\tilde{a}$ to be (see [18] for details),

$$\frac{\mathrm{d}a}{\mathrm{d}\tilde{a}} = \frac{\mathrm{d}}{\mathrm{d}\tilde{a}}\left(\frac{\tilde{a}}{\sqrt{F}}\right) = F^{-1/2}\left(1 - \kappa\sqrt{1 + w_\varphi(\tilde{a})}\sqrt{\frac{\rho_\varphi}{6\tilde{H}^2}}\right). \tag{14}$$

As it can be seen from above, the sign of $\mathrm{d}a/\mathrm{d}\tilde{a}$ is determined by the term inside the parenthesis. The condition for $\mathrm{d}a/\mathrm{d}\tilde{a} < 0$, or expansion-collapse duality becomes

$$w_\varphi(\tilde{a}) > \mathcal{C}(\tilde{a}) \tag{15a}$$

$$\mathcal{C}(\tilde{a}) = \frac{6\tilde{H}^2}{\kappa^2\rho_\varphi(\tilde{a})} - 1. \tag{15b}$$

Thus, the condition of expansion-collapse duality between Einstein-Jordan frames can be written as a threshold imposed on the equation of state of the quintessence field φ, even when there are other components in the Einstein frame. The Hubble parameter ($\tilde{H}$) incorporates the contribution from all the other components present in the Einstein frame universe. Depending upon whether (15a) is satisfied, there might be a range of $\tilde{a}$, or possibly multiple ranges of $\tilde{a}$, during which the Jordan frame collapses while the Einstein frame expands. The possible 'turn around' of the Jordan frame ($\mathrm{d}a/\mathrm{d}\tilde{a} = 0$) can be determined by setting

$$w_\varphi(\tilde{a}) = \mathcal{C}(\tilde{a}), \tag{16}$$

provided such a solution does exist. Starting with the relation between Hubble parameters in the Jordan (H) and Einstein ($\tilde{H}$) frames (see [11]),

$$H = \sqrt{F}\tilde{H} - \frac{1}{2\sqrt{F}}\frac{\mathrm{d}F}{\mathrm{d}\tilde{t}}, \tag{17}$$

one can explicitly show that at the 'turn-around' of the Jordan frame, the Jordan frame Hubble parameter indeed vanishes, $H_{\text{turn-around}} = 0$.

It is also to be noted that the condition for expansion-collapse duality has a significantly simple form. Given an equation of state parameter w_φ, one only requires the knowledge of the energy densities of the components in the Einstein frame in order to check whether the condition is satisfied. The form of the Jordan frame action, even the solution of the field $\varphi(\tilde{a})$ or potential $V(\varphi)$ do not appear explicitly in the condition. Thus, as mentioned before, the reconstruction of Jordan frame action is not required in order to predict the expansion-collapse duality for a quintessence-$f(R)$ pair.

Let us now consider the example of quintessence model with logarithmic equation of state (8), where the Einstein frame universe also contains non-relativistic matter or dust. The condition (15) in this case becomes (see [18])

$$w_\varphi(\tilde{a}) > \mathcal{C}(\tilde{a}), \text{ where} \tag{18a}$$

$$w_\varphi(\tilde{a}) = w_0 - w' \ln \tilde{a}, \tag{18b}$$

$$\mathcal{C}(\tilde{a}) = 1 + 2\frac{\Omega_{m0}}{\Omega_{\varphi 0}} \exp\left(3w_0 \ln \tilde{a} - \frac{3}{2}w'(\ln \tilde{a})^2\right), \tag{18c}$$

Ω_{m0}, $\Omega_{\varphi 0}$ are the density parameters of dust and φ at $\tilde{a} = 1$. The evolution of the Jordan frame scale factor $a(\tilde{a})$ is plotted in Fig. 1(a). In the absence of dust ($\Omega_{m0} = 0$), the Jordan frame initially expands with the Einstein frame. The 'turn around' in the Jordan frame occurs at $\tilde{a} = \exp\left((w_0 - 1)/w'\right)$. In the late time limit of the Einstein frame ($\tilde{a} \to \infty$), the Jordan frame universe completely collapses ($a \to 0$). However, as the fraction of dust in the Einstein frame increases, the Jordan frame collapse staggers. For a realistic value of dust to dark energy ratio ($\Omega_{m0}/\Omega_{\varphi 0} \sim 0.3/0.7$), the Jordan frame does not collapse and the Jordan frame scale factor always increases monotonically with respect to that of the Einstein frame. In fact, it can be argued that in the presence of dust, quintessence model with observationally consistent logarithmic equation of state does not lead to the expansion-collapse duality (see [18]).

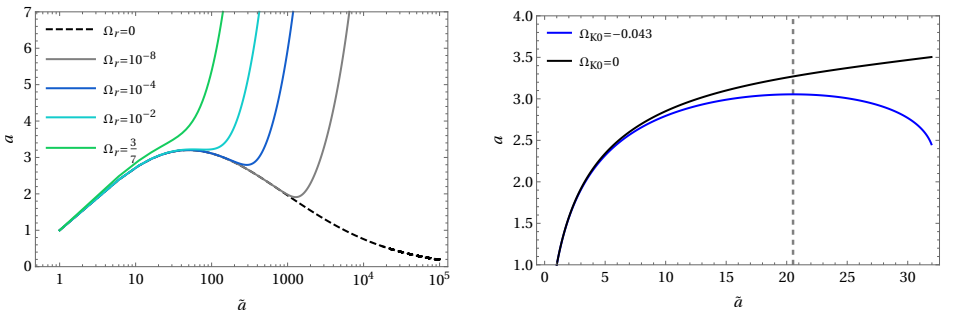
Finally, let us consider the effect of spatial curvature in the Jordan frame collapse for the same quintessence model. In the presence of positive spatial curvature and dust, the condition (15) becomes (see [18])

$$w_\varphi(\tilde{a}) > \mathcal{C}(\tilde{a}), \text{ where} \tag{19a}$$

$$w_\varphi(\tilde{a}) = w_0 - w' \ln \tilde{a}, \tag{19b}$$

$$\begin{aligned}\mathcal{C}(\tilde{a}) = {} & 1 + 2\frac{\Omega_{m0}}{\Omega_{\varphi 0}} \exp\left(3w_0 \ln \tilde{a} - \frac{3}{2}w'(\ln \tilde{a})^2\right) \\ & + 2\frac{\Omega_{K0}}{\Omega_{\varphi 0}} \exp\left((1 + 3w_0) \ln \tilde{a} - \frac{3}{2}w'(\ln \tilde{a})^2\right),\end{aligned} \tag{19c}$$

where $\Omega_K = -K/(\tilde{a}\tilde{H})^2 = \Omega_{K0}\tilde{a}^{-2}$, K is the spatial curvature parameter in the FRW metric. The expansion-collapse duality condition in this case is plotted in Fig. 2. We can see from (19c), the contribution from positive spatial curvature,[19] or negative Ω_{K0}, brings down the threshold $\mathcal{C}$, allowing for w_φ to eventually



(a) (b)

Fig. 1. The scale factor in the Jordan frame (a) is plotted as a function of the scale factor in the Einstein frame ($\tilde{a}$). The quintessence parameters are taken to be $(w_0, w') = (-0.87, -0.48)$, from [16]. (a) Jordan frame collapse in the presence of dust, without spatial curvature. $\Omega_r = \Omega_{m0}/\Omega_{\varphi 0}$ is the ratio of the density parameter of dust to that of the quintessence field, at current Einstein frame universe. In the absence of dust ($\Omega_r = 0$), the Jordan frame scale factor $a \to 0$ while the Einstein frame scale factor $\tilde{a} \to \infty$. However, in the presence of dust ($\Omega_r \neq 0$), the Jordan frame collapse eventually comes to a stop and the Jordan frame starts to expand again. For a realistic value of $\Omega_r = \Omega_{m0}/\Omega_{\varphi 0} \sim 0.3/0.7$, the Jordan frame does not go through a collapsing phase, it always expands monotonically with the Einstein frame. (b) Jordan frame collapse in the presence of dust and spatial curvature. In the presence of a small positive spatial curvature ($\Omega_{K0} = -0.043, \Omega_{m0} = 0.315,\ \Omega_{\varphi 0} = .728$), the Jordan frame collapse can be recovered (blue curve). The Jordan frame universe goes through a turn-around at $\tilde{a} \sim 20.52$ (represented by the vertical dashed line) after which the Jordan frame scale factor starts to decrease.

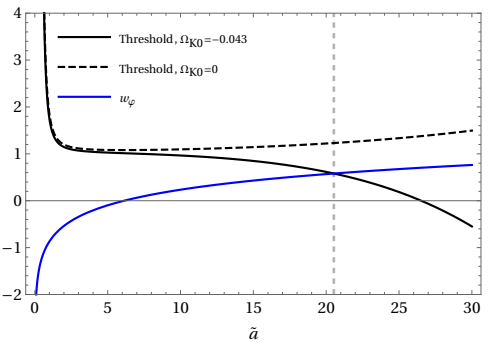


Fig. 2. The equation of state parameter w_φ and the threshold $\mathcal{C}$ (as in (19c)) are plotted as functions of the Einstein frame scale factor. The choice of parameters are: $(w_0, w') = (-0.87, -0.48)$ (from [16]), $\Omega_{m0} = 0.315$, $\Omega_{\varphi 0} = .728$, $\Omega_{K0} = -.043$ (from [19]). The 'turn-around' in the Jordan frame occurs at $w_\varphi(\tilde{a}) = \mathcal{C}(\tilde{a})$ (represented by the vertical dashed line), after which $(w_\varphi > \mathcal{C})$ the Jordan frame collapses. The plots demonstrate that in the absence of spatial curvature Ω_{K0}, w_φ (blue plot) never reaches $\mathcal{C}$ (black dashed plot), hence the Jordan frame collapse never begins. However, even a small positive spatial curvature ($\Omega_{K0} = -.043$) brings down the threshold $\mathcal{C}$ (black plot) enough for w_φ to overcome it eventually. For this case the 'turn-around' ($w_\varphi = \mathcal{C}$) occurs at $\tilde{a} \sim 20.52$, the Jordan frame starts to collapse afterwards.

overcome it. Therefore, the positive spatial curvature may recover the Jordan frame collapse in the presence of dust, at least for a finite duration. The evolution of the Jordan frame scale factor in this case is plotted in Fig. 1(b).

4. Summary and discussion

Dark energy, implemented by a quintessence field in the Einstein frame, can effectively be described by an $f(R)$ gravity theory in the Jordan frame. In this paper we classify quintessence models based on whether they lead to expansion-collapse duality between Einstein and Jordan frames, i.e., while the Einstein frame expands, the Jordan frame collapses or *vice versa*. We show that in order for the quintessence–$f(R)$ gravity pair to have such a feature, the equation of state of the quintessence must overcome a certain threshold. We derive a general condition for the expansion-collapse duality which is applicable to quintessence models with arbitrary, time-dependent equation of state parameters. The condition also holds true in the presence of any other components in the Einstein frame.

As an example, we consider the quintessence model with logarithmic equation of state parameter. We show that if the quintessence field is the sole component in the Einstein frame, this model does lead to the expansion-collapse duality, in fact the Jordan frame universe completely collapses in the late time limit of the Einstein frame. However, even the subdominant presence of dust in the Einstein frame prevents the Jordan frame collapse. If we also consider a small positive spatial curvature in the universe, the Jordan frame collapse can be recovered for a finite duration.

In general, the map between expanding and collapsing geometries at the field equation level may have potentially interesting implications on the cosmological perturbations in these frames. Further studies can reveal how perturbation in a collapsing universe corresponds to the perturbations in an expanding universe.

Space Research Institute (IKI), Russian Academy of Sciences Profsoyuznaya str. 84/32, Moscow, 117997, Russia

The Dark Energy became now a commonly-accepted paradigm of cosmology, but its physical essence remains absolutely unknown, and its numerical values are drastically different in the early and modern Universe. The Dark Energy is usually introduced in the contemporary literature either by postulating some additional terms in the Lagrangians or by employing the empirical equations of state. In the present work, we try to look at this problem from a more general point of view, namely, employing the quantum-mechanical uncertainty relation between the time and energy in the Mandelstam–Tamm form, which is appropriate for the long-term evolution of quantum systems. This leads us to the time-dependent effective Lambda-term, decaying as $1/t$. The corresponding cosmological model possesses a number of quite appealing features: (1) While in the standard cosmology there are a few very different expansion stages (governed by the Lambda-term, radiation, dust-like matter, and Lambda-term again), our model provides a universal description of the entire evolution of the Universe by the same "quasi-exponential" function. (2) As follows from the analysis of causal structure, the present-day cosmological horizon comprises a single domain developing from the Big Bang. Therefore, the problems of homogeneity and isotropy of the matter, the absence of topological defects, etc. should be naturally resolved. (3) At last, our model naturally explains the observed approximately flat 3D space, i.e., solution with zero curvature is formed "dynamically", starting from the arbitrary initial conditions.

Keywords: Dark Energy; Inflation; Uncertainty relation.

1. Introduction

The concept of Dark Energy (or the effective Λ-term in Einstein equations) represents now a commonly-accepted paradigm both in the cosmology of early and present-day Universe. A crucial role of the effective Λ-term in the early Universe was recognized in the early 1980s, when it was introduced as a driving force of the inflationary stage of the cosmological evolution;[1] while its significance at the present time was recognized in the very end of 1990s, when the accelerated expansion of the Universe was observed.[2] However, despite an active involvement into a huge number of theoretical works, a physical nature of the Dark Energy remains unknown. Besides, it is unclear why densities of the Dark Energy in the early and modern Universe are absolutely different.

In fact, the first inflationary models of the early Universe, discussed in the 1980s, were formulated on the quite solid physical basis steaming from the elementary-particle physics. Namely, it was assumed that the effective Λ-term was associated with a nonzero value of the potential energy of the Higgs field in its symmetry-broken state formed after a phase transition in the expanding and cooling Universe.[3] Unfortunately, a further research in this direction failed to derive a reasonable value of the Λ-term from the existing models of elementary particles, such as the electroweak or Grand Unification theories. As a result, a subsequent development of the inflationary concept of the early Universe was based mostly on the empirical Lagrangians, where some additional terms with a scalar field (the so-called inflaton) were added quite arbitrarily, without any attempts to associate them with the underlying theory of elementary particles. At last, when the accelerated expansion of the contemporary Universe was observed in the late 1990s, and it became necessary to introduce the Λ-term (or Dark Energy) into the "standard" cosmological model, this was done again only in terms of the empirical equations of state of the cosmological matter or, in a more elaborate theoretical approach, by means of the empirical Lagrangians similar to the inflationary ones.

In view of the above circumstances, there is now a clear need for a more solid conceptual basis for explanation of the Λ-term, i.e., stemming from other well-established physical laws and theories. One such approach is well known: this is the so-called Sakharov induced gravity,[4] going back to 1960s. The cornerstone of this concept is that the vacuum modes of the fundamental quantum fields (e.g., electroweak, chromodynamic, etc.) are perturbed if the space–time is curved. As a result, the effective Lagrangian acquires the additional terms, which are proportional to the various degrees of the curvature $\mathcal{R}$.[a] Thereby, the first-order term will represent the standard Einstein–Hilbert part of the Lagrangian (apart from the Λ-term); the term of zero order will be just the effective ("induced") Λ-term; and there should be also the higher-order terms of $\mathcal{R}$. About a decade later, this idea was implemented in the inflationary model by Starobinsky[5] and later evolved into a wide range of the so-called $f(\mathcal{R})$ theories. (However, it should be kept in mind that the ingredient responsible for the inflation in such theories is usually the quadratic rather than zero-order term of the curvature.) Unfortunately, since we do not have the ultimate theory of elementary particles, the exact form of the function f cannot be derived, and it is commonly specified "by hand", so that the required cosmological predictions can be obtained. From this point of view, the most of $f(\mathcal{R})$ theories are based on the same type of Lagrangians with arbitrary additional terms (but without the additional scalar fields); for a review, see Refs. 6 and 7.

The aim of the present paper is to discuss yet another conceivable universal approach to the emergence of the effective Λ-term, namely, based on the quantum-mechanical uncertainty relation between the time and energy. Let us mention that

[a]Strictly speaking, the Lagrangian can contain also a number of other invariants composed of the curvature tensor.

some qualitative ideas about a probable role of the uncertainty relation in cosmology were put forward some time ago by Coe,[8] but the corresponding quantitative treatment looked unreasonable. Here, we shall discuss another development of this idea, performed in our recent works.[9–11]

2. Basic Equations

2.1. *Uncertainty Relations*

As is known, the uncertainty relations are one of cornerstones of quantum mechanics. In the case of canonically conjugate variables (e.g., the coordinate x and momentum p_x), they can be derived in the rigorous and universal way by averaging the corresponding quantum commutators. This leads to the inequalities like $\Delta p_x \Delta x \geq \hbar/2$, and similarly for other pairs of conjugate quantities. The uncertainty relations are most widely employed in the problem of quantum measurements. However, they can be sometimes useful also in dealing with other properties of the quantum systems: a well-known example—which is considered in many textbooks—is estimating parameters of the ground state of a hydrogen atom.

Meanwhile, it should be kept in mind that the uncertainty relation between the time t and energy E is a quite exceptional case, because the time and energy are not the canonically conjugate operators in the non-relativistic quantum mechanics (instead, t is the independent variable in Schrödinger equation). So, the time–energy uncertainty relation is commonly derived by various "Gedankenexperiments"; and the resulting coefficients in the right-hand side, in general, can be different:

$$\Delta E \Delta t \geq C_{\mathrm{UR}} \hbar/2, \tag{1}$$

where C_{UR} is the numerical coefficient on the order of unity ('UR' implies here the uncertainty relation). In the standard Heisenberg's case, pertinent to the problem of measurements, $C_{\mathrm{UR}} = 1$. On the other hand, the case of the long-term evolution of a quantum system was considered by Mandelstam and Tamm[12] in 1945, and it was found that in this situation $C_{\mathrm{UR}} = \pi$. It is interesting that this work remained almost unknown for a few decades and attracted considerable attention of the scientific community only in the recent time; for more details, see Ref. 13. So, it is widely used now in such branches of physics as quantum optics, quantum information processing, etc.; and it was the aim of our recent studies[9–11] to employ it in cosmology.

2.2. *The Modified Friedmann Equation*

The starting point of our consideration is the standard Robertson–Walker cosmological metric:

$$ds^2 = c^2 dt^2 - R^2(t) \left[\frac{dr^2}{1 - kr^2} + r^2 (d\theta^2 + \sin^2\theta \, d\varphi^2) \right], \tag{2}$$

where t is time, r, θ, and φ are the dimensionless spherical coordinates, R is the scale factor of the Universe, c is the speed of light, and the coefficient k equals 1, 0, and –1 for the closed, flat, and open Universe.

Temporal evolution of this metric is governed by the well-known Friedmann equation (e.g., Ref. 14):

$$H^2 \equiv \left(\frac{\dot{R}}{R}\right)^2 = \frac{8\pi G}{3c^2}\,\rho - kc^2\frac{1}{R^2} + \frac{c^2}{3}\,\Lambda\,, \tag{3}$$

where H is the Hubble parameter, ρ is the energy density of matter in the Universe (both visible and dark), G and Λ are the gravitational and cosmological constants.

It is well known that Λ-term in the right-hand side of Eq. (3) can be formally attributed to the vacuum energy density $\rho_{\rm v}$:

$$\Lambda = \frac{8\pi G\rho_{\rm v}}{c^4}\,; \tag{4}$$

and then it becomes reasonable to estimate the vacuum energy from the uncertainty relation (1) with the equality sign, assuming that Δt is the total period of the cosmological evolution t. However, since the uncertainty relation should be applied to the energy rather than the energy density, it is necessary to specify the characteristic spatial volume; the most evident choice being the Planck volume $l_{\rm P}^3$ (where $l_{\rm P} = \sqrt{G\hbar/c^3}$ is the Planck length).[b]

Consequently, we arrive at the following effective Λ-term:

$$\Lambda(t) = \frac{4\pi C_{\rm UR}}{c\,l_{\rm P}}\,\frac{1}{t}\,; \tag{5}$$

and its substitution into Eq. (3) leads to the modified Friedmann equation:

$$H^2 \equiv \left(\frac{\dot{R}}{R}\right)^2 = \frac{8\pi G}{3c^2}\,\rho - kc^2\frac{1}{R^2} + \frac{4\pi C_{\rm UR}}{3\tau}\,\frac{1}{t}\,, \tag{6}$$

where $\tau = l_{\rm P}/c = \sqrt{G\hbar/c^5}$ is the Planck time.

A very unusual feature of this equation is the explicit dependence on time in the right-hand side. As far as we know, such situation was never considered in cosmology. However, as will be seen from the subsequent treatment, this time dependence does not result in any anomalous behavior.

The numerical coefficient $C_{\rm UR}$ remains essentially unknown. Since the uncertainty relation (1) was used with the equality sign, this coefficient can actually take the values from π up to infinity (but it cannot be less than π).

[b] As was pointed out by Starobinsky (private communication), yet another conceivable choice for the characteristic spatial scale might be the size of the cosmological horizon. However, as will be discussed below in Sec. 5, this option looks less reasonable.

3. The Simplest Solution and Its Main Properties

To get the simplest solution of Eq. (6), let us assume that the three-dimensional space is perfectly flat (i.e., $k \equiv 0$), and the energy density of ordinary matter is negligible (i.e., $\rho = 0$). Then, the resulting equation is easily integrated, and the solution can be written as

$$R(t) = R^* \exp\left[\sqrt{\frac{16\pi C_{\mathrm{UR}}}{3}}\sqrt{\frac{t}{\tau}}\,\right], \tag{7}$$

where $R^* = R(0)$ is the constant of integration; and we consider only the case of $R(t)$ increasing with time, i.e., corresponding to the expanding Universe. (In principle, there may be also a contracting solution, with minus sign in the argument of the exponential function.)

So, even the simplest solution (7) suggests us an interesting version of the cosmological model, outlined in Fig. 1. Instead of the standard model, composed of the four very different stages (namely, the inflationary one with exponential expansion, then the stages dominated by radiation and non-relativistic matter with power-like expansion, and finally the modern exponential stage), the uncertainty-mediated model describes everything by the universal "quasi-exponential" function (7). The corresponding Hubble parameter gradually decays with time as $1/\sqrt{t}$.

The age of the Universe T (i.e., the period from $t = 0$ to the present time) can be easily found from Eq. (6), remembering that $k \equiv 0$ and $\rho = 0$:

$$H_0^2 = \frac{4\pi C_{\mathrm{UR}}}{3\tau}\,\frac{1}{T}\,. \tag{8}$$

Next, taking into account that age of the Universe in the standard cosmological model T^* is commonly estimated as $1/H_0$, we get:

$$T \approx (T^*/\tau)\,T^*, \tag{9}$$

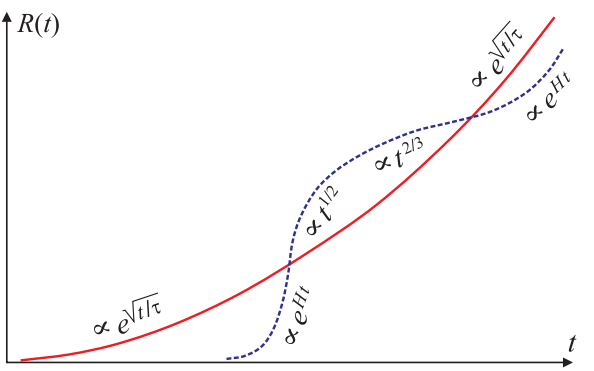

Fig. 1. Temporal variation of the scale factor of the Universe $R(t)$ in the standard cosmological model (dashed blue curve) and in the proposed uncertainty-mediated model (solid red curve).

if the numerical coefficient C_{UR} is assumed to be on the order of unity. Since $T^* \approx 4{\cdot}10^{17}\,\mathrm{s}$ and $\tau = 5{\cdot}10^{-44}\,\mathrm{s}$, this age in the proposed model will be greater than in the standard cosmology by the huge factor $(T^*/\tau) \approx 10^{61}$.

Nevertheless, this disagreement should not be a crucial failure of our model. Really, the "standard" age of the Universe T^* is measured from the onset of the hot Big Bang. If its evolution is supplemented by the preceding inflationary stage, this age will formally tend to infinity (because the expansion function e^{Ht} starts at $t \to -\infty$). So, the huge age of the Universe in the uncertainty-mediated model, described by the "universal" function (7), is not surprising.

4. The Model of Inflation

As is known, emergence of the inflationary paradigm in the early 1980s was caused by the inability of the "old" cosmological model—governed by radiation and ordinary matter—to resolve a few conceptual problems, such as a homogeneity and isotropy of the observed Universe, the absence of the topological defects, a surprising flatness of the three-dimensional space, etc. A presence of the early stage with very fast expansion (usually, the exponential one) was postulated as a universal remedy to treat all these issues.[1,3] So, it is interesting to check if the "quasi-exponential" expansion (7) can resolve the above-listed problems.

4.1. *Causal Structure of the Space–Time*

The problems of homogeneity and isotropy, as well as the absence of topological defects are closely related to the causal structure of the space–time under consideration. From our point of view, the most convenient way to analyze this issue is using the conformal diagrams.[15] Namely, in terms of the conformal time

$$\eta = \int dt/R(t) \tag{10}$$

the light rays in the curved Universe will be presented by the straight lines inclined at $\pm\pi/4$; and the causality (light) cones will look like the regular triangles, as shown in Fig. 2.

As distinct from the previous formulas, the null point of time was shifted here to the instant of observation; $\eta = -\eta_0$ corresponds to the "birth" of the Universe; and $\eta = -\eta^*$ is the instant at which the Universe is observed. Particularly, this may be the instant of plasma recombination—when the matter became transparent—if we speak about the observations in electromagnetic waves; or this may be the instant of symmetry-breaking phase transition of Higgs fields—when the ordinary matter was formed—if we speak about formation of the topological defects (such as the domain walls, cosmic strings, or monopoles, depending on the symmetry group involved). Accordingly, x_{p} is the size of the domain observable at the present time, and x_{f} is the size of the domain whose state can be "equilibrated" (causally connected) during the preceding cosmological evolution.

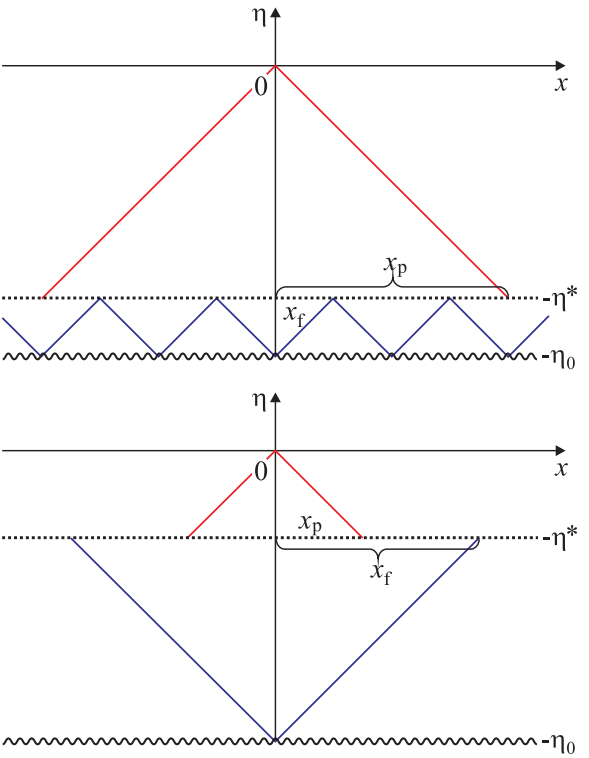

Fig. 2. Causal structure of space–time in the old "pre-inflationary" models (top panel) and in the inflationary models of the Universe (bottom panel). The lower (blue) triangles are the future causality cones developing from the birth of the Universe, and the upper (red) triangle is the past causality cone, representing the part of the Universe observed at the present time.

As is seen in the top panel of Fig. 2, a crucial drawback of the old "pre-inflationary" cosmology was that the observable region of space $x_{\rm p}$ (e.g., by the instant of recombination or by the instant of phase transition) comprised a large number of domains N developing independently from the birth of the Universe. This is because a difference between the conformal times η_0 and η^* in the case of power-like expansion of the Universe is rater small. As follows from the detailed calculations,[10]

$$N \approx \left\{\left[1-\left(\frac{T-t^*}{T}\right)^{\frac{1+3w}{3(1+w)}}\right]^{-1}-1\right\}^{-3} \gg 1\,, \tag{11}$$

where w parameterizes the effective equation of state of the cosmological matter, $p = w\rho$ ($w = 0$ for the non-relativistic matter, and $w = 1/3$ for the radiation); and $T(\eta_0)$ is the age of the Universe. As a result, one should expect that, for example, the observed CMB radiation will be strongly anisotropic (if t^* is associated with the instant of recombination), or a large number of topological defects will be formed

at the boundaries between the domains[16–19] (if t^* is associated with the instant of phase transition).

The situation changes radically if the inflationary stage with exponential expansion is present. Really, if $R(t) \propto e^{Ht}$, then

$$\eta(t) \propto -e^{-Ht} \to -\infty \quad \text{at} \quad t \to -\infty\,. \tag{12}$$

In other words, there will be a huge interval of conformal time before the instant η^*, corresponding to the observable structure. Consequently, the entire observable region $x_{\rm p}$ will be well within a single domain of causality $x_{\rm f}$ or, more exactly,[10]

$$N \approx \exp\bigl[-\sqrt{3\Lambda}\,c\,(T-t^*)\bigr] \ll 1\,, \tag{13}$$

as is seen in the bottom panel of Fig. 2. This is, in fact, the main reason why the inflationary model easily resolved the crucial problems of the "old" cosmology.

At last, what should we expect in the uncertainty-mediated cosmological model? Will the quasi-exponential expansion law (7) be a reasonable alternative to the pure exponential expansion? A quite straightforward but cumbersome calculation[10] results in

$$N \approx \left(\frac{16\pi C_{\rm UR}}{3}\right)^{3/2} \left(\frac{T-t^*}{\tau}\right)^{3/2} \exp\left[-4\sqrt{3\pi C_{\rm UR}}\left(\frac{T-t^*}{\tau}\right)^{1/2}\right] \ll 1\,, \tag{14}$$

i.e., the corresponding conformal diagram will be qualitatively the same as in the bottom panel of Fig. 2. In other words, the problems of homogeneity and isotropy of matter distribution, the absence of topological defects, etc. can be resolved by the uncertainty-mediated approach as efficiently as by the standard inflationary scenario.

4.2. *The Problem of Singularity*

A presence of the initial singularity in the power-like solution of the Friedmann equation with ordinary matter was also considered for a long time as a serious drawback of the cosmological model, but a considerably less attention is usually paid to this issue nowadays. Anyway, the quasi-exponential solution (7) of the uncertainty-mediated model evidently avoids the problem of singularity. However, this is achieved in a different way than in the standard inflationary model: in our case, the function $R(t)$ takes a finite value at $t = 0$ and becomes indefinite at $t < 0$; while in the standard exponential inflation the singularity is actually shifted to minus infinity.

Besides, let us mention that the uncertainty-mediated solution (7), in principle, if favorable for constructing a bounce-type model of the Universe, when a contraction at $t < 0$ is followed by the expansion at $t > 0$. Really, since the modified solution (7) with a minus sign in the argument of exponential function also satisfies the Friedmann equation, the decreasing and increasing branches can be fit to each other at $t = 0$.

4.3. *Formation of the Flat Three-Dimensional Space*

Yet another important conceptual problem of the old "pre-inflationary" cosmology was why the observed three-dimensional space is approximately flat with a high degree of accuracy. If we do not assume *a priori* that $k \equiv 0$ in the Friedmann equation (3), but the Λ-term is absent and the ordinary matter is described by the equation of state $p = w\rho$, then its energy density ρ will depend on the scale factor as $1/R^{3(1+w)}$, i.e., $1/R^3$ in the case of non-relativistic (dust-like) substance and $1/R^4$ in the case of radiation.[14] On the other hand, the curvature term decays as $1/R^2$ and, therefore, it will inevitably dominate after some time if the evolution begins from the arbitrary (generic) initial conditions. In other words, the approximately flat three-dimensional space cannot be formed "dynamically", and it is necessary to impose the artificial constraint $k \equiv 0$.

This problem is naturally resolved in the framework of classical inflationary scenario: if Λ is non-zero and approximately constant, then the second (curvature) term in the right-hand side of Eq. (3) becomes negligible as compared to the third (vacuum energy) term in the course of time and, therefore, the approximately flat three-dimensional space will be formed starting from the generic initial conditions.

Finally, what is the situation in the uncertainty-mediated cosmological model, described by the modified Friedmann equation (6)? In this case, it is not so easy to compare the magnitudes of the various terms in the right-hand side, because one of them depends immediately on t, while others depend on the function $R(t)$. However, assuming in the first approximation that $\rho = 0$ and utilizing the simplest solution (7), we get:

$$\lim_{t \to \infty} \frac{1/t}{1/R^2(t)} = \lim_{t \to \infty} \frac{R^2(t)}{t} = \infty\,, \tag{15}$$

as can be proved, for example, applying the L'Hôpital's rule two times. Consequently, we should expect that the role of the curvature term will become negligible in the course of time. Strictly speaking, this argumentation is not a rigorous mathematical proof, because the above-mentioned solution (7) was obtained under assumption $k \equiv 0$. However, a more accurate treatment in Ref. 11 leads to the same result. Therefore, the uncertainty-mediated model resolves the problem of flatness as efficiently as the standard inflationary scenario.

5. Discussion and Conclusions

1. As follows from the above consideration, the uncertainty-mediated cosmological model provides a unified description of the entire evolution of the Universe on the basis of the well-established physical principle—the quantum-mechanical uncertainty relation. Besides, it resolves all major problems of the early Universe and, therefore, can serve as a reasonable alternative to other inflationary scenarios.
2. Unfortunately, a few conceptual issues still remain questionable. Firstly, this is the basic idea of estimating the vacuum energy density from the uncertainty

relation. Secondly, it is not sufficiently clear what is the physical scale at which the uncertainty relation should be applied. We assumed above that this is the Planck volume. However, as was pointed out by Starobinsky (private communication), this might be also the cosmological horizon. In this case, the vacuum energy derived from the uncertainty relation would be extremely small and insignificant for the cosmological evolution. Nevertheless, from our point of view, the Planck volume is a more reasonable choice because the uncertainty relation should be applied to a fixed physical system, while the horizon is evidently an object changing with time.

3. It is also unclear how the ordinary matter can be created in the framework of the uncertainty-mediated scenario, since it was completely ignored in the simplest solution (7). So, it might be necessary to introduce the additional field(s) whose decay will produce the ordinary substance, as it is commonly postulated in other inflationary models. On the other hand, if the presence of ordinary matter is assumed *a priori*, it is unclear if it will destroy the inflationary stage (i.e., if the scale factor $R(t)$ will collapse into a singularity) under extrapolation backwards in time. To answer this question, it is necessary to obtain more general solutions of the modified Friedmann equation (6).
4. At last, a number of the additional physical effects, such as leptogenesis, bariosynthesis, formation of the large-scale structure, the spectrum of CMB fluctuations, etc. should be considered in more detail to draw the ultimate conclusion on viability of the uncertainty-mediated cosmological model.

Conformal dilaton gravity, antipodal mapping and black hole physics on a warped spacetime

R. J. Slagter

An exact time-dependent solution of a black hole is found in a conformally invariant gravity model on a warped Randall-Sundrum spacetime, by writing the metric $g_{\mu\nu} = \omega^{\frac{4}{n-2}}\tilde{g}_{\mu\nu}$. Here $\tilde{g}_{\mu\nu}$ represents the "un-physical" spacetime and ω the dilaton field, which will be treated on equal footing as any renormalizable scalar field. It is remarkable that the 5D and 4D effective field equations for the metric components and dilaton fields can be written in general dimension $n = 4, 5$. The location of the horizon(s) are determined by a quintic polynomial. This polynomial is related to the symmetry group of the icosahedron, isomorphic with the Galois group A_5. We applied the antipodal mapping on the axially symmetric black hole spacetime and make some connection with the information and firewall paradoxes. The dilaton field can be used to describe the different notion the in-going and outside observers have of the Hawking radiation by using different conformal gauge freedom. The disagreement about the interior of the black hole is explained by the antipodal map of points on the horizon. The free parameters of the solution can be chosen in such a way that $\tilde{g}_{\mu\nu}$ is singular-free and topologically regular, even for $\omega \to 0$.

Keywords: Conformal Invariance; Dilaton Field; Black Holes; Brane World Models; Antipodal Map; Quintic Polynomial

1. Introduction

One of the greatest challenges of modern physics will be the construction of a quantum-gravity model. In the vicinity of a horizon of a black hole and in the very early universe, these quantum gravity effects will come into play. The quantum features of a black hole were investigated, decades ago, by Hawking in his epic work on radiation effects of a black hole[1] by vacuum polarization. This radiation would be thermal and would contain no information. The black hole will eventually evaporate, and one could say that information is lost, because the anti-particles will fall into the black hole. This would violate quantum mechanics (QM). Related to this issue, is the holographic principle,[2] which states that the interior volume of spacetime of a black hole containing the information of the in-going particles is dual to the surface of the horizon. Could it be that the information is still at the horizon? The idea was extended to the well-known Anti-de Sitter/Conformal Field Theory (AdS/CFT) correspondence: is some way, the information must be present in the Hawking radiation. This model relies heavily on string theory, but would solve the information paradox, by introduction the notion of complementarity of the

in- and outside of the black hole. The in-going and out-going particles are entangled and the information of the in-going particle is also reflected back. However, this viewpoint conflict causality.[3] The previously emitted Hawking radiation and the corresponding in-going particles are independent systems and at the same time indirect entangled. Another solution for the information paradox, which don't rely on string theory, is the introduction of a firewall.[4] The entanglement between the in-going and out-going particles is broken by a high energetic shield. The freely in-falling observer encounters high-energy particles at the horizon. This viewpoint conflicts general relativity, i.e., violation of the equivalence principle. Free falling observers, when falling through the horizon, perceive spacetime as Minkowski, so will not notice the horizon at all. A fundamental issue which is omitted in all the treatments as described above, is the time-dependency of the spacetime structure near the horizon. The emitted Hawking particle will have a back-reaction effect on the spacetime.[5,6] Could it be possible, that the topology of the black hole must be revised? It is well know, that quantum field theory on a curved spacetime opens the possibility that a field theory can have different vacuum states. It can have intrinsic statistical features from a change in topology and not from from a priori statistical description of the matter fields. A spacetime with a given local geometry admits in principle, different possible global topologies. One can consider the modification of the spacetime topology of the form $\widehat{\mathcal{M}}/\Gamma$, where Γ is a discrete subgroup of isometries of $\mathcal{M}$,[7–10] without fixed points. $\widehat{\mathcal{M}}$ is non-singular and is obtained from its universal covering $\mathcal{M}$ by identifying points equivalent under Γ. A particular interesting case is obtained, when Γ is the antipodal transformation on $\mathcal{M}$

$$J: \quad P(X) \to \widehat{P}(\widehat{X}). \tag{1}$$

where the light-cone of the antipode of $P(X)$ intersects the light-cone of $P(X)$ only in two point (at the boundary of the spacetime). This is the so-called "elliptic interpretation"[11] of spacetime, where antipodal points represents in fact the same world-point or event. The future and past event horizon intersect each other as a projected cylinder $\mathbb{R}_1 \times \mathbb{S}_1/\mathbb{Z}_2$.[a] At the intersection one then identifies antipodal points. One must realize that the antipodal map is a boundary condition at the horizon, only observable by the outside observer. On a black hole spacetime, the inside is removed. So nothing can escape the interior, since there is no interior. The field theories formulated on $\mathcal{M}$ and $\widehat{\mathcal{M}}$ are globally different, while locally $\mathcal{M}$ and $\widehat{\mathcal{M}}$ are identically. The emitted radiation is only locally thermal. Antipodal identification, however, destroys the thermal features in the Fock space construction. In the construction, one needs unitary evolution operators for the in-going and out-going particles.[5,12] In order to avoid wormhole constellations or demanding "an other universe" in the construction of the Penrose diagram, it is essential that the asymptotic domain of $\mathcal{M}$ maps one-to-one onto the ordinary spacetime in order

[a]We work here in polar coordinates, because the spinning black hole we will consider, has a preferred spin axis. The antipodal identification is then $(U, V, z, \varphi) \to (-U, -V, -z, \pi + \varphi)$.

to preserve the metric. In fact, one deals with one black hole. A consequence is that time-inversion take place in region II of the Penrose diagram, so interchange of the creation and annihilation operators and entangling positive energy particles at the horizon with positive energy antiparticles at the antipodes. So the antipodal identification is not in conflict with the general CPT invariance of our world. Further, for the outside observer, the thermodynamically mixed state is replaced by a pure state. So the Hawking particles at opposite sides of the black hole are entangled. The former representation that observers has no access to the inside of the black hole is no longer valid. One arrives by this new geometrical description at pure quantum states for the black hole. It will solve, moreover, the information paradox and firewall problem as well.[b] The gravitational back-reaction as proposed by 't Hooft,[13,14] suggests a cut-off of high momenta, which avoids the firewall. The in-going particle has a back-reaction on the other particles, leading to an unitary S-matrix. The gravitational interaction between the in-going and out-going particles will be strong, because we are dealing here with a strongly curved spacetime near the horizon. Using a "cut-and-paste" procedure, one replaces the high-energy particles ("hard"), i.e., mass or momentum of the order of the Planck mass, by low-energy ("soft") particles far away. These hard particles just caused the firewall problem. Hard particles will also influence the local spacetime (to become non-Schwarzschild) and causes the Shapiro effect. The interaction with the soft particles is described by the Shapiro delay. Effectively, all hard particles are quantum clones of all soft particles. By this "firewall-transformation", we look only at the soft particle clones. They define the Hilbert space and leads to a unitary scattering matrix. The net result is that the black hole is actually in a pure state, invalidating the entanglement arguments in the firewall paradox. The entanglement issue can be reformulated by considering the two regions I and II in the maximally extended Penrose diagram of the black hole, as representing two "hemispheres" of the same black hole. It turns out that the antipodal identification keeps the wave functions pure[6] and the central $r = 0$ singularity has disappeared. This gravitational deformation will cause transitions from region I to II in the Penrose diagram. The fundamental construction then consist of the exchange of the position operator with the momentum operator of the in-going particles, which turn them into out-particles. Hereby, 't Hooft expands the moment distributions and position variables in partial waves in (θ, φ).[5] So the Hawking particles emerging from I are entangled with the particles emerging from II. An important new aspect is the way particles transmit the information they carry across the horizon. In the new model, the Hawking particles emerging from I are maximally entangled with the particles emerging from II. The particles form a pure state, which solves the information paradox. In order to describe the more realistic black holes, such as the axially symmetric Kerr black hole, it is not possible

[b]The technical aspects in constructing the unitary S-matrix can be found in the literature, as provided by the references.

to ignore the dynamics of the horizon. Moreover, one must incorporate gravitation waves. There is another reason to consider axially symmetry. A spherical symmetric system cannot emit gravitation waves.[15] Astronomers conjecture that most of the black holes in the center of galaxies are of the Kerr type. A linear approximation is, of course, inadequate in high-curvature situations. In the linear approximation, the waves don't carry enough energy and momentum to affect their own propagation. The notion of the "classical" Hartle-Hawking vacuum thermal state, with a temperature $T \sim \frac{1}{M} \sim \kappa$ and the luminosity $\frac{dM}{dt} \sim -\frac{1}{M^2}$ must also be revised when the mass reaches the order of the Planck mass. On the Kerr black hole spacetime no analog of the Hartle-Hawking vacuum state exists. The Killing field ξ^μ generates a bifurcate Killing horizon ($\xi^\mu \xi_\mu = -1$ at infinity) and possesses spacelike orbits near infinity.[16] Another aspect of the huge curvature in the vicinity of the horizon, will be the problem of constructing a renormalizable (and maintaining unitarity) quantum gravity model of the Standard Model fields, which must be incorporated in the Lagrangian. Up till now, no convincing theory of quantum gravity is available. Many attempts were made in order to make a renormalizable and unitary quantum gravity model. One also can try to construct a renormalizable model, by adding fourth order derivative terms of the curvature tensor (Euler-term). However, one looses unitarity. Also the "old" effective field theory (EFT) has its problems. One ignores what is going on at high energy. In order to solve the anomalies one encounters in calculating the effective action, one can apply the so-called conformal dilaton gravity (CDG) model.[5,6,17] CDG is a promising route to tackle the problems arising in quantum gravity model, such as the loss of unitarity close to the horizon. One assumes local conformal symmetry, which is spontaneously broken (for example by a quartic self-coupling of the Higgs field). Changing the symmetry of the action was also successful in the past, i.e., in the SM of particle physics. A numerical investigation of a black hole solution of a non-vacuum CDG model, was recently performed.[18] The key feature in CDG, is the splitting of the metric tensor $g_{\mu\nu} = \omega^{\frac{4}{n-2}} \tilde{g}_{\mu\nu}$, with ω the dilaton field. Applying perturbation techniques (and renormalization/dimensional regularization), in order to find the effective action and its divergencies, one first integrate over ω (shifted to the complex contour), considered as a conventional renormalizable scalar field and afterwards over $\tilde{g}_{\mu\nu}$ and matter fields. The dilaton field is locally unobservable. It is fixed when we choose the global spacetime and coordinate system. If one applies this principle to a black hole spacetime, then the energy-momentum tensor of ω influences the Hawking radiation. When $\tilde{g}_{\mu\nu}$ is flat, then the handling of the anomalies simplifies considerably.[14] When $\tilde{g}_{\mu\nu}$ is non-flat, the problems are more deep-seated. It is well known, that the antipodal transformation, or inversion, is part of the conformal group.[19] So conformal invariant gravity models could fit very well the models of antipodal mapping as described above. In this context, the modification of GRT by an additional spacetime dimension could be an alternative compromise, because Einstein gravity on the brane will be modified by the very embedding itself and opens up

a possible new way to address the dark energy problem.[20,c] These models can be applied to the standard Friedmann-Lemaître-Robertson-Walker (FLRW) spacetime and the modification on the Friedmann equations can be investigated.[21] Recently, Maldacena, et al.,[22] applies the RS model to two black hole spacetimes and could construct a traversable macroscopic wormhole solution by adding only a 5D U(1) gauge field (see also Maldacena[23]). However, an empty bulk would be preferable. In stead, one can investigate the contribution of the projected 5D Weyl tensor on the 4D brane. It carries information of the gravitational field outside the brane. If one writes the 5D Einstein equation in CDG setting, it could be possible that an effective theory can be constructed without an UV cutoff, because the fundamental scale M_5 can be much less than the effective scale M_{Pl} due to the warp factor. The physical scale is therefore not determined by M_{Pl}. In this manuscript we will apply the antipodal map on a spinning black hole spacetime in conformal dilaton gravity applied to a warped 5D spacetime.

2. Conformal Transformations and Antipodal Mapping

2.1. *The origin of the antipodal mapping*

The antipodal map originates from the so-called "elliptic" interpretation.[11] If one considers the hyperboloid H, $-t^2+x^2+y^2+z^2+w^2 = R^2$, then the space-like sections through the origin are ellipses and the time-like sections are hyperbola branches. Since the de Sitter spacetime can be isometrically embedded as a hyperboloid in $\mathbb{R}^5$, one can take $R^2 = -\frac{3}{\Lambda}$. If one suppresses the coordinates (z, w), we have the $\mathbb{R}^3$ Minkowski metric. Lorentz transformations (LT's) around the origin transforms H into itself. Circles on H represent space at different epochs. The bottle-neck parallel is a spatial geodesic, while the others are not. Further, the circumferences contract from $z = -\infty$ to $z = 0$ and then expand. A LT of $\mathbb{R}^3$ turns the bottle-neck into an ellipse, cut out of H with an angle $< 45^o$ with the (x, y)-plane. See figure 1. All the ellipses are equivalent space-like geodesics since each of them is transferred by a suitable automorphism into the bottle-neck, which is one of them. One defines the antipodal map

$$J : P(t, x, y) \to \widehat{P}(-t, -x, -y), \tag{2}$$

on H. The antipodicity is Lorentz invariant. When the angle approaches 45^o, then the ellipses degenerate into a couple of parallel generators (g_1, g_2) (null geodesics). The other plane of 45^o delivers the set (g_3, g_4). The sets (g_1, g_4) and (g_2, g_3) form, for example, the light-cones at the points M and $\widehat{M}$. If one moves upwards along t, the inner angles of the light-cones decrease. Note that the light-cones at P and $\widehat{P}$ has no point in common and the antipodes are joined by a space-like geodesic. Now Schrödinger proposed to identify P and $\widehat{P}$ with the same physical world-point or

[c]There is another argument in favor of a (warped) 5D spacetime. It turns out, as we shall see, that a surface in 4D can be immersed to 5D, like a Klein bottle.

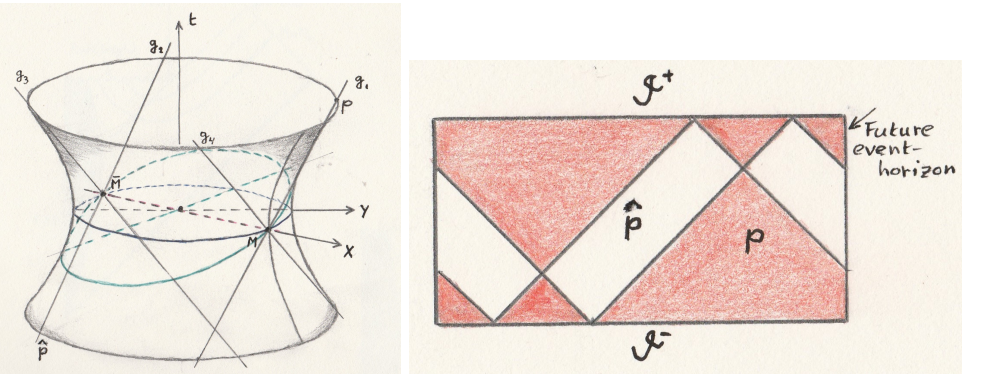

Fig. 1. Hyperboloid H representing the $\mathbb{R}^3$ spacetime of the compactified de Sitter universe $\mathbb{R}^5$ ((z, w) suppressed). Right: the Penrose diagram. The antipodal points P and $J(P)$ are spacelike separated. An observer moving in de Sitter spacetime cannot meet both P and $J(P)$. He cannot receive a message from $P, J(P)$. Moreover, he cannot receive a message from P and send a message to $J(P)$.

event. One half of H, containing no antipodal points, represents the "whole world". Thereafter, Schrödinger argues in a clever way that the total potential of experiences of any observer is complete and embraces the same events for any two observers, whatever their world lines be. But there is a price we have to pay for.[d] The direction of the arrow of time is lost (or the distinction between the "fore-cone" and "after-cone" is lost). The allotment of past and future is undecidable. The elliptic model is time-reversible. This can open perspective to the general CPT invariance of our world. The real problems arise, when one considers thermodynamical systems, as is the case for the Hawking effect in the vicinity of the horizon of a black hole. Then the entropy comes into play. Note, quoting Schrödinger, "the irreversible laws of thermodynamics can only be based on the statistical microscopically reversible systems on condition that statistical theory be autonomous in defining the arrow of time. If any other law of nature determines this arrow, the statistical theory collapses."

In a pseudo-polar frame $(\chi, T, \theta, \varphi)$ we can write the line element

$$ds^2 = -R^2 dT^2 + R^2 \cosh^2 T \Big[d\chi^2 + \sin^2 \chi (d\theta^2 + \sin^2 \theta d\varphi^2) \Big], \tag{3}$$

where $0 < \chi < 2\pi$. The antipodal map becomes now

$$J : (T, \chi, \theta, \varphi) \to (-T, \pi + \chi, \pi - \theta, \pi + \varphi). \tag{4}$$

[d]This price is worth paying in the black hole situation, when the information paradox will be solved by the antipodal map. The antipodal half is not time orientable. There is a breakdown of the global distinction between past and future in the interior of the black hole.

We already mentioned that de Sitter can be embedded as a hyperboloid in 5D Minkowski. We then say that $J : X^\mu \to -X^\mu$ is an inversion.[e] There exist another coordinate system (introduced by de Sitter himself) in which the line element is written as

$$ds^2 = -\left(1 - \frac{\rho^2}{R^2}\right) dT'^2 + \frac{1}{(1 - \frac{\rho^2}{R^2})} d\rho^2 + \rho^2 (d\theta'^2 + \sin^2 \theta' d\varphi'^2), \tag{5}$$

where we have taken the velocity of the LT $\tanh T = \frac{t}{y}$. This is the static de Sitter and the spaces of constant time are all equivalent. There are singularities for $x = \pm R$ ($\chi = \pm 90^o$), i.e., the points $(M, \widehat{M})$. However, as also observed by Schrödinger, this static model is not adequate for applying the antipodal map. In order to apply the antipodal map on a black hole spacetime in a more general setting, one needs a time dependent spacetime.

2.2. *The "classical" Hawking effect and its problems*

The famous result of Hawking states, that a black hole will radiate at "sufficiently" late times like a black body at a temperature

$$kT \sim \frac{\kappa}{2\pi} = \frac{\hbar c^3}{8\pi GM}, \tag{6}$$

with κ the surface gravity and M the mass. The entropy should then be $S_{bh} = \frac{kc^3}{4\hbar} A$, with A the area of the horizon. However, one runs into problems by the back-reaction effect of the particle creation, which will alter the area. It is questionable if the ordinary laws of thermodynamics can be applied to a black hole. It is clear that these laws must be constrained to form quantum states with orthonormality and unitarity conditions. Suppose that an isolated black hole completely evaporate within a finite time. Loss of quantum coherence should then occur i.e., an initially pure quantum state should evolve to a mixed state. In general, in the classical picture, a black hole cannot causally influence its exterior, so it is hard to understand the mechanism by which thermal equilibrium could be achieved. Observe that the state of the field at late times in the region I of the Penrose diagram (and so the particles flux reaching infinity) is described by a density matrix by the S-matrix analysis. The particles present in region I are strongly correlated with the particles which entered the black hole at earlier times. Consider now in figure 2 the evolution of two Cauchy surfaces ("time" Σ_1 to "time" Σ_2). When the black hole disappears from the spacetime, then at late times, the entire state of the field is mixed. If one takes the "out" Hilbert space to be the Fock space of the particles propagating out to infinity at late times, one cannot describe particle creation and scattering by an ordinary S-matrix. The initial pure state will evolve to a final density matrix.

[e]The inversion $X_\mu \to -\frac{X_\mu}{X^2}$ (as well as the dilatations) is part of the conformal group.[19] We shall see in the next sections that in general the conformal group is a projective group from 5D. The fifth "degree of freedom" is a sort of gauge space.

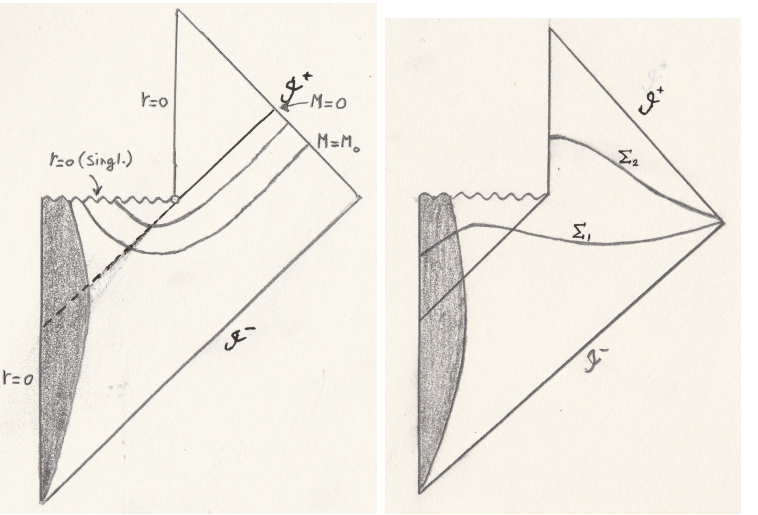

Fig. 2. Left: formation and evaporation of the Schwarschild black hole. The contour $M = 0$ lies at the retarded time corresponding to the final evaporation. The geometry is flat above this contour. Right: Loss of quantum coherence: evolution from a pure state to a mixed state.[16]

So we have a breakdown of quantum theory. The antipodal model, however, could "repair" this breakdown.

3. The Black Hole Solution on a 5D Warped Spacetime in Conformal Dilaton Gravity

3.1. *The 5D warped spacetime*

Let us consider the 5D spacetime warped spacetime[21,24]

$$ds^2 = \omega(t,r,y)^2\Big[-N(t,r)^2dt^2+\frac{1}{N(t,r)^2}dr^2+dz^2+r^2(d\varphi+N^\varphi(t,r)dt)^2+dy^2\Big], \quad (7)$$

where y is the extra dimension and ω a warp factor in the formulation of Randall-Sundrum's (RS) 5D warped spacetime with one large extra dimension and negative bulk tension Λ_5. The Standard Model (SM) fields are confined to the 4D brane, while gravity acts also in the fifth dimension. Originally, the RS model was applied to a 5-dimensional anti-de Sitter (AdS) spacetime with a positive brane tension. This is the so-called RS-1 model, with one brane. The RS-2 model treats two branes with $\mathbb{Z}_2$ symmetry. However, the effective cosmological constant on the brane can be zero by fine tuning with the negative Λ_5. In the RS model there is a bound state of the graviton confined to the wall as well as a continuum of Kaluza-Klein (KK) states. Four dimensional gravity is then recovered on the brane and the hierarchy problem seems to be solved. Since the pioneering publication of RS, many investigation were done in diverge domains. In particular, Shiromizu et.al.,[24,25] extended the RS model to a fully covariant curvature formalism. It this extended model, an effective

Einstein equation is found on the brane, with on the right-hand side a contribution from the 5D Weyl tensor which carries information of the gravitational field outside the brane. So the brane world observer may be subject to influences from the bulk. The field equations are (were we took an empty bulk)[18]

$$^{(5)}G_{\mu\nu} = -\Lambda_5\, ^{(5)}g_{\mu\nu}, \tag{8}$$

$$^{(4)}G_{\mu\nu} = -\Lambda_{eff}\, ^{(4)}g_{\mu\nu} + \kappa_4^{2\,(4)}T_{\mu\nu} + \kappa_5^4 \mathcal{S}_{\mu\nu} - \mathcal{E}_{\mu\nu}, \tag{9}$$

where we have written

$$^{(5)}g_{\mu\nu} = {}^{(4)}g_{\mu\nu} + n_\mu n_\nu, \tag{10}$$

with n^μ the unit normal to the brane. Here $^{(4)}T_{\mu\nu}$ is the energy-momentum tensor on the brane and $\mathcal{S}_{\mu\nu}$ the quadratic contribution of the energy-momentum tensor $^{(4)}T_{\mu\nu}$ arising from the extrinsic curvature terms in the projected Einstein tensor. Further,

$$\mathcal{E}_{\mu\nu} = {}^{(5)}C^\alpha_{\beta\rho\sigma} n_\alpha n^{\rho\,(4)} g_\mu^{\beta\,(4)} g_\nu^\sigma, \tag{11}$$

represents the projection of the bulk Weyl tensor orthogonal to n^μ. The effective gravitational filed equations on the brane are not closed. One must solve at the same time the 5D gravitation field in the bulk.

3.2. *The conformal dilaton gravity (CDG) model on a 5D warped spacetime*

One can distinguish several possible "routes" to the unification of GR and QFT. One can start, for example, with a given classical theory and applies heuristic quantization rules. One then can make a division in canonical and covariant approaches, i.e., uses a Hamiltonial formalism or employs covariance at some stage. The CDG model we consider here, is part of the covariant approach to quantum gravity. The key feature in CDG, is the splitting of the metric tensor[5,17]

$$g_{\mu\nu} = \omega^{\frac{4}{n-2}} \tilde{g}_{\mu\nu}, \tag{12}$$

with ω the dilaton field and $\tilde{g}_{\mu\nu}$ the "un-physical" spacetime. At high energy, ω will be treated as a (renormalizable) quantum field. One can prove that the action (without matter terms for the time being)

$$S = \int d^n x \sqrt{-\tilde{g}} \Big[\frac{1}{2} \xi \omega^2 \tilde{R} + \frac{1}{2} \tilde{g}^{\mu\nu} \partial_\mu \omega \partial_\nu \omega + \Lambda \kappa^{\frac{4}{n-2}} \xi^{\frac{n}{n-2}} \omega^{\frac{2n}{n-2}} \Big], \tag{13}$$

is conformal invariant under

$$\tilde{g}_{\mu\nu} \to \Omega^{\frac{4}{n-2}} \tilde{g}_{\mu\nu}, \quad \omega \to \Omega^{-\frac{n-2}{2}} \omega. \tag{14}$$

The covariant derivative is taken with respect to $\tilde{g}_{\mu\nu}$. For details, see Slagter.[18] Now we implement the 5D warped spacetime Eq. (7). So

$$ {}^{(5)}g_{\mu\nu} = \omega^{4/3}{}^{(5)}\tilde{g}_{\mu\nu}, \qquad {}^{(5)}\tilde{g}_{\mu\nu} = {}^{(4)}\tilde{g}_{\mu\nu} + n_\mu n_\nu, \tag{15} $$

and write again

$$ {}^{(4)}\tilde{g}_{\mu\nu} = \bar{\omega}^2 \bar{g}_{\mu\nu}. \tag{16} $$

Variation of the action leads to the field equations

$$ \xi\omega\tilde{R} - \tilde{g}^{\mu\nu}\tilde{\nabla}_\mu\tilde{\nabla}_\nu\omega - \frac{2n}{n-2}\Lambda\kappa^{\frac{4}{n-2}}\xi^{\frac{n}{n-2}}\omega^{\frac{n+2}{n-2}} = 0 \tag{17} $$

and

$$ \omega^2\tilde{G}_{\mu\nu} = T^{\omega}_{\mu\nu} - \Lambda\tilde{g}_{\mu\nu}\kappa^{\frac{4}{n-2}}\xi^{\frac{2}{n-2}}\omega^{\frac{2n}{n-2}}, \tag{18} $$

with

$$ T^{\omega}_{\mu\nu} = \tilde{\nabla}_\mu\tilde{\nabla}_\nu\omega^2 - \tilde{g}_{\mu\nu}\tilde{\nabla}^2\omega^2 + \frac{1}{\xi}\Big(\frac{1}{2}\tilde{g}_{\alpha\beta}\tilde{g}_{\mu\nu} - \tilde{g}_{\mu\alpha}\tilde{g}_{\nu\beta}\Big)\partial^\alpha\omega\partial^\beta\omega. \tag{19} $$

From the 5D Einstein equations Eq. (8) one obtains $\omega(t,r,y) = \omega_1(t,r)\omega_2(y)$, with $\omega_2(y) = l$=constant (the length scale of the extra dimension). The dilaton equations Eq. (17) is superfluous. Note that the effective Einstein equations Eq. (9) contains the $\mathcal{E}_{\mu\nu}$, while $T_{\mu\nu}$ and $\mathcal{S}_{\mu\nu}$ are taken zero in our case. The dilaton equation is again superfluous.

It turns out that one can write the field equations for ω and N in the form $(n = 4, 5)$

$$ \ddot{\omega} = -N^4\omega'' + \frac{n}{\omega(n-2)}\Big(N^4\omega'^2 + \dot{\omega}^2\Big), \tag{20} $$

$$ \ddot{N} = \frac{3\dot{N}^2}{N} - N^4\Big(N'' + \frac{3N'}{r} + \frac{N'^2}{N}\Big) $$

$$ -\frac{n-1}{(n-3)\omega}\Big[N^5\Big(\omega'' + \frac{\omega'}{r} + \frac{n}{2-n}\frac{\omega'^2}{\omega}\Big) + N^4\omega'N' + \dot{\omega}\dot{N}\Big]. \tag{21} $$

One can solve these equations exact (we took $\Lambda_{eff} = 0$):

$$ \omega = \Big(\frac{a_1}{(r+a_2)t + a_3 r + a_4}\Big)^{\frac{1}{2}n-1}, $$

$$ N^2 = \frac{1}{5r^2}\frac{10a_2^3r^2 + 20a_2^2r^3 + 15a_2r^4 + 4r^5 + C_1}{C_2(a_3+t)^4 + C_3}, \tag{22} $$

with a_i some constants. There is a constraint equation

$$ \bar{\omega}'' = -\frac{2n}{n-2}\frac{\Lambda l\kappa^{\frac{4}{(n-2}}\xi^{\frac{n-2}{4(n-1)}}\bar{\omega}^{\frac{n+2}{n-2}}}{N^2} - \frac{\omega'N'}{N} - \frac{\omega'}{2r} + \frac{4}{n-2}\frac{\dot{\bar{\omega}}^2}{\bar{\omega}N^4} - \frac{\dot{\bar{\omega}}\dot{N}}{N^5}, \tag{23} $$

which l the dimension of y. The solution for the two dilaton fields ω and $\bar{\omega}$ differs only by the different exponent $\frac{3}{2}$ and 1 respectively. The solution For the metric

component is the same (apart from the constants). The solution for the angular momentum component is

$$N^{\varphi} = F_n(t) + \int \frac{1}{r^3 \bar{\omega}^{\frac{n-1}{n-3}}} dr. \tag{24}$$

The Ricci scalar for $\bar{g}_{\mu\nu}$ ($\Lambda = 0$) is given by

$$\bar{R} = \frac{12}{N^2}\Big[\dot{\bar{\omega}}^2 - N^4 \bar{\omega}'^2\Big], \tag{25}$$

with is consistent with the null condition for the two-dimensional (t, r) line element, when $\bar{R} = 0$. One can easily check that the trace of the Einstein equations is zero. Note that N^2 can be written as

$$N^2 = \frac{4\int r(r+a_2)^3 dr}{r^2[C_2(a_3+t)^4 + C_3]}. \tag{26}$$

So the spacetime seems to have two poles. However, the $r = 0$ is questionable. The conservation equations become

$$\bar{\nabla}^{\mu}\mathcal{E}_{\mu\nu} = \bar{\nabla}^{\mu}\Big[\frac{1}{\bar{\omega}^2}\Big(-\Lambda\kappa^{2\,(4)}\bar{g}_{\mu\nu}\bar{\omega}^4 + {}^{(4)}T_{\mu\nu}{}^{(\bar{\omega})}\Big)\Big], \tag{27}$$

which yields differential equations for $\ddot{N}'$ and $\dot{N}$ as boundary conditions at the brane. It can be described as the non-local conservation equation. In the high energy case close to the horizon, one must include the $\mathcal{S}_{\mu\nu}$ term. So the divergence of $\mathcal{E}_{\mu\nu}$ is constrained. In the non-conformal case, Eq. (27) contains on the right hand side also the quadratic correction $\mathcal{S}_{\mu\nu}$ of the matter fields on the brane. The effective field equations, Eq. (9), are then not a closed system. One needs the Bianchi equations. In fact, $\mathcal{E}_{\mu\nu}$ encodes corrections from the 5D graviton effects and are for the brane observer non-local. In our model under consideration, we have only the $T^{(\omega)}_{\mu\nu}$ term and no source terms (only the 5D Λ_5). But it still sources the KK modes. The dilaton ω plays the role of a "scalar field". But we don't need the 5D equations themselves, because the solution for N is the same! It is only the $\omega^{4/3}$ which represents the 5D contribution. There is no exchange of energy-momentum between the bulk and brane. If one applies the model to a FLRW model,[26] then the evolution equations are very complicated. Inhomogeneous and anisotropic effects from the 4D matter radiation distribution on the brane are sources for the 5D Weyl tensor $\mathcal{E}_{\mu\nu}$ and cause non-local back-reaction on the brane. One needs an approximation scheme in order to find the missing evolution equation for $\mathcal{E}_{\mu\nu}$.

The locations of the horizon's and ergo-spheres are found by solving $N^2 = 0$ and $\bar{g}_{tt} = 0$ respectively. N^2 becomes singular at coordinate time $t = t_H = -b_3 + \sqrt[4]{-\frac{C_3}{C_2}}$. However, $\bar{g}_{\mu\nu}$ can be made regular everywhere and singular free by suitable choices of the parameters b_i, c_i and C_i. For $C_1 = 0$, $\bar{g}_{\mu\nu}$ has one real zero $r_H = \sim |1.606 b_2|$ and two complex zero's $\sim (0.178 \pm 0.638I)b_2$. In figure 3 we plotted the possible graphs. If one ignores the contribution from the bulk, then N^2 has for $C_1 = 0$ no real roots, so only naked singularities. The contribution from the bulk then generates at least one horizon.

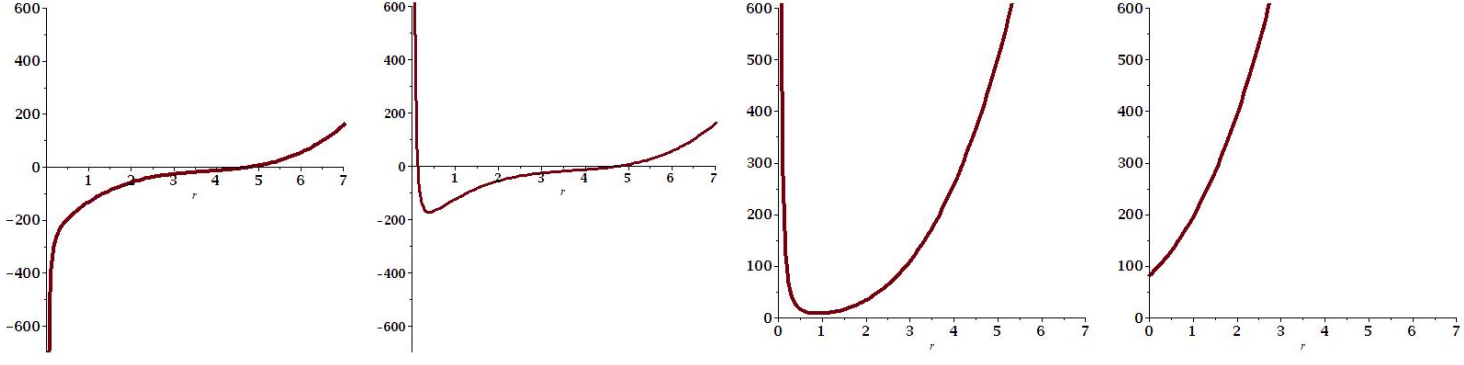

Fig. 3. Four possible plots of N^2 as function of r.

3.3. *Penrose diagram*

If we define the coordinates, $dr^* \equiv \frac{1}{N_1(r)^2} dr$ and $dt^* \equiv N_2(t)^2 dt$, then our induced spacetime can be written as

$$ds^2 = \omega^{4/3}\bar{\omega}^2\Big[\frac{N_1^2}{N_2^2}\Big(-dt^{*2} + dr^{*2}\Big) + dz^2 + r^2\Big(d\varphi + \frac{N^\varphi}{N_2^2}dt^*\Big)^2\Big], \tag{28}$$

with

$$N_1^2 = \frac{10b_2^3r^2 + 20b_2^2r^3 + 15b_2r^4 + 4r^5 + C_1}{5r^2}, N_2^2 = \frac{1}{C_2(t+b_3)^4 + C_3} \tag{29}$$

and

$$r^* = \frac{1}{4}\sum_{r_i^H} \frac{r_i^H \log(r - r_i^H)}{(r_i^H + b_2)^3}, \qquad t^* = \frac{1}{4C_2}\sum_{t_i^H} \frac{\log(t - t_i^H)}{(t_i^H + b_3)^3}. \tag{30}$$

The sum it taken over the roots of $(10b_2^3r^2 + 20b_2^2r^3 + 15b_2r^4 + 4r^5 + C_1)$ and $C_2(t+b_3)^4 + C_3$, i. e., r_i^H and t_i^H. This polynomial in r defining the roots of N_1^2, is a quintic equation, which has some interesting connection with Klein's icosahedral solution (see appendix). Further, one can define the azimuthal angular coordinate $d\varphi^* \equiv (d\varphi + \frac{N^\varphi}{N_2^2}dt^*)$, which can be used when an incoming null geodesic falls into the event horizon. φ^* is the azimuthal angle in a coordinate system rotating about the z-axis relative to the Boyer-Lindquist coordinates. Next, we define the coordinates[28] (in the case of $C_1 = C_3 = 0$ and 1 horizon, for the time being)

$$\begin{aligned} U_+ = e^{\kappa(r^* - t^*)}, \quad V_+ = e^{\kappa(r^* + t^*)} \qquad r > r_H \\ U_- = -e^{\kappa(r^* - t^*)}, \quad V_- = -e^{\kappa(r^* + t^*)} \qquad r < r_H, \end{aligned} \tag{31}$$

with κ a constant. The spacetime becomes

$$ds^2 = \omega^{4/3}\bar{\omega}^2\Big[\frac{N_1^2}{N_2^2}\log\Big(UV\Big)^{\frac{1}{2\kappa}} dUdV + dz^2 + r^2 d\varphi^{*2}\Big]. \tag{32}$$

In figure 4 we plotted the Penrose diagram (left). The antipodal points $P(X)$ and $\bar{P}(\bar{X})$ are physically identified. If we compactify the coordinates,

$$\tilde{U} = \tanh U, \qquad \tilde{V} = \tanh V, \tag{33}$$

then the spacetime can be written as

$$ds^2 = \omega^{4/3}\bar{\omega}^2\Big[H(\tilde{U}, \tilde{V})d\tilde{U}d\tilde{V} + dz^2 + r^2 d\varphi^{*2}\Big], \tag{34}$$

with

$$H = \frac{N_1^2}{N_2^2}\frac{1}{\kappa^2 \operatorname{arctanh}\tilde{U} \operatorname{arctanh}\tilde{V}(1 - \tilde{U}^2)(1 - \tilde{V}^2)}. \tag{35}$$

We can write r and t as

$$r = r_H + \Big(\operatorname{arctanh}\tilde{U} \operatorname{arctanh}\tilde{V}\Big)^{\frac{1}{2\kappa\alpha}}, \quad t = t_H + \Big(\frac{\operatorname{arctanh}\tilde{V}}{\operatorname{arctanh}\tilde{U}}\Big)^{\frac{1}{2\kappa\beta}}, \tag{36}$$

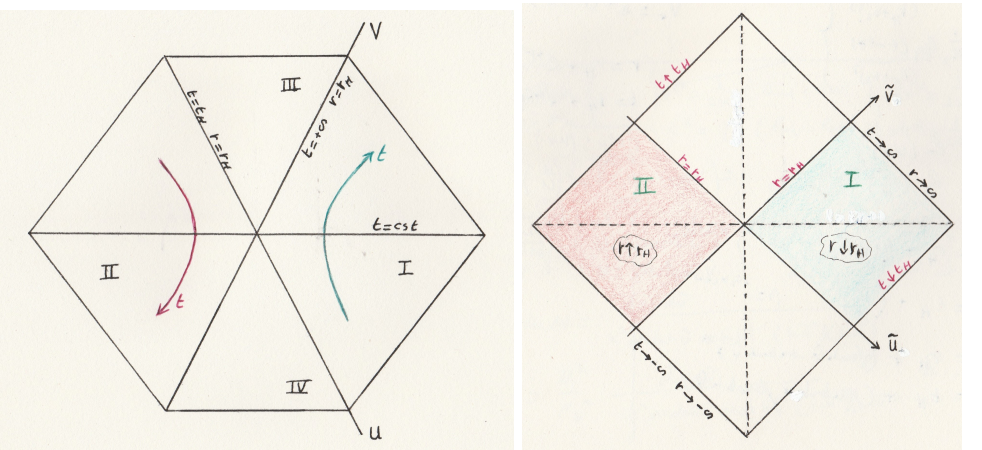

Fig. 4. Left: Kruskal diagram for $\bar{g}_{\mu\nu}$ in (U, V)- coordinates. If one approaches the horizon from the outside and passes the horizon, one approaches from the "otherside" the horizon. Right: Kruskal diagram for $\bar{g}_{\mu\nu}$ in $(\tilde{U}, \tilde{V})$- coordinates.

with

$$\alpha = \frac{r_H}{4(r_H + b_2)^3}, \qquad \beta = \frac{1}{4C_2(t_H + b_3)^3}. \tag{37}$$

Observe that N_1 and N_2 can be expressed in $(\tilde{U}, \tilde{V})$. The Penrose diagram is drawn in figure 4 (right). Note that ds^2 and H are invariant under $\tilde{U} \to -\tilde{U}$ and $\tilde{U} \to -\tilde{U}$. $\tilde{g}_{\mu\nu}$ is regular everywhere and conformally flat. The "scale-term" H is consistent with the features of the Penrose diagram. Now we have still the φ dependency. We assume no z-dependency. It is expected that the differential equation for ω can be separated in a (U, V) part and a φ part. The method of 't Hooft can then be applied. In the next sections, we will briefly come back to this issue.

4. Related Issues of the New Black Hole Solution

4.1. *Treatment of the quantum fields*

The physical identification in the de Sitter spacetime of $P(X)$ and $\widehat{P}(\widehat{X})$ are considered as different representations in Kruskal space of one and the same Schwarzschild event. There is only one world with one singularity and one exterior region. Fields which are symmetric under J are identified as

$$\Psi_{JS} = \frac{1}{2}\Big[\Psi(X) + \widehat{\Psi}(\widehat{X})\Big]. \tag{38}$$

One then builds these fields from fields with arguments specified in I.[8] Each of these fields, positive or negative frequency in I, can be extended to global spacetime surfaces. However, due to the time reversal, the inner product on the full Hilbert space have zero norm for the symmetric fields. One then defines negative frequency

functions $\Psi^{\uparrow}_{(-)}(X) = \Psi^{\downarrow}_{(+)}(JX)$ and $\Psi^{\downarrow}_{(-)}(X) = \Psi^{\uparrow}_{(+)}(JX)$, where the arrows stands for the solutions on the future/past singularity. The symmetric (anti-) solutions ($\epsilon = \pm 1$) are then

$$\Psi^{(1)}_{JS}(X) = \frac{1}{2}\Big[\Psi^{\uparrow}_{(+)}(X) + \epsilon\Psi^{\downarrow}_{(-)}(X)\Big], \quad \Psi^{(2)}_{JS}(X) = \frac{1}{2}\Big[\Psi^{\downarrow}_{(+)}(X) + \epsilon\Psi^{\uparrow}_{(-)}(X)\Big]. \quad (39)$$

Introducing then reflection and transmission coefficients, one can construct a wave function regular at the singularities, $\Psi^{(r)}_{JS} = \frac{\epsilon K}{(K+\epsilon)^2}\Big[\Psi^{(1)}_{JS} + \epsilon\Psi^{(2)}_{JS}\Big]$, with $K = e^{\pi\omega/\kappa}, \kappa = 1/4M$. Thereafter, one constructs hermitian field operators for the Fock space. Next, one needs the renormalized expectation value of the stress-energy tensor $< T_{\mu\nu} >$ in the "semiclassical" equations of Einstein $G_{\mu\nu} = 8\pi G < T_{\mu\nu} >$. If one assumes that there is a $r = 0$ singularity, then back-reaction will be small in the vicinity of the horizon (at least for massless fields). The spacetime can then be approximated by Schwarzschild geometry. The mass will decrease slowly with time and evaporates. In a flat spacetime, this is easily done, because the vacuum is well defined. One can calculate the zero-energy state and can construct finite quantum operators. In curved spacetime, the vacuum state is dependent of the boundary condition for the propagators (positive frequency modes). In principle, we can follow the method of Sanchez (for the de Sitter spacetime) for the dilaton field and our "un-physical" spacetime $\bar{g}_{\mu\nu}$ ($\Lambda = 0$),

$$< \bar{\omega}^2 > \bar{G}_{\mu\nu} =< T^{(\omega)}_{\mu\nu}(\bar{\omega}, \bar{g}_{\mu\nu} > - < \bar{\omega}^2 > \mathcal{E}_{\mu\nu}, \quad (40)$$

where $T^{(\omega)}_{\mu\nu}$ depends on the geometry and boundary conditions (see Eq. (19)). Further, $< T^{(\omega)} >= - < \bar{\omega}^2 > \bar{R}$, because $\mathcal{E}_{\mu\nu}$ is traceless. We have now contributions from the antipode:

$$< T^{(\omega)}_{\mu\nu} > \rightarrow < T^{(\omega)}_{\mu\nu} > \pm < \widehat{T}^{(\omega)}_{\mu\nu} >, \quad < \bar{\omega}^2 > \rightarrow < \bar{\omega}^2 > \pm < \widehat{\bar{\omega}^2} > . \quad (41)$$

In the simplified de Sitter space, one then easily construct Green functions[9]

$$G_{\alpha JS}(X, X') = e^{2\alpha}\Big[G(X.X') + G(X, JX')\Big],$$

$$G_{\alpha JA}(X, X') = e^{2\alpha}\Big[G(X.X') - G(X, JX')\Big], \quad (42)$$

with α labels the one parameter family of the de Sitter vacua. The expectation values for a scalar field and the energy momentum tensor can then be calculated. One obtain, for example,[8]

$$< \widehat{\Phi^2_{JS,JA}} >= \frac{1}{16\pi\cos\pi\nu}\left[m^2 + \left(\xi - \frac{1}{6}\right)R\right], \quad (43)$$

with $\nu = (9/4 - M^2/H^2)^{1/2}, M^2 = m^2 + \xi R$, m the mass of the field and $H \sim \Lambda$. In our case we have no scalar field, but instead ω. The expression for $T_{\tilde{U}\tilde{U}}$ becomes[30]

$$T^{(\omega)}_{UU} = \frac{c_1 e^{-2c_1 U}}{c_3^2 c_4^2 (c_2\rho + c_3)^2}(c_2 c_3 \rho^2 F(U) - c_1^2 c_2^2 \rho^2 + c_1 c_3^2), \quad (44)$$

which can be used to evaluate the expectation value. In order to apply the full antipodal map, one includes the φ-dependency in the dilaton equation. The relevant operator (d'Alembertian) can be separated in the used coordinate system. The relevant φ contribution comes from periodic Mathieu functions (in variable φ). They converge uniformly on all compact sets in the z-plane. Next, one applies the method of 't Hooft, by expanding the position variables $u^{\pm}(z,\varphi)$ and momentum distributions $p^{\pm}(z,\varphi)$ in the partial waves of Mathieu functions.[f] Further, one then calculates the gravitational shift $\delta\tilde{U}(z,\varphi)$, in order to carry a particle over from I to II, or back,[6] using the Shapiro delay.

4.2. *The surface gravity and the conformal gauge*

Since we have now the description of the antipodal map in our black hole spacetime, we will look more closely at the conformal invariance. First of all, one should rely in the dynamical situation on (conformal) Killing vectors in order to describe the spacetime symmetries. Our Lagrangian is conformal invariant under Eq. (14), so we can use the freedom of the conformal factor Ω. Remember, different ω means different notion of the vacuum state for the in-going and outside observer, so they will use different conformal gauge freedom. It is desirable that for the out-going observer, the surface gravity of the horizon is conformal invariant. Further, conformal transformations must preserve affinely parameterized null geodesics. This will deliver Ω for the in-going observer. We can define out-going and in-going null normals[18] for $\bar{g}_{\mu\nu}$

$$\begin{aligned} \bar{l}^{\mu} &= (1, N\sqrt{N^2 - r^2N^{\varphi 2}}, 0, 0), \\ \bar{m}^{\mu} &= \Big(-\frac{1}{2r^2N^{\varphi 2} - 2N^2}, -\frac{N}{2\sqrt{N^2 - r^2N^{\varphi 2}}}, 0, 0\Big). \end{aligned} \tag{45}$$

with $\bar{l}^{\mu}\bar{l}_{\mu} = \bar{m}^{\mu}\bar{m}_{\mu} = 0$, $\bar{l}^{\mu}\bar{m}_{\mu} = -1$. The surface gravity then becomes

$$\kappa = 2N\Big(\partial_r(\sqrt{N^2 - r^2N^{\varphi 2}}) + \partial_t\Big(\frac{1}{N}\Big)\Big) = 2N\Big(\partial_t\sqrt{\bar{g}_{rr}} - \partial_r\sqrt{\bar{g}_{tt}}\Big). \tag{46}$$

This is consistent with the metric definition of κ.

4.3. *The meaning of the warped spacetime*

Let us now return to $g_{\mu\nu} = \omega^{4/3}\bar{\omega}^2\bar{g}_{\mu\nu}$. In the CDG setting, the evaporation of the black hole is also determined by the complementarity transformation of ω between the in-going and outside observer. Our spacetime is now ($b_4 = b_3b_2$)

$$\begin{aligned} ds^2 = \omega^{4/3}\bar{\omega}^2\Big[(C_2(t+b_3)^4 + C_3)\frac{(10b_2^3r^2 + 20b_2^2r^3 + 15b_2r^4 + 4r^5 + C_1)}{5r^2}\cdot \\ \Big(-dt^{*2} + dr^{*2}\Big) + dz^2 + r^2\Big(d\varphi + \frac{N^{\varphi}}{N_2^2}dt^*\Big)^2\Big], \end{aligned} \tag{47}$$

[f] So the spherical harmonics are replaced by the Mathieu harmonics

with

$$\omega^{4/3}\bar{\omega}^2 = \frac{1}{(r+c_2)^2(t+c_3)^2(r+b_2)^2(t+b_3)^2}, \tag{48}$$

We observe that $\omega^{4/3}\bar{\omega}^2$ approaches zero for coordinate time $t \to \infty$, so $g_{\mu\nu}$ shrinks to zero, so the distant observer sees a gradually shrinking black hole when the metric time runs to infinity. Further, the only contribution from the 5D spacetime is the $\omega^{4/3}$. Remarkable, the projected Weyl component is necessary in order to obtain the same form of N^2 and to avoid naked singularities. So $\omega^{4/3} = [(r + c_2)^2(t + c_3)^2]^{-1}$ is the "scale" term from the 5D warped spacetime (the warpfactor in the RS model is the product of y-dependent part and ω part). Suppose one wants combine the conformal transformation with an internal symmetry transformation, i.e., a spacetime transformation. In particular, the scale transformations. One can proof in that case, $\Box \log \Omega = 0$,[19] which is consistent with our 2D null hypersurface of Eq. (32). Further, in dimension $n \neq 4$ only the scale-invariant theories based upon scalar fields (so ω from 5D) are conformally invariant. Conclusion: $\bar{\omega}$ of our $\bar{g}_{\mu\nu}$ can be used in non-vacuum models. An additional advantage of the warped spacetime in connection with cosmology and hierarchy problem, was already mentioned in the introduction. A new aspect will be the embedding of the 5D in the 4D spacetime and the relation with the 3D BTZ blackhole solution.

4.4. *The relation with the 3D Baňados-Teitelboim-Zanelli black hole*

In the spacetime under consideration, the dz^2 term can be omitted. One obtains then the 3D Baňados-Teitelboim-Zanelli (BTZ) black hole spacetime. It solves the Einstein equations with a negative cosmological constant.[29] The BTZ solution is related to the AdS/CFT correspondence and intensively studies in connection with black hole entropy issues. However, we should like to take the cosmological constant zero. In a former study,[30] an exact solution was found in a CDG setting in Eddington-Finkelstein retarded coordinates (U, ρ) (or advanced V) where the antipodal map $(U, V, \varphi) \to (-U, -V, \varphi + \pi)$ is applicable:

$$ds^2 = \frac{e^{-2c_1 U}}{(c_2\rho + c_3)^2}\Big[\pm\frac{c_1(c_3^2 - c_2^2\rho^2)}{c_2 c_3}dU^2 - 2dUd\rho + dz^2 + \rho^2\Big(d\xi + F(U)dU\Big)^2\Big], \tag{49}$$

which is Ricci flat, while $\tilde{R}^{(4)} = \frac{6c_1c_2}{c_3}$. The function $F(U)$ will be fixed when matter terms are incorporated (i.e. for example, a scalar gauge field). The metric Eq. (49) will then contain a term $b(U, \rho)^2 d\varphi^2$ and a relation like $(N^\xi)' = \frac{b}{\eta^2 X^2 + \omega^2}$ will be obtained. It has no curvature singularity. The location of the apparent horizon in U:

$$\rho_{AH} = \pm\frac{c_3}{\sqrt{c_2(c_2 + \frac{c_3}{c_1}F(U)^2)}}, \tag{50}$$

with

$$\frac{d\rho}{dU} = \frac{1}{2} e^{-2c_1 U} \cdot \begin{cases} -\frac{c_1}{c_2 c_3} & \ldots\ldots\ldots \rho \to 0 \\ \frac{c_3 F(U)^2 + c_1 c_2}{c_2^2 c_3} & \ldots \rho \to \infty \\ 0 & \ldots\ldots\ldots\ldots \rho = \rho_{AH} \end{cases} \tag{51}$$

which is independent of ω. Here C_i are constants and $F(U)$ a function determined by the non-diagonal contribution. Further, we have

$$\lim_{\rho \to 0} g_{UU} \to \pm \frac{c_1}{c_2 c_3 e^{2c_1 U}}, \tag{52}$$

So when the evaporation speeds up, it approaches zero. We are dealing here with null-radiation in the (ρ, z)-plane. One could compare this solution with that found by Chan[32] in standard GR of a spinning black hole. They also find a solution for $F(U)$ which is determined by an energy-momentum tensor of null spinning dust. It is again curious that the "uplifted" BTZ has the same solution, comparable with the "up-lifting" 5D[30]

5. Metric Fluctuation and Hawking Radiation

In the original deviation of the Hawking radiation, one uses the propagation of a linear quantized field in a classical background metric. However, near the horizon, high-frequencies metric fluctuations can contribute to the vacuum polarization and the impact of gravitational back reactions can be large. These zero-point fluctuations result in a modification of the Hawking radiation by gravitational waves.[31] One could question what the effect is of these waves in our CDG model, where we have instead the dilaton field. Of course, one should need a quantum gravitational approach, which is not available yet. So need some approximation. However, effect of the scattering of these quanta at the horizon can be investigated in the context of the antipodal mapping considered here.[g] Without the contribution of the metric fluctuations, the mean number of quanta reaching $\mathcal{J}^+$ takes the form

$$< \bar{n}_\lambda >_0 \sim \frac{1}{e^{2\pi E_+/\kappa} - 1}, \tag{53}$$

with E_+ the energy measured at $\mathcal{J}^+$ for the out modes. This is the Planck distribution with temperature $T = \kappa/2\pi = (8\pi M)^{-1}$. The correction terms can then be calculated by using the s-modes of a quantum massless scalar field and by using the fact that the in-going and out-going modes decouple.[31] One makes use of the mean energy flux, by calculating $dE/dU = 4\pi r^2 < T_{UU} >_{ren}$, where the renormalized surface gravity is used. However, in this approximation, the reflection conditions are at r=0, with in our antipodal map must be revised (we have no inside). We can

[g] A suitable approximation is the high-frequency approximation applied to a Vaidya spacetime, where the not-flat background spacetime is distorted by the gravitational waves.[33] A recent application was provided by Slagter.[34,35]

use the (U,U) energy-momentum component of our model and can apply Eq. (41) for the antipodal contribution.

Notice that the meaning of the local dilaton $\bar{\omega}$, is twofold. First, it determines the metric fluctuations (one also must incorporate in the dilaton equation the φ-dependency). Secondly, The in-going observer will use a different conformal gauge freedom Ω on $\bar{\omega}$ to describe the vacuum. Further, $\bar{\omega}$ is locally unobservable, unless we include metric fluctuations (gravitational waves. It will be necessary to compare this with the usual contribution using the Bunch-Davies method (and to taken into count the antipodal contribution). Note that the outside observer will use a different gauge and he/she experiences a mass $\sim \omega^2 N^2$ and Hawking radiation $\sim \partial_U(\omega^2 N^2)$, while for the in-going observer it is part of his vacuum. On the other hand, the outside observer is not aware of the antipodal identification. One could also say that they disagree about the observed scales. Or differently stated, they disagree about the back reaction from the Hawking radiation.

6. Conclusion and Outlook

We find an exact time dependent solution in the conformal dilaton gravity model on a warped 5D spacetime. The spacetime is written as ${}^{(5)}g_{\mu\nu} = \omega^{4/3\,(5)}\tilde{g}_{\mu\nu}$ and ${}^{(4)}\tilde{g}_{\mu\nu} = \bar{\omega}^{2\,(4)}\bar{g}_{\mu\nu}$. In our model, ω can be seen as the contribution from the bulk, while $\bar{\omega}$ is the brane component. It is conjectured that the different conformal gauge freedom, Ω, the in-going and outside observers possess, can be calculated by demanding a conformal invariant surface gravity and the preservation of affinely parameterized null geodesics. This means that the complementarity is expressed by the different notion of the vacuum state. The solution guarantees regularity of the action when $\omega \to 0$. We don't need a Weyl term in the action (generates negative metric states). In stead, we have a contribution from the bulk, i.e., the electric part of the 5D Weyl tensor. It is remarkable that the 5D field equations and the effective 4D equations can be written for general dimension n, with $n = 4, 5$. The energy-momentum tensor of the time-dependent dilaton, determining also the Hawking radiation, can be calculated exactly. By suitable choice of the parameters, the spacetime $\bar{g}_{\mu\nu}$ can be regular and singular free. This exact solution, nonetheless without mass terms, can be used to tackle the deep-seated problem of the black hole complementarity: the infalling and outside observer experience different ω by the choice of Ω. The next task is to incorporate mass into our model and investigate the dilaton-scalar field interaction. The conformal invariance will then spontaneously be broken.

Appendix: The Quintic Horizon Equation and Related Issues

Our quintic polynomial, determining the horizons,

$$f = r^5 + \frac{15}{4}b_2 r^4 + 5b_2^2 r^3 + \frac{5}{2}b_2^3 r^2 + \frac{C_1}{4} = 0, \tag{54}$$

can be written by a, so-called Tschirnhaus transformation, in the form

$$r^5 - \frac{15b_2}{16}(C_1 + b_2^5)r^2 - \frac{125b_2^3}{256}(C_1 + b_2^5)r - \frac{1}{16}(C_1 + b_2^5)^2 = 0 \qquad (55)$$

By scaling, this form can be reduced to the Bring-Jerrard form $r^5 + r - c$, with c a function of b_2 and C_1.[27] There is an interesting relation between the symmetry group of the icosahedron and our quintic equation. The symmetry group is isomorphic with the Galois group A_5 (of an irreducible quintic polynomial). The icosahedron is dual to the dodecahedron, i.e., their symmetries are isomorphic. The A_5 is interesting in physics, because it is a simple group having no invariant subgroups. It has three orbits, which are invariant under the antipodal map. So the connection with the Möbius group is clear. For details, we refer to Toth.[27] It is conjectured that our quintic polynomial (Eq. (54)) has a deep-seated relation with the 5D spacetime solution. Further, it is remarkable that the resulting quintic equation is independent of the dimension of our manifold ($n = 4, 5$). Moreover, the nice fitting of the antipodal map in our model cannot be a coincident. From Eq. (26) we observe that the derivative of f is $5r(r + b_2)^3$. So it is expected that our quintic equation results from a immersion[h] of a closed surface S in $\mathbb{R}^3$ into $\mathbb{R}^4$. This is currently under investigation by the author.

From neutrino masses to the full size of the universe — Some intriguing aspects of the tetron model

B. Lampe

Theoretical Physics, Universität Hamburg, Hamburg, Germany
E-mail: Lampe.Bodo@web.de

The universe according to the tetron model consists of invisible tiny constituents, elastically bound with bond length about the Planck length and binding energy the Planck energy. A tetron transforms as the fundamental fermion(=octonion) representation **8** of SO(6,1). With respect to the decomposition $SO(6,1) \to SO(3,1) \times SO(3)$ it possesses spin 1/2 and isospin 1/2, i.e. a tetron represents an isospin doublet of Dirac spinors. The 24 known quarks and leptons arise as eigenmode excitations of a tetrahedral fiber structure, which is made up from 4 tetrons (plus 4 antitetrons) and extends into 3 additional 'internal' dimensions. While the laws of gravity are due to the elastic properties of the tetron bonds, particle physics interactions take place within the internal fibers. I will concentrate on two of the most intriguing features of the model:
- understanding small neutrino masses from the conservation of isospin, and, more in general, calculating the spectrum of quark and lepton masses. This is obtained from the tetron model's interpretation of the Higgs mechanism.
- the possibility to determine the full size of the universe from future dark energy measurements. This is obtained from the tetron model's interpretation of the dark energy phenomenon.

Finally, the dark energy equation of state, i.e. the equation of state of the tetron background will be derived.

Keywords: Tetron model; quark and lepton masses and mixings; neutrino masses; full size of the universe; dark energy equation of state.

1. Introduction

In the following sections some implications of the tetron model[1–4] of particle physics and cosmology will be presented.

In this model the universe itself is an elastic medium composed of invisible constituents which are bound at Planck energy. While the laws of gravity are due to the elastic properties of the medium, particle physics interactions take place within internal fibers, with the characteristic internal energy being the Fermi scale. All ordinary matter quarks and leptons are constructed as quasiparticle excitations of this internal fiber structure. Since the quasiparticles fulfill Lorentz covariant wave equations, they perceive the universe as a 3+1 dimensional spacetime continuum lacking a preferred rest system. Any type of mass/energy induces curvature on the spacetime continuum as determined by the Einstein equations.

Now in the following I want to explain some details of these statements.

2. Quark and Lepton Masses from Excitations of Internal Tetrahedrons

In the tetron model the ground state of our universe looks like illustrated in Figure 1. In this figure the large horizontal arrow stands for the 3 dimensions of physical space, while the tetrahedrons extend into 3 additional internal dimensions. The picture is a little misleading because in the tetron model physical space and internal dimensions are assumed to be completely orthogonal. This means the whole game is actually played within a large altogether 6 dimensional space, 3 physical dimensions and 3 internal ones.

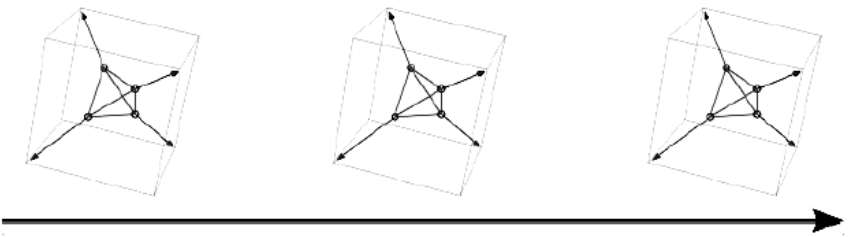

Fig. 1. The global ground state of the tetron model after the electroweak symmetry breaking.

If you ask: why this structure?, I can say at this point that the tetrahedral structure is introduced in order to explain the observed quark and lepton spectrum, which means to get exactly 24 excitation states with the correct multiplet structure.

Before discussing the excitations, let us first consider the ground state Figure 1 in some more detail. As you can see, each tetrahedron is made up from 4 constituents called 'tetrons', depicted as the white dots[a]. The white arrows denote the 'isospins', i.e. internal spin vectors of the tetrons. This means the tetrons have a spin in physical space and in addition an internal spin in internal space. As turns out, the interactions of the internal spins play an important role for particle physics and for electroweak symmetry breaking.

It is important to note, that the 4 isospin vectors in Figure 1 define tetrahedrons, too. Due to the pseudovector property of these vectors their tetrahedral symmetry group actually is a Shubnikov group.[5–7] This means, while the coordinate symmetry is S_4, the arrangement of isospin vectors respects the tetrahedral Shubnikov symmetry

$$G_4 := A_4 + CPT(S_4 - A_4) \tag{1}$$

where $A_4(S_4)$ is the (full) tetrahedral symmetry group and CPT the usual CPT operation except that P is the parity transformation in physical space only. Since

[a] Actually, antitetrons are needed as well. For details see the review.[3]

the elements of $S_4 - A_4$ contain an implicit factor of internal parity, the symmetry (1) certifies CPT invariance of the local ground state in the full of R^{6+1}.

2.1.

In the situation depicted in Figure 1 a symmetry breaking has already taken place, because the isospins are aligned between all the tetrahedrons.

Before the symmetry breaking, which means above a certain temperature, isospins are distributed randomly, corresponding to a local $SU(2) \times U_1$ symmetry[b], but when the universe cools down, there is a phase transition, and the isospins freeze into the aligned structure, breaking the symmetry from $SU(2) \times U_1$ to the discrete 'family group' G_4. And the important point to note is, this temperature can be identified with the Fermi scale.[2]

How does this work out in detail? Mathematically, a tetron is assumed to transform as the fundamental spinor representation of SO(6,1). This representation is 8-dimensional and sometimes called the octonion representation.

With respect to the decomposition of $SO(6,1) \to SO(3,1) \times SO(3)$ into the 3-dimensional base space and the 3-dimensional internal space, a tetron possesses spin 1/2 and isospin 1/2. This means it can rotate both in physical space and in internal space, and corresponds to the fact that a tetron Ψ decomposes into an isospin doublet $\Psi = (U, D)$ of two ordinary SO(3,1) Dirac fields U and D.

$$8 \to (1,2,2) + (2,1,2) = ((1,2) + (2,1), 2) \tag{2}$$

Using this, one can now rigorously define the isospin vectors used and drawn in Figure 1:

$$\vec{Q} = \Psi^\dagger \vec{\tau} \Psi \tag{3}$$

where τ are the internal spin Pauli matrices. Actually one has to distinguish chiral isospin vectors

$$\vec{Q}_L = \frac{1}{2}\Psi^\dagger(1-\gamma_5)\vec{\tau}\Psi \qquad\qquad \vec{Q}_R = \frac{1}{2}\Psi^\dagger(1+\gamma_5)\vec{\tau}\Psi \tag{4}$$

and for tetrons and antitetrons, but this complication will not be discussed in the present talk.[3]

A typical interaction Hamiltonian between such isospin vectors of 2 tetrons a and b looks like this

$$H_H = -J\,\vec{Q}_a \vec{Q}_b \tag{5}$$

So it has the form of a Heisenberg interaction - but for isospins, not for spins. The coupling J is called the 'isomagnetic exchange coupling'.

The mathematical treatment of the excitations arising from (5) is similar to that of magnons in ordinary magnetism, but the physics here is much different. Since

[b]Weak parity violation, i.e. the appearance of $SU(2)_L$, is discussed in.[3]

the isospin vibrations take place in internal space, they are pointlike in physical space. Furthermore, they inherit their fermion nature from the fermion property of the vibrating tetron.

In reality, the Hamiltonian is somewhat more complicated than (5) due to the appearance of antitetrons and of the fact that inner- and inter-tetrahedral interactions are present, the inner ones with 'exchange coupling' $j = -O(1)$ GeV (strong interaction scale) and the inter ones with $J = O(100)$ GeV (weak interaction scale). j and J have different sign, because j leads to the frustrated 'antiferromagnetic' ground state of a single tetrahedron, while J is responsible for the 'ferromagnetic'[c] alignment of neighboring tetrahedrons.[1]

This alignment can be shown to be the microscopic origin of the electroweak symmetry breaking, and furthermore it allows to calculate the quark and lepton masses. I refer here to references[1] and[2]. In these papers you can find all the details - how to construct the electroweak order parameter, the Higgs field and how to calculate the quark and lepton masses and mixings from the isospin couplings.

At this point it must be enough to show that among the 24 isospin excitations which are the quarks and leptons, there are 3 almost massless modes which correspond to the neutrinos. This has to do with the conservation of total isospin. Namely, the masses of the neutrinos are particularly suppressed because the 3 neutrino modes correspond to the vibrations of the 3 components of the total internal angular momentum vector in one tetrahedron

$$\vec{\Sigma} := \sum_{a=1}^{4} \vec{Q}_a = \sum_{a=1}^{4} \Psi_a^\dagger \vec{\tau} \Psi_a \tag{6}$$

Whenever this quantity is conserved

$$d\vec{\Sigma}/dt = 0 \tag{7}$$

the neutrino masses will strictly vanish. In fact, the Heisenberg type of interactions (5) conserve total internal angular momentum. Therefore, they fulfill (7) and give no contribution to the neutrino masses. Further details can be found in.[1]

So $\vec{\Sigma}$ is the total internal angular momentum (total isospin), and the conservation equation for the 3 components of $\vec{\Sigma}$ leads to 3 of the 24 eigenmodes being massless. Contributions to the neutrino masses come from tiny torsional interactions which violate the conservation of isospin.[1]

3. The Full Size of the Universe from a Simple Spring Model

From this point on, I do not want to give more details on the particle physics implications, but want to concentrate on gravity and cosmological aspects. In order to include gravity in the tetron model, it is assumed that there is not only an interaction among the isospin vectors in internal space, but also a binding among tetrons

[c] I am using the language of magnetism, although interactions of isospins and not of spins are considered here.

in physical space, and that this binding is elastic. In other words, our universe is a 3-dimensional elastic medium expanding within some larger 6-dimensional space, and it can acquire curvature both in space and time.

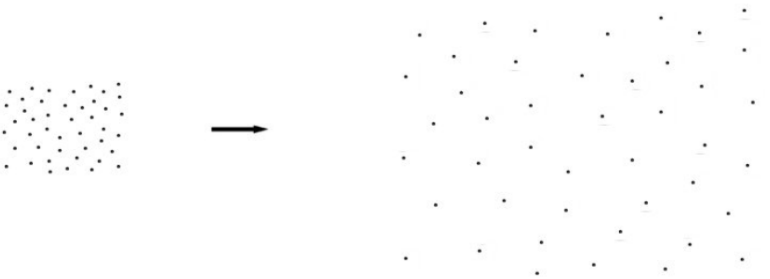

Fig. 2. Expansion of the empty universe consisting of tetrahedrons which look pointlike in physical space.

In 3-dimensional physical space, the expansion looks as shown in Figure 2. Note that in physical space the tetrahedrons are pointlike because they extend only into the internal dimensions. This means, you do not see the tetrahedral structure, you only see points which are bound with bond length about the Planck length and binding energy the Planck energy.

In the beginning, that means before the expansion started, the universe was created in a sudden so to say inflationary condensation process from an ultrahot tetron gas and afterwards was pushed to expansion by the condensation energy. Quark and matter particles were created as quasiparticle excitations of the tetrons gliding on the elastic medium. Since the quasiparticles fulfill Lorentz covariant wave equations, they perceive the universe as a 3+1 dimensional spacetime continuum lacking a preferred rest system. Any type of mass/energy induces curvature on the spacetime continuum as determined by the Einstein equations.

Now in the next step I want to draw a connection between the smallest and the largest scales of the universe, namely between the tetron binding structure at Planck length and the size of the universe as a whole. For that purpose, let us consider the binding energy of 2 tetrahedrons as a function of the bond length L, so this means the binding energy of 2 dots in Figure 3 as a function of their distance. It is assumed, that this function has a minimum at some bond length L_s and that at present we are at bond length L_0 roughly equal to the Planck length. Then the function looks like in Figure 3.

From this figure one concludes that the universe is expanding towards an equilibrium corresponding to an average bond length L_s. So the whole universe is carrying out an extremely low frequency breathing vibration $\omega \ll 10^{-10} yrs^{-1}$ around L_s, and all the tetron bonds on average are vibrating in accord with the universe. One

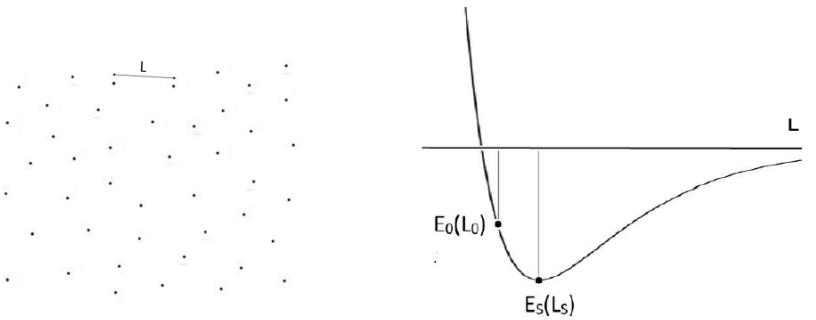

Fig. 3. Binding energy E of 2 neighboring tetrahedrons as a function of their distance L.

can work out the details of this picture and indeed show that this effect accounts for the present accelerated expansion as given by the dark energy observations.[4]

An important point to note is that in future more precise dark energy measurements may allow to extract the breathing frequency ω of the universe, and from ω one can determine the full size radius a of the universe according to the simple formula

$$a = \frac{L}{L_s}\frac{c}{\omega} \tag{8}$$

where c is the speed of light.

3.1.

The remainder of this section is devoted to the proof of (8) within a simple spring type model, and to carry the idea of the universe as an extremely low frequency oscillatory system to the end.

In addition, these considerations will allow to derive the dark energy equation of state,[11] i.e. the equation of state of the invisible tetron background substrate. The relation between tetron density and pressure is a characteristic property of the bound tetron system. Actually, the elastic tetron universe resembles a fluid with elastic bonds among its constituents rather than an ordered solid, and so the fluid equation seems an appropriate way of description[d].

By 'full size' is meant the diameter of the 3-dimensional elastic medium which according to the tetron model is our universe. As a measure of this size I shall take a(t) as appears in the standard FLRW line element

$$ds^2 = -c^2dt^2 + a(t)^2\left[\frac{dr^2}{1-kr^2} + \cdots\right] \tag{9}$$

a(t) is assumed to have dimension of length and dr^2 to be dimensionless.

[d]But note, the stiffness $\zeta = \frac{c^7}{\hbar G^2} \approx 10^{112}\frac{kg}{ms^2}$ of the tetron bonds is large enough, that this fluid pours out into only 3 of the 6 dimensions.

Following reference[4] a harmonic oscillatory term $\sim \omega^2(a - a_s)$ appears in the modified FLRW equations in addition to the cosmological constant Λ

$$\ddot{a} = -\frac{4\pi}{3}G\rho a - \omega^2(a - a_s) + \frac{\Lambda}{3}c^2 a \tag{10}$$

The assumption of a breathing vibration with $a(t) \sim L(t)$ then leads to an identical equation for L(t):

$$\ddot{L} = -\frac{4\pi}{3}G\rho L - \omega^2(L - L_s) + \frac{\Lambda}{3}c^2 L \tag{11}$$

The interpretation of the cosmological constant term within the tetron model will be postponed to later sections. For the moment, let us simply forget about Λ. Then the empty universe behaves harmonic with frequency ω, the reason being that its tetrahedral constituents follow a harmonic elastic interaction, i.e. the binding energy among the internal tetrahedrons in the neighborhood of the minimum at L_s can be approximated by a parabola, see Figure 3.

While characteristic frequencies ω and H_0(=Hubble constant) of the universe are tiny, the frequency $f_s = f(t_s)$ of a single tetron spring is extremely large and given by

$$f(t) = \frac{1}{T(t)} = \frac{c}{L(t)} \tag{12}$$

where $T(t) = L(t)/c$ is the time dependent Planck time.

In accordance with reference[4] I have introduced time dependent Planck quantities

$$L(t) = \sqrt{\frac{\hbar(t)G(t)}{c^3}} \qquad T(t) = \sqrt{\frac{\hbar(t)G(t)}{c^5}} \qquad M(t) = \sqrt{\frac{\hbar(t)c}{G(t)}} \tag{13}$$

with present day values at t=0:

$$L_0 = 1.6 \times 10^{-35} m \qquad M_0 = 2.2 \times 10^{-8} kg \qquad T_0 = 5.4 \times 10^{-44} s \tag{14}$$

Inverting (13), a time dependent Planck and Newton constant is induced

$$\hbar(t)c = E(t)L(t) \tag{15}$$

$$G(t) = c^4 L(t)/E(t) \tag{16}$$

No time dependence of c is indicated, because in the present model there is none - at least if one uses the so-called cosmic coordinates t and r appearing in the line element (9).

3.2.

Coming to the details of the spring model, it is assumed that at each point of the elastic universe each direction can be approximated as a serial connection of N harmonic springs which connect N+1 constituents (= internal tetrahedrons). These

can be thought to lie approximately on a straight line running from one end of the universe to the other. The spatial extension of the universe is then given by

$$a(t) = NL(t) \tag{17}$$

Clearly, this includes the additional very simplifying assumption that the expanding universe has the approximate form of a cube.

The mass μ of any one of the spring chains is given by the sum of all constituent rest masses M_{rest} in the chain, i.e.

$$\mu = NM_{rest} \tag{18}$$

where M_{rest} is the rest mass of one internal tetrahedron. The value of M_{rest} is unknown but should be typically of the order of the Planck mass.

Since in the neighborhood of L_s the binding energy $E(t) = E(L(t))$ is assumed to be quadratic in L, it must have the form

$$E(L) = E_s + \frac{d}{2}(L - L_s)^2 = M_{rest}c^2 - E_{bind} + \frac{1}{2}M_{rest}c^2\left(1 - \frac{L}{L_s}\right)^2 \tag{19}$$

i.e. E(L) is a sum of a constant energy E_s plus a variable component, which vanishes at $L(t_s) = L_s$. E_s comprises the binding energy of 2 tetrahedrons at L_s as well as their possible rest mass

$$E_s = E_{rest} - E_{bind} = M_{rest}c^2 - E_{bind} \tag{20}$$

It is to be noted that (19) does not meet the condition $E(L = \infty) = M_{rest}c^2$, so it holds only in the neighborhood of $L = L_s$. Note further that M_{rest} could in principle be any value, even much larger than E_{bind}. To have a bound state one needs a local minimum of $E(L)$ at L_s but not necessarily a negative $E(L_s)$, i.e. the condition

$$E_{bind} > E_{rest} \tag{21}$$

is not compelling - although present dark energy data seem to give a hint this inequality is true and furthermore in the simple spring model it will be needed for consistency of energy conservation eq. (27).

3.3.

The spring constant of a single spring is $d = M_{rest}f(t_s)^2$ with $f(t)$ from eq. (12). The basic reason why the breathing frequency ω of the universe is so small whereas the fundamental frequency $f = 1/T$ of its tetron constituents is so large, arises from the following fact: Consider one chain of strings stretching from one end of the universe to the other, each spring with a constant d. Then the serial connection of N springs is itself a harmonic oscillator with a much smaller combined spring constant

$$D = d/N \tag{22}$$

Note that the springs connected in parallel belong to different chains and do not contribute to the effective overall chain constant D.

Using $D = \mu\,\omega^2$ one can express the (extremely small) frequency ω of the universe in terms of the (extremely large) Planck frequency $f_s = f(t_s)$:

$$\omega^2 = \frac{D}{\mu} = \frac{d/N}{NM_{rest}} = \frac{1}{N^2} f_s^2 = \frac{c^2}{N^2 L_s^2} \tag{23}$$

Thus, the full extension (17) of the universe at equilibrium can be given as

$$a_s = NL_s = \frac{c}{\omega} \tag{24}$$

in a similar way as the observable(=Hubble) radius is given as c/H_0.

The present size of the universe is somewhat smaller than a_s and given by (8). These equations show that a precise enough measurement of the dark energy effect (i.e. of ω) can lead to an estimate for the full size of the universe.

3.4.

The spring model is also of use to better understand the FLRW theory within the general elasticity ansatz. The essence of the FLRW model is contained in the following equations
(i) the Friedmann equation for the Hubble parameter $\dot{a}/a$ and
(ii) the 'fluid equations' for the densities ρ_{tet} and ρ_{mat} of tetrons and (ordinary and dark) matter, respectively. Both, the tetron substrate and the matter content of the universe are assumed to be separate uniformly distributed perfect fluids with mass energy densities $\rho_{tet}(t)$ and $\rho_{mat}(t)$ and pressure $p_{tet}(t)$ and $p_{mat}(t)$.

3.4.1.

In the present model one can write down an equation for the conservation of energy in a matter-free spacially flat tetron universe

$$N^3 \frac{M_{rest}}{2} \dot{a}^2 + 3N^3 \frac{M_{rest} c^2}{2} \left(1 - \frac{a}{a_s}\right)^2 = -N^3 E_s \tag{25}$$

the conserved energy being the kinetic plus potential energy of the system of N^3 masses M_{rest} and $3N^3$ springs which make up the empty universe. The system is furthermore assumed to be in a breathing mode. Then, the difference in neighboring spring positions $x_{n+1}(t) - x_n(t)$ within one of the spring chains is n-independent and given by $L(t) - L_s$ for each spring n, and the velocity difference by $\dot{x}_{n+1} - \dot{x}_n = \dot{L}(t)$.

Comparing (25) to the corresponding matter-free FLRW equation

$$\frac{1}{2}\dot{a}^2 + \frac{3c^2}{2}\left(1 - \frac{a}{a_s}\right)^2 - \frac{1}{6}\Lambda c^2 a^2 = 0 \tag{26}$$

one finds 3 differences:
- There is no Λ-term in (25). Any cosmological constant contribution from tetrons has been removed in (25), because for the matter free elastic tetron substrate the binding forces do not drive the universe with Λa^2 to infinity, but with $\omega^2(a-a_s)^2$ to a_s. As will turn out later in section 3.4.3, in the presence of matter a cosmological constant reappears because the time dependent[4] Newton constant (16) implies a time dependent matter contribution to the cosmological constant.[8–10]

- There is a nonvanishing constant contribution $\sim E_s$ on the rhs, where there is 0 in FLRW. This has to do with the fact that the Friedmann equation only counts contributions to the spacetime curvature, where a constant binding energy of the tetron constituents does not matter. The FLRW model does not know about the cosmic constituents and uses the freedom to put their background binding energy to zero. In other words, a constant (like the binding energy $E_s = E(L_s)$ at equilibrium $a = a_s$) does not contribute to any cosmic expansion. E_s is the background tetron binding energy which leads to the flat elastic substrate being built from free tetrons, but does not at all contribute to its possible curvature or expansion.

- In order to have consistency with aforegoing formulas, in (26) I have pulled out a factor of 3 from the definition of the cosmic frequency ω.

3.4.2.

So far we have considered an empty universe built up from an elastic substrate of bound tetrons (or, more precisely, of bound internal tetrahedrons). If, in addition, matter is present in the universe, the modified Friedmann equation becomes

$$\frac{1}{2}\dot{a}^2 + \frac{3}{2}\omega^2(a-a_s)^2 = \frac{4\pi}{3c^2}G\rho_{mat}a^2 + \frac{1}{6}\Lambda_{mat}c^2a^2 - \frac{E_s}{M_{rest}} \tag{27}$$

where ρ_{mat}/c^2 denotes the mass density of ordinary plus dark matter. As before in (25), the constant term $\sim E_s$ is not relevant when forming the time derivative of (27) in order to obtain the equation for the curvature/acceleration $\ddot{a}$.

Equation (27) includes a cosmological constant contribution Λ_{mat} due to ordinary and dark matter. This contribution derives from the time dependence of the Newton constant $G = c^4L(t)/E(L(t))$ and will now be proven to be time dependent, too.

3.4.3.

In order to determine Λ_{mat} and its time dependence, we turn to the cosmological fluid equations. Both the expanding tetron background and the matter distribution will be approximated as separate fluids distributed homogeneously over the universe with energy densities $\rho_{tet}(t)$, $\rho_{mat}(t)$ and pressure $p_{tet}(t)$ and $p_{mat}(t)$.

For the tetronic fluid the appropriate form of the fluid equation is the ordinary one

$$\dot{\rho}_{tet} + 3(\rho_{tet} + p_{tet})\frac{\dot{a}}{a} = 0 \tag{28}$$

because the spring coupling d is constant and the time dependent Newton coupling not involved. In terms of a single tetrahedron with physical volume L^3 around it the density of the tetronic 'dark energy' fluid is

$$\rho_{tet}(t) = \frac{E}{V} = \frac{E_s}{L^3} + \frac{E_{rest}}{2L_s^3}\left(1 - \frac{L(t)}{L_s}\right)^2 \tag{29}$$

where $E_s = E(L_s)$ is the Planck energy at equilibrium and $M_{rest} = E_{rest}/c^2$ is the tetrahedral rest mass, cf. eq. (20).

Similarly, the dark energy pressure is obtained to be

$$p_{tet} = -\frac{\partial E}{\partial V} = \frac{E_{rest}}{3L_s^3}\left(1 - \frac{L}{L_s}\right) + O(L - L_s)^2 \tag{30}$$

and it can be checked that (29) and (30) indeed fulfill eq. (28).

These equations correspond to an equation of state parameter

$$w = \frac{p_{tet}}{\rho_{tet}} = \frac{E_{rest}}{3E_s}\left(1 - \frac{L}{L_s}\right) + O(L - L_s)^2 \tag{31}$$

To compare this with various other dark energy equations of state suggested in the literature one may consult.[11]

3.4.4.

For matter and dark matter the suitable form of the fluid equation can be derived from the Bianchi identity

$$T^{\mu}_{\nu;\mu} = 0 \tag{32}$$

for the energy-momentum tensor in general relativity. In case of a time dependent Newton and cosmological constant one has[8–10]

$$\frac{d}{dt}\left[G\rho_{mat} + \frac{c^4}{8\pi}\Lambda_{mat}\right] + 3G(p_{mat} + \rho_{mat})\frac{\dot{a}}{a} = 0 \tag{33}$$

On the other hand, for the late time cosmology under consideration, matter can be approximated in the standard way as uniformly distributed dust. Ordinary and dark matter should then fulfill the ordinary fluid equation

$$\dot{\rho}_{mat} + 3(p_{mat} + \rho_{mat})\frac{\dot{a}}{a} = 0 \tag{34}$$

by means of

$$p_{mat} = 0 \tag{35}$$

$$\rho_{mat}(a) = \rho_{mat}(a_s)\frac{a_s^3}{a^3} \tag{36}$$

Comparing (33) and (34) one concludes, that any imbalance coming from the time dependency of G must be cancelled by a time dependence of Λ_{mat} according to[8–10]

$$\dot{G}\rho_{mat} + \frac{c^4}{8\pi}\dot{\Lambda}_{mat} = 0 \tag{37}$$

In the present approach all time dependencies arise only through $a(t) = NL(t)$. Therefore using

$$\frac{d}{dt} = \dot{a}\frac{d}{da} = \dot{L}\frac{d}{dL} \tag{38}$$

one can calculate Λ_{mat} from the scale dependence of G eq. (16)

$$\Lambda_{mat}(a) = \Lambda_{mat}(a_s) + 8\pi \int_a^{a_s} da\ \rho_{mat}(a)\frac{d}{da}\frac{L}{|E(L)|} \tag{39}$$

with $L = a/N$. In the quadratic approximation used throughout this paper, where one considers the neighborhood of $a = a_s$, one can carry out the integral in (39) to obtain the a(t) dependence of Λ_{mat}:

$$\Lambda_{mat}(a) = \Lambda_{mat}(a_s) + \frac{8\pi\rho_{mat}(a_s)}{|E_s|}(L_s - L) + O(L - L_s)^2 \tag{40}$$

Here, $\rho_{mat}(a_s)L_s^3/|E_s|$ is the ratio of average energy of matter within a Planck volume L_s^3 over one tetrahedral binding energy E_s. Since there are much more bound tetrons than matter particles in the universe, the cosmological constant due to (40) is extremely small. This can be seen more explicitly by rewriting (40) as

$$\Lambda_{mat}(a) - \Lambda_{mat}(a_s) = 8\pi\frac{\rho_{mat}(a_s)}{\rho_{tet}(a_s)}\frac{L_s - L}{L_s^3} \approx 8\pi\frac{\rho_{mat}(a_0)}{\rho_{tet}(a_0)}\frac{L_0 - L}{L_0^3} \tag{41}$$

and using approximate values $L_0 - L \approx -L_0$ and

$$\rho_{mat}(a_0)/c^2 = 2.6\ 10^{-27}\frac{kg}{m^3} \tag{42}$$

$$\rho_{tet}(a_0)/c^2 = \frac{M_0}{L_0^3} = 0.54\ 10^{97}\frac{kg}{m^3} \tag{43}$$

3.5.

In the literature one often finds the argument that there should be enormous contributions to the cosmological constant from zero point fluctuations of the matter fields. This is 'proven' by summing up the zero point energies $\hbar\omega_k/2$ of all existing fields over all modes with wave vectors k

$$\rho_{quant} = \frac{\hbar}{2}\int \frac{d^3k}{(2\pi)^3}\omega_k \tag{44}$$

and using the Planck scale as UV cutoff. This leads to an enormous number of the order of $\rho_{quant} \sim E_s/L_s^3$ - actually the same order as ρ_{tet} eqs. (29) and (43) which is no wonder, because both the claimed quantum effects and the tetron properties are derived from the Planck scale.

If true, such a huge contribution ρ_{quant} to the cosmological constant would immediately tear the universe into pieces. This then is usually considered a fundamental unsolved problem and runs under the name 'cosmological constant problem'. The suggested solutions often lead to a cascade of fine tuning problems.

In the tetron model the situation is much simpler. As discussed before, the Planck energy $E_0 \sim E_s$ contained in the neighborhood volume L_0^3 of one bound constituent is the binding energy of tetrons in an empty flat spacetime and does not affect the curvature(=accelerated expansion), because it is a constant contribution in the conservation of energy law (27). Furthermore, quantum fluctuations do not exist by themselves at any point in the universe, but are an artefact of the discreteness of the universe[3] and arise only in the process of detecting and measuring a matter field gliding as quasiparticle excitation on the discrete tetron background.

For these reasons the cosmological constant does not get a contribution from quantum fluctuations.

4. Remark on the Strong Interaction

In the preceeding sections we have obtained an understanding of gravity as well as of the electroweak symmetry breaking. How does the strong interaction among quarks fit into the tetron picture?

The dominant features of the strong interaction are the linear attractive potential at low energies and asymptotic freedom at high energies. In the tetron model the strong interaction is related to disturbances by the triplet isospin excitations(=quarks) of the local frustrated ground state which is formed by a single tetrahedron of isospin vectors. As triplet states of G_4, quarks disturb the ground state's isomagnetism, whereas leptons are G_4-singlets, i.e. 'isomagnetically' neutral. They do not disturb the ground state and therefore do not take part in the strong interaction. As shown in,[1,3] the isomagnetic ground state energy of a single tetrahedron is roughly $E_{QCD} \approx 1$ GeV corresponding to a characteristic length scale $L_{QCD} \approx 10^{-15}$m.

The linear potential between two G_4-triplets, vulgo a quark Q and an antiquark $\bar{Q}$, arises as follows: Since the inner-tetrahedral exchange energy $j = E_{QCD}$ is relatively small, the 'antiferromagnetic' effects leading to the local frustrated tetrahedral state have a much longer range L_{QCD} than the weak interactions which are induced by the 'ferromagnetic' inter-tetrahedral exchange energies $J = O(100)$ GeV. The triplet excitations corresponding to the two quarks are characterized by small vibrations $\vec{\Delta}_Q$ and $\vec{\Delta}_{\bar{Q}}$ of the isospin vectors $\vec{S}$. When the distance between the two excitations becomes larger than L_{QCD}, an additional pair $\vec{\Delta}_q$ and $\vec{\Delta}_{\bar{q}}$ is excited on intermediate tetrahedrons in order to reduce the original 'antiferromagnetic' suspense between $\vec{\Delta}_Q$ and $\vec{\Delta}_{\bar{Q}}$. (I am using the language of magnetism, although interactions of isospins and not of spins are considered here.) The associated cost in energy is proportional to the number of $q\bar{q}$ pairs created, and the potential V between Q and $\bar{Q}$ therefore increases linearly with distance:

$$V = F|x| \qquad\qquad F \approx -j < \vec{\Delta}_Q \vec{\Delta}_{\bar{Q}} > /L_Q \tag{45}$$

where $< \vec{\Delta}_Q \vec{\Delta}_{\bar{Q}} >$ is the isospin correlation between the sites, on which the isospins vibrate, and L_{QCD} the length where all this becomes relevant. The confinement

energy is hence proportional to the original 'antiferromagnetic' exchange energy j induced on the disturbances Q and $\bar{Q}$. The ratio x/L_{QCD} is the number of times, an additional pair of excitations has to be created from the 'sea'.

In summary, a single quark Q increases the energy of the system in its neighborhood L_{QCD} not only by its flavor-dependent mass(=excitation energy) but by an additional energy necessary to 'pick up a $q\bar{q}$ pair from the sea'. This energy is flavor independent, because it does not depend on the flavor Q, which flavors q are excited. The flavors q correspond to an average of the light quarks u, d and s. So when a Q and a $\bar{Q}$ are torn apart, at some distance $x \approx L_{QCD}$ a light $q\bar{q}$ pair is formed, because otherwise the single quark Q could not endure the disturbance of the ground state. In the end a sort of string appears obtained by $Q\bar{q}q\bar{q}'...\bar{Q}$ pairs. Any time a new $q\bar{q}$ pair is created, energy is to be taken from the environment, so the associated cost in energy is proportional to the number of $q\bar{q}$ pairs and the potential between quark and antiquark therefore increases linearly with distance as indicated in (45).

Readers familiar with the quark model, will recognize that one is led directly to the classic ideas of the quark model. For example, using the linear potential (45) masses of mesons and baryons can be estimated just as in the quark model. Since mesons and baryons are G_4-singlets, the 'isomagnetic' disturbances induced by quarks get neutralized in these bound states, i.e. mesons and baryons do not disturb the frustrated 'antiferromagnetic' ground state of a single tetrahedron.

The role of the length L_{QCD} (and the energy E_{QCD}), below (above) which the creation of a light quark-antiquark is enforced, therefore is the same as in the Standard Model. At distances above L_{QCD} one has confinement, while below L_{QCD} the strong force diminishes. Virtual bound quark-antiquark pairs are formed which as gluons mediate an interaction of the original $Q\bar{Q}$ pair which effectively can be described by the QCD Lagrangian. As well known, this interaction dies out when the energies involved go to infinity, i.e. one has asymptotic freedom.

5. Summary

Introducing an additional level of matter, the tetron model offers a unified understanding of particle physics and gravitation. While particle physics processes are induced by 'isomagnetic' interactions in internal fibers with a tetrahedral substructure, gravity arises from elastic forces among the tetrons.

The internal tetrahedral structure is introduced in order to explain the elementary particle spectrum of quarks and leptons (6 singlets and 6 triplets after the spontaneous electroweak symmetry breaking). The 24 states of the 3 quark/lepton families are not truly fundamental particles but can be identified as quasi particle wave excitations of a tetrahedron formed by isospin vectors.

Since the quasiparticles fulfill Lorentz covariant wave equations, they perceive the universe as a 3+1 dimensional spacetime continuum lacking a preferred

rest system. Any type of mass/energy induces curvature on this continuum as determined by the Einstein equations.

The tetron model stands for a material understanding of the hitherto abstract particle symmetries $SU(3) \times SU(2)_L \times U(1)$ of the Standard Model of particle physics as well as of their breaking. In the tetron model the Higgs mechanism arises from the alignment of internal isospin vectors of neighboring tetrahedrons, and the Higgs field corresponds to a joint excitation of a neighboring tetron-antitetron pair. One may draw an analogy between particle physics and superconductivity. In this analogy the tetron model corresponds to the BCS theory of superconductivity, whereas the analog of the particle physics Standard Model in this comparison would be the Landau-Ginzberg approach.

Summary parallel session AT5

Reinoud Jan Slagter
Astronomisch Fysisch Onderzoek Nederland (ASFYON),
University of Amsterdam (on leave)
E-mail: info@asfyon.com

Keywords: Conformal dilaton gravity.

It is believed that the understanding of the quantum mechanical properties of gravity at very high energy is one of the major challenges of modern physics. This circumstance occurs, for example, close to the horizon of a black hole or just after the big bang at the Planck scale. There are many ways to attack the problems. One can modify General Relativity rigorously or moderately. One can try to construct a renormalizable model, by adding fourth order derivatives of the curvature tensor to the Lagrangian, try to construct an effective field theory, apply superstring models and many more. However, all these modifications cause problems, such as the appearance of anomalies, loss of unitarity, loss of renormalizability, or one needs ghost fields and gauge-fixing terms. One could also use conformal dilaton gravity models. Conformal invariance is an exact symmetry and spontaneously broken, comparable with the Higgs mechanism.

In the parallel session diverse alternative models pass the review.

Beckwith uses information from a paper deriving a Lorentz-violating energy-momentum relation entailing an exact momentum cutoff as stated by G. Salesi. Salesi in his work allegedly defines Pre Planckian physics, whereas Beckwith restricts himself to an application to GW generation and DE formation in the first $10^{-39}s$ to $10^{-33}s$ or so in the early universe. This procedure is inacted due to an earlier work whereas referees exhibited puzzlement as to the physical mechanism for release of Gravitons in the very early universe. The calculation is meant to be complementary to work done in the Book "Dark Energy" by M. Li, X-D. Li, and Y. Wang, and also a calculation for Black hole destruction as outlined by Karen Freeze, et. al. The GW generation will be when there is sufficient early universe density so as to break apart Relic Black holes but he claims that this destruction is directly linked to a Lorentz violating energy-momentum G. Salesi derived, which he adopts, with a mass m added in the G. Salesi energy momentum results proportional to a tiny graviton mass, times the number of gravitons in the first 10^{-43} seconds.

Slagter presents an exact time-dependent solution of a black hole is found in a conformally invariant gravity model on a warped Randall-Sundrum spacetime, by

writing the metric $g_{\mu\nu} = \omega^{\frac{4}{n-2}} \tilde{g}_{\mu\nu}$. Here $\tilde{g}_{\mu\nu}$ represents the "un-physical" spacetime and ω the dilaton field, which will be treated on equal footing as any renormalizable scalar field. In the case of a five-dimensional warped spacetime, he thereafter writes ${}^{(4)}\tilde{g}_{\mu\nu} = \bar{\omega}^{2(4)}\bar{g}_{\mu\nu}$. The dilaton field $\bar{\omega}$ can be used to describe the different notion the in-going and outside observers have of the Hawking radiation by using different conformal gauge freedom. The disagreement about the interior of the black hole is explained by the antipodal map of points on the horizon. The free parameters of the solution can be chosen in such a way that $\bar{g}_{\mu\nu}$ is singular-free and topologically regular, even for $\omega \to 0$. It is remarkable that the 5D and 4D effective field equations for the metric components and dilaton fields can be written in general dimension $n = 4, 5$. From the exact energy-momentum tensor in Eddington-Finkelstein coordinates, he is able to determine the gravitational wave contribution in the process of evaporation of the black hole. It is conjectured that, in context of quantization procedures in the vicinity of the horizon, unitarity problems only occur in the bulk at large extra-dimension scale.

Jain starts his presentation with the proposition that the zero modes can contribute towards divergence in the entanglement entropy and the nature of the divergent term can be either log or log(log). However, a clear understanding of what leads to these two different forms of zero mode divergence is still lacking. So, in order to throw some light along this direction, he investigates how these two different divergent behaviours can be seen as a signature of a crossover in the zero mode limit for the ground state entanglement.

Hartmann investigates an old hypothesis that there exists an intimate connection between weak interaction and gravity, symbolized by the relationship between the Fermi and Newton's constants. He analyzes the hypothesis that the effect of matter upon the metric that represents gravitational interaction in General Relativity is an effective one. He concludes that this leads to consider gravitation to be the result of the interaction of two neutral spinorial fields (g-neutrinos) with all kinds of matter and energy. He presents three examples with only one g-neutrino: two static and spherically symmetric configurations and a cosmological framework for an isotropic dynamical universe. Without self-interaction, the associated effective geometry is precisely the Schwarzschild metric. On the other hand, a self-interacting g-neutrino generates a new gravitational black-hole.

Lampe applies the tetron model of invisible tiny constituents in a cosmological model, elastically bound with bond length about the Planck length and binding energy the Planck energy. A tetron transforms as the fundamental fermion(=octonion) representation 8 of $SO(6,1)$. With respect to the decomposition $SO(6,1) \to SO(3,1) \otimes SO(3)$ a tetron possesses spin 1/2 and isospin 1/2, i.e. it represents an isospin doublet of Dirac spinors. The 24 known quarks and leptons arise as eigenmode excitations of a tetrahedral fiber structure, which is made up from 4 tetrons and extends into 3 additional 'internal' dimensions. While the laws of gravity are due to the elastic properties of the tetron bonds, particle physics interactions take

place within the internal fibers. He concentrates on two of the most intriguing features of the model: - understanding small neutrino masses from the conservation of isospin, and, more in general, calculating the spectrum of quark and lepton masses. This is obtained from the tetron model's interpretation of the Higgs mechanism. The possibility to determine the full size of the universe from future dark energy measurements. This is obtained from the tetron model's interpretation of the dark energy phenomenon.

Lapponi applies the model of a perfectly reflecting accelerating mirror to the null-shell of a collapsing black hole. He then investigates an extension of this model to mirror semi-transparency and derive a general expression for the corresponding Bogoliubov coefficients. He introduces the concept of "impulsive accelerated mirrors", corresponding to those mirrors that are accelerated via an impulsive force. He shows that this treatment guarantees analytic solutions of Bogolubov coefficients. In particular, he evaluates the corresponding particle production from the so-obtained Bogoliubov coefficients. Finally, he recognizes that the mirror, as a Gaussian quantum channel, acts between the spacetime regions of left-past and right-future. As a consequence he studies the loss/amplification properties of this quantum channel, alongside the noise it creates and evaluates its capacities in transmitting classical and quantum information.

Boundary conditions for the Klein-Gordon field on Lifshitz spacetimes

Lissa de Souza Campos

Physics Department, University of Pavia,
Pavia, PV 27100, Italy
E-mail: lissa.desouzacampos01@universitadipavia.it

Boundary conditions have physical consequences. On Lifshitz spacetimes, the Klein-Gordon equation gives rise to an initial-boundary value problem that admits a plethora of physically-sensible boundary conditions. Considering a free, scalar, massive quantum field theory on a four-dimensional Lifshitz spacetime with critical exponent $z = 2$, I layout how to construct two-point functions for ground and thermal states, of local Hadamard form, satisfying the canonical commutation relations, and compatible with Robin and mode-dependent boundary conditions. Each one relates to an inequivalent dynamics, but they are all equivalently physically-sensible—only an experiment could single one out. The results I present here are part of a joint work with C. Dappiaggi and D. Sina.[1]

Keywords: Klein-Gordon equation; Robin boundary conditions; Lifshitz spacetime.

Introduction

In this paper I outline part of a joint work with C. Dappiaggi and D. Sina presented in Ref. 1, elaborating on the talk I have given on the Sixteenth Marcel Grossmann Meeting.[2] The goal is to bring awareness to the fact that on Lifshitz spacetimes there are infinitely many physically-sensible boundary conditions naturally arising within a free, scalar quantum field theoretical framework. In particular, I show how to construct two-point functions for ground and thermal states on a four-dimensional Lifshitz spacetime Lif with dynamical critical exponent $z = 2$ compatible with Robin and mode-dependent boundary conditions.

Lif is a metric-solution of Hořava-Lifshitz gravity.[3] This gravity theory provides an alternative to General Relativity by breaking Lorentz invariance with a Lifshitz scaling between time t and space $\underline{\mathrm{x}}$ of the form:

$$t \mapsto \delta^z t \quad \text{and} \quad \underline{\mathrm{x}} \mapsto \delta \underline{\mathrm{x}} \quad \text{with} \quad z > 1. \tag{1}$$

Although the goal of introducing Lifshitz scaling in the theory was to allow its quantization, i.e. to be a theory of quantum gravity, such anisotropic scaling has manifold applications, from cosmology, through AdS/CFT correspondence, to condensed matter physics.[4] Since its initial proposition by Hořava in 2009,[5] it has gone through several developments,[6] and examples relating the dynamical critical exponent z with "real world" quantum critical systems have been elaborated.[7] Hořava-Lifshitz gravity itself lies beyong the scope of this work; here, the focus is on the quantization of a free scalar field on the background solution Lif.

Let us endow Lif with polar coordinates (t, r, θ, φ), where $t \in \mathbb{R}$, $r \in (0, \infty)$, $\theta \in [0, \pi)$ and $\varphi \in [0, 2\pi)$; its line-element reads

$$ds^2 = -\frac{r^4}{L^4}dt^2 + \frac{L^2}{r^2}dr^2 + r^2 d\theta^2 + r^2\theta^2 d\varphi^2, \tag{2}$$

where $L > 0$ is a length scale. The time coordinate t identifies a global, timelike, irrotational, Killing vector field ∂_t, making Lif a static spacetime. The Lifshitz horizon at $r = 0$ corresponds to a singularity of coordinate type, since neither the Ricci scalar, given by

$$\mathcal{R} = -\frac{22}{L^2}, \tag{3}$$

nor the Kretschmann scalars diverges there. The Lifshitz boundary at $r = \infty$ can be seen as an anisotropic conformal infinity,[8] but it also admits other definitions, see e.g. Ref. 9. I avoid going into details in this regard since I take $r \to \infty$ to be merely an asymptotic radial infinity for the bulk theory, as in Ref. 10. The crucial impact of this asymptotic behavior in the analysis performed here is that it results on Lif being non-globally hyperbolic.

Next, let us consider a free, scalar field $\Psi : \mathsf{Lif} \to \mathbb{R}$ with mass m_0 and coupled to the scalar curvature $\mathcal{R}$ through a parameter $\xi \in \mathbb{R}$. Its dynamics is governed by the Klein-Gordon equation:

$$(\Box - m_0^2 - \xi\mathcal{R})\Psi = 0, \tag{4}$$

where $\Box = g^{\mu\nu}\nabla_\mu\nabla_\nu$ is the D'Alembertian operator, while g is the metric tensor associated to Equation (2). On Lif, the Klein-Gordon equation gives rise to an initial-boundary value problem. Given suitable initial data on a spacelike surface, corresponding solutions might not exist; if they exist, then each boundary condition selects a different solution, identifying an inequivalent dynamics. To guarantee such initial-boundary value problem is well-posed and physically meaningful, I follow the standard approach of looking for self-adjoint extensions of the radial part of the Klein-Gordon operator. This restriction guarantees the dynamics obtained are physically-sensible, as specified by the work of Ishibashi and Wald.[11,12]

For some boundary conditions, depending on the value of the effective mass, the two-point functions possess bound state contributions: *bound states* are poles of the two-point function. In our case, the set of bound states coincide with the set of poles of the Green function of the radial part of the Klein-Gordon equation. Since we impose self-adjointness on the radial part, they are, in fact, elements of the point spectrum of the radial Green function. Accordingly, they are a subset of the quasi-normal modes. Withall, since the physical meaning of bound state contributions is not well-understood, I rule them out by delineating the boundary conditions for which no bound states arise. Subsequently, by employing a prescription applicable on an static spacetime, as performed in Refs. 13–19, I obtain two-point functions that solve the Klein-Gordon equation in each entry, satisfy the canonical commutation relations and are of local Hadamard form. The analysis I present is consistent

with previous works regarding the scalar field on Lifshitz spacetimes[10, 20–23] and it generalizes them in different aspects: first, it takes into account more general boundary conditions; second, it specifies which of these boundary conditions yields physically sensible two-point functions; third, it provides explicit (though not in closed-form) expressions for the two-point functions.

The layout of this paper mirrors my talk.[2] First, in Section 1, taking into account the symmetries of the spacetime, I show that the Klein-Gordon equation reduces to a radial equation, I find the radial solutions and I study their square-integrability. Second, in Section 2, I construct the radial Green function. Then, in Section 3, I show how we can rule out the bound states and focus on physically-sensible boundary conditions. With all these ingredients in hands, in Section 4, I turn to spectral theory of differential operators and to algebraic quantum field theory to write down well-defined, physically-sensible, explicitly expressions for the two-point functions for the ground and thermal states.

1. Solving the Klein-Gordon equation

Let $Y_\ell^m(\theta,\varphi)$ be the eigenfunctions of the Laplacian operator on $\mathbb{R}^2$ in polar coordinates, with eigenvalues λ_ℓ^m. Since Lif is a static spacetime, consider the following ansatz

$$\Psi(t,r,\theta,\varphi) = e^{-i\omega t} R(r) Y_\ell^m(\theta,\varphi). \tag{5}$$

Substituting Equation (5) in the Klein-Gordon equation (4) entails that $R(r)$ is a solution of the radial equation:

$$AR(r) := R''(r) + \frac{5}{r}R'(r) + \left(\frac{L^6}{r^6}\omega^2 + \frac{L^2}{r^4}\lambda_\ell^m - \frac{L^2}{r^2}\right) R(r) = 0. \tag{6}$$

By applying transformations on both the independent and dependent variables,

$$r \mapsto u = \frac{iL^3\omega}{r^2} \in i(0,\infty) \quad \text{and} \quad R(u) = e^{-u/2}\left(\frac{u}{iL^3\omega}\right)^{\frac{1}{2}(2+\nu)} w(u), \tag{7}$$

the radial equation (6) yields a confluent hypergeometric equation

$$uw''(u) + (b_0 - u)w'(u) - a_0 w(u) = 0, \text{ with } \begin{cases} a_0 := \frac{1+\nu}{2} + \frac{i\lambda}{4L\omega}, \\ b_0 := 1+\nu, \\ \nu := \sqrt{4 + L^2\mu^2}. \end{cases} \tag{8}$$

Therefore, the radial solutions are given in terms of the confluent hypergeometric functions M and U.[24] Numerically satisfactory bases of solutions of Equations (6) and (8), close to the point u_0, are respectively given by $\{R_{1(u_0)}(u), R_{2(u_0)}(u)\}$ and $\{w_{1(u_0)}(u), w_{2(u_0)}(u)\}$, with $w_{j(u_0)}$ as in Table 1 and

$$R_{j(u_0)}(u) = e^{-u/2}\left(\frac{u}{iL^3\omega}\right)^{\frac{1}{2}(2+\nu)} w_{j(u_0)}(u), \text{ for } j \in \{1,2\}. \tag{9}$$

Table 1. Suitable bases of the confluent hypergeometric equation (8).

Endpoint	Suitable Basis
$u = 0 \equiv r = \infty$	$\begin{cases} w_{1(0)}(u) = M(a_0, b_0; u) \\ w_{2(0)}(u) = (iL^3\omega)^{\nu} u^{1-b_0} M(a_0 - b_0 + 1, 2 - b_0; u) \end{cases}$
$u = i\infty \equiv r = 0$	$\begin{cases} w_{1(\infty)}(u) = U(a_0, b_0; u) \\ w_{2(\infty)}(u) = e^u U(b_0 - a_0, b_0; -u) \end{cases}$

To obtain self-adjoint extensions of the radial part of the Klein-Gordon operator, we turn to Sturm-Liouville theory. Rewriting the radial equation as a Sturm-Liouville problem gives

$$AR(r) =: (L_{\omega^2} - \omega^2)R(r) = -\frac{1}{r^{-1}}\left(\frac{d}{dr}\left(\frac{r^5}{L^6}\frac{d}{dr}\right) + \frac{r}{L^4}\left(-\mu^2 r^2 + \lambda_\ell^m\right)\right) R(r) = 0. \tag{10}$$

Taking Equation (10) into account, we look for solutions $R(r)$ in the space of square-integrable functions with respect to the measure $r^{-1}dr$. In addition, the radial operator A is positive and symmetric on the Hilbert space $L^2((0,\infty), r^{-1}dr)$ when we take its domain to be $C_0^\infty((0,\infty))$.

Since the endpoints $r = 0$ and $r = \infty$ are singular, we perform an asymptotic analysis to check square-integrability of the radial solutions, as follows. As $r \to 0$ the radial solutions defined in Equation (9) together with Table 1 behave like

$$|R_{1(0)}(r)|^2 \sim e^{+\frac{L^3}{r^2}\operatorname{Im}(\omega)}, \tag{11a}$$

$$|R_{2(0)}(r)|^2 \sim e^{-\frac{L^3}{r^2}\operatorname{Im}(\omega)}. \tag{11b}$$

As $r \to \infty$, we have instead

$$R_{1(\infty)}(r) \sim r^{-2-\nu}, \tag{11c}$$

$$R_{2(\infty)}(r) \sim r^{-2+\nu}. \tag{11d}$$

According to Weyl's endpoint classification,[25] it follows that $r = 0$ is limit point, and that, if $\nu \in (0,1) \cup (1,2)$, then $r = \infty$ is limit circle. That is, the unique solution $R_0(r)$ that belongs to $L^2((0, r_0), r^{-1}dr)$ for all $r_0 < \infty$ is given by

$$R_0(r) = \Theta(-\operatorname{Im}(\omega))R_{1(0)}(r) + \Theta(\operatorname{Im}(\omega))R_{2(0)}(r). \tag{12}$$

Contrastingly, if $\nu \in (0,1) \cup (1,2)$, there is a one-parameter family of solutions $R_\gamma(r)$, with $\gamma \in [0, \pi)$, belonging to $L^2((r_0, \infty), r^{-1}dr)$ for all $r_0 < \infty$, given by

$$R_\gamma(r) = \cos(\gamma)R_{1(\infty)}(r) + \sin(\gamma)R_{2(\infty)}(r). \tag{13}$$

Define the Wronskian W for differentiable functions $f_1(x)$ and $f_2(x)$ as $W_x\left[f_1(x), f_2(x)\right] := f_1(x)\frac{df_2(x)}{dx} - \frac{df_1(x)}{dx}f_2(x)$. The solutions of Equation (13) satisfy the (generalized) Robin boundary conditions parametrized by γ:

$$\lim_{r\to\infty}\left(\cos(\gamma)W_r[R_\gamma(r), R_{1(\infty)}(r)] + \sin(\gamma)W_r[R_\gamma(r), R_{2(\infty)}(r)]\right) = 0. \tag{14}$$

When $\nu \notin (0,1)\cup(1,2)$, $r=\infty$ is also limit point and the only square-integrable solution to be considered is given by the principal solution, which coincides with (13) for $\gamma = 0$. This corresponds to imposing Dirichlet boundary condition and yields a unique dynamics. On this account, from now on let us focus on the more interesting scenario, where alternative boundary conditions give inequivalent dynamics, and consider only effective masses such that $\nu \in (0,1)\cup(1,2)$. In the latter case, given that $r=0$ is limit point and that $r=\infty$ is limit circle, from standard singular Sturm-Liouville theory[25] follows that A admits a one-parameter family of self-adjoint extensions in one-to-one correspondence with the (generalized) Robin boundary conditions.

2. Constructing the radial Green function

For R_0, R_γ and L_{ω^2} as obtained in the previous section, let $\mathcal{G}_\omega(r,r')$ be a Green function of the radial equation. It satisfies

$$((L_{\omega^2}-\omega^2)\otimes\mathbb{1})\mathcal{G}_\omega(r,r') = (\mathbb{1}\otimes(L_{\omega^2}-\omega^2))\mathcal{G}_\omega(r,r') = \frac{\delta(r-r')}{r^{-1}} \tag{15}$$

and it can be written as[26]

$$\mathcal{G}_\omega(r,r') = \frac{1}{\mathcal{N}_\omega}\left(\Theta(r'-r)R_0(r)R_\gamma(r') + \Theta(r-r')R_0(r')R_\gamma(r)\right). \tag{16}$$

For $\operatorname{Im}\omega < 0$, the normalization $\mathcal{N}_\omega$ reads:

$$\mathcal{N}_\omega = 4\nu\{B_0\cos(\gamma) - A_0\sin(\gamma)\}, \text{ with } \begin{cases} A_0 := \frac{\Gamma(1-b_0)}{\Gamma(a_0-b_0+1)}, \\ B_0 := \frac{\Gamma(b_0-1)}{\Gamma(a_0)}(iL^3\omega)^{-\nu}. \end{cases} \tag{17}$$

As shown in Ref. 1, the radial solutions defined above satisfy useful properties with respect to complex conjugation:

$$R_0(r,\overline{\omega}) = \overline{R_0(r,\omega)} \quad \text{and } R_\gamma(r,\overline{\omega}) = \overline{R_\gamma(r,\omega)}. \tag{18a}$$

As a consequence, the radial Green function and its normalization are such that

$$\mathcal{N}_{\overline{\omega}} = \overline{\mathcal{N}_\omega} \quad \text{and} \quad \mathcal{G}_{\overline{\omega}} = \overline{\mathcal{G}_\omega}. \tag{19}$$

In the next section, we study the poles of $\mathcal{G}_\omega(r,r')$ in the ω-complex plane. The properties above, in Equation (19), simplify our analysis since they imply that we can restrict our attention to either the upper or lower half of the ω-complex plane, and by conjugation, understand the behavior on the other half.

3. Rulying out the poles

The poles of the radial Green function are the frequencies ω for which

$$\mathcal{N}_\omega = 0. \tag{20}$$

As mentioned in the introduction, we refer to these frequencies as bound states; and in the scope of obtaining well-defined two-point functions, we exclude the boundary conditions for which they arise. Given the symmetry properties of the radial Green function with respect to complex conjugation, let us set $\mathrm{Im}(\omega) < 0$.

For Dirichlet and Neumann boundary conditions the analysis is straightforward. One just needs to take into account Equation (20) together with Equations (17) and the fact that the Euler Gamma function $\Gamma(z)$ satisfy $1/\Gamma(z) = 0 \iff z \in \mathbb{Z}_0^-$. We find that for Dirichlet boundary condition, $\gamma = 0$, the frequencies for which Equation (20) holds all lie in the upper half of the complex plane. That is, no bound states occur. For Neumann boundary condition, $\gamma = \pi/2$, bound states are also absent if $\nu \in (0, 1)$; however, if $\nu \in (1, 2)$, then for each λ_ℓ^m there is a unique pole with negative imaginary part at

$$\omega_p = -i\frac{\lambda_\ell^m}{2L(1-\nu)}. \tag{21}$$

For Robin boundary conditions, $\gamma \in (0, \pi/2) \cup (\pi/2, \pi)$, the analysis is less direct. First, we view Equation (20) as the following transcendental equation

$$\chi(\omega) := \tan(\gamma) - \Xi(\omega) = 0, \text{ with } \Xi(\omega) := \frac{B_0}{A_0}. \tag{22}$$

Then, by noting that Equation (22) admits a solution for all frequencies such that $\Xi(\omega) \in \mathbb{R}$, and by studying the function $\Xi(\omega)$, one can show that there is a one-to-one correspondence between the the boundary conditions for which bound states arise and the image $\mathbf{I} \subset \mathbb{R}$ of $\Xi(\omega)$ for $\omega = -i|\,\mathrm{Im}(\omega)|$. As a result, the physically-sensible boundary conditions are given by $\gamma \in \mathbb{R} \setminus \mathbf{I}$. Details of this analysis can be found in Ref. 1, but the distilled results are collected in the following table.

Table 2. Boundary conditions for which no bound states arise.

ν	mode-independent	mode-dependent
$(0, 1)$	$\gamma \in [0, \pi/2]$	$\gamma \in \left[0, \arctan\left(\left(\frac{-\lambda_\ell^m L^2}{4}\right)^{-\nu} \frac{\Gamma(\nu)}{\Gamma(-\nu)}\right)\right]$
$(1, 2)$	$\gamma = 0$	

4. Constructing the two-point functions

Analogously to the ansatz for the solutions to the Klein-Gordon equation, as in Equation (5), consider the following ansatz for the integral kernel of a positive

bisolution of the Klein-Gordon equation $G^+ \in \mathcal{D}'(\mathsf{Lif}^2)$, for $x = (t, r, \theta, \varphi) \in \mathsf{Lif}$,

$$G^+(x, x') = \lim_{\varepsilon \to 0^+} \int\limits_{\sigma(\triangle)} d\Sigma(\ell, m) \int_0^\infty d\omega e^{-i\omega(t-t'-i\varepsilon)} \widehat{G}_\omega(r, r') Y_\ell^m(\theta, \varphi) Y_\ell^m(\theta', \varphi'), \tag{23}$$

where $Y_\ell^m(\theta, \varphi)$ are the real-valued eigenfunctions of the Laplacian operator $\triangle$ with spectrum $\sigma(\triangle)$ and associated measure $d\Sigma(\ell, m)$, while $i\varepsilon$ implements the standard regularization.

To obtain an explicit expression for the radial component $\widehat{G}_\omega(r, r')$, in the following I employ the same steps as performed on other static spacetimes in Refs. 13–19. On one hand, imposing the canonical commutation relations on the antisymmetric part of Equation (23) entails that $\widehat{G}_\omega(r, r')$ is symmetric with respect to $r \leftrightarrow r'$ and gives the following identity

$$\int_{\mathbb{R}} \omega d\omega \widehat{G}_\omega(r, r') = \frac{\delta(r - r')}{r^{-1}}. \tag{24}$$

On the other hand, consider the radial Green function $\mathcal{G}_\omega(r, r')$ constructed in Section 2. Recalling that $\mathcal{G}_\omega(r, r')$ is not defined when $\mathrm{Im}(\omega) = 0$, let $\mathcal{C}^\infty$ be the infinite radius limit of a two semi-disks centered on the ω-complex plane and not touching the real axis, as illustrated in Ref. 1. For the boundary conditions for which the radial Green function has no poles, its spectral resolution[25,26] reads

$$\frac{1}{2\pi i} \oint_{\mathcal{C}^\infty} d(\omega^2) \mathcal{G}_\omega(r, r') = -\frac{\delta(r - r')}{r^{-1}}. \tag{25}$$

By performing the contour integral of Equation (25) and comparing it with Equation (24) we find the radial component of ansatz given in Equation (23):

$$\widehat{G}_\omega(r, r') = \frac{1}{4\pi\nu} \frac{\mathrm{Im}\left(B_0 \overline{A_0}\right)}{|B_0 \cos(\gamma) - A_0 \sin(\gamma)|^2} R_\gamma(r) R_\gamma(r'). \tag{26}$$

Alltogether, with respect to the Killing field ∂_t and for $\widehat{G}_\omega(r, r')$ given by Equation (26), a two-point function with integral kernel given by Equation (23) identifies the unique ground-state of a free, scalar, massive Klein-Gordon field on a Lifshitz spacetime. For a thermal-state at inverse-temperature β, its integral kernel reads instead

$$G_\beta^+(x, x') = \lim_{\varepsilon \to 0^+} \int\limits_{\sigma(\triangle)} d\Sigma(\ell, m) \int_0^\infty d\omega \, T_\omega(t, t') \widehat{G}_\omega(r, r') Y_\ell^m(\theta, \varphi) Y_\ell^m(\theta', \varphi'), \tag{27}$$

with

$$T_\omega(t, t') := \left[\frac{e^{-i\omega(t-t'-i\varepsilon)}}{1 - e^{-\beta\omega}} + \frac{e^{+i\omega(t-t'+i\varepsilon)}}{e^{\beta\omega} - 1} \right]. \tag{28}$$

Two-point functions with integral kernel given either by Equation (23) or Equation (27) identify Gaussian states of local Hadamard form[27] that satisfy the canonical commutation relations—they are physically-sensible two-point functions. Last, but most importantly, note that each boundary condition identifies a different two-point function.

5. Conclusions

The results presented here are part of the work in Ref. 1, where also generalizations to a hyperbolic and to a spherical Lifshitz topological black hole were considered. We demonstrated that on a Lifshitz spacetime, a Klein-Gordon field with effective mass $m^2 \in \left(-\frac{4}{L^2}, -\frac{3}{L^2}\right)$ admits a one-parameter family of Robin boundary conditions at $r \to \infty$ parametrized by $\gamma \in [0, \pi/2]$. In turn, each $\gamma \in [0, \pi/2]$ identifies a distinct two-point function. In addition, we found that for $m^2 \in \left(-\frac{4}{L^2}, -\frac{3}{L^2}\right) \cup \left(-\frac{3}{L^2}, -\frac{2}{L^2}\right)$, λ-mode dependent boundary conditions are also admissible. We call attention to the fact that, in the absence of a reason to justify selecting Dirichlet boundary condition over the others, all of these boundary conditions are of equal relevance—they all yield physically-sensible quantizations. Since these generalized quantizations arise naturally within the quantum field theoretical framework, we hope our results stimulates research in the direction of understanding their physical significance.

The analysis outlined here applies straightforwardly to higher dimensional Lifshitz spacetimes of critical exponent $z = 2$. That is not the case for $z > 2$, however, given that the choice of critical value affects drastically the classification, and hence the solutions, of the radial part of the Klein-Gordon equation. In Ref. 1, we constructed two-point functions not only on this spacetime, but also on Lifshitz topological black holes.[28] With this in mind, an interesting follow up work would be to perform a numerical analysis to understand how the topology and the choice of a boundary condition affects vacuum fluctuations, as performed for topological black holes of Einstein gravity in Ref. 29. Moreover, in this framework one can further directly obtain the transition rate of a static Unruh-DeWitt detector in the infinite interaction time limit, following the same prescription of Ref. 14, and study the effects of different boundary conditions and topologies in the perspective of a particle detector.

Acknowledgments

This work was part of a collaboration[1] with C.Dappiaggi and D.Sina, whom I thank and gratefully acknowledge; and it was partially based on the MSc thesis of D.S. submitted to the University of Pavia on March 2021. My work was supported by a PhD scholarship of the University of Pavia.

Based on our original work published in Ref.[1], we investigate an autonomous system analysis in terms of new expansion-normalized variables for homogeneous and anisotropic Bianchi-I spacetimes in $f(R)$ gravity in the presence of anisotropic matter. It is demonstrated that with a suitable choice of the evolution parameter, the Einstein's equations are reduced to an autonomous 5-dimensional system of ordinary differential equations for the new variables. Furthermore, for a large class of functions $f(R)$, which includes several cases commonly considered in the literature, all the fixed points are polynomial roots, and thus they can be determined with good accuracy and classified for stability. In addition, typically for these cases, any fixed point corresponding to isotropic solutions in the presence of anisotropic matter will be unstable. The assumption of a perfect fluid as source and or the vacuum cases imply some dimensional reductions and even more simplifications. In particular, it is found that the vacuum solutions of $f(R) = R^{\delta+1}$ with δ a constant are governed by an effective bi-dimensional phase space which can be constructed analytically, leading to an exactly soluble dynamics. It is also shown that several results already reported in the literature can be re-obtained in a more direct and easy way by exploring our dynamical formulation.

Keywords: Modified gravity theories; autonomous system analysis

1. Introduction

According to recent various cosmological observations including Type Ia Supernovae, cosmic microwave background (CMB) radiation and large scale structure, in addition to inflation[2–4] in the early universe, the current expansion of the universe is also accelerating. This is the so-called dark energy problem. There are two representative approaches to study the issue of dark energy. One is to introduce some unknown matter called dark energy with the negative pressure in general relativity.

The other is to modify gravity at large scales (for reviews of dark energy and modified gravity theories, see, e.g., Refs.[5–17]). As one of the popular modified gravity theories, $f(R)$ gravity has been proposed.[18–20]

In this article, based on our original reference[1], we extend the so-called expansion-normalized variables[21] to write down the dynamical equations of $f(R)$ gravity for a homogeneous and anisotropic Bianchi-I metric in the presence of an anisotropic fluid, as a 5-dimensional system of ordinary differential equations. We show that some further assumptions may lead to considerable simplifications in the equations, and for several examples we end up with analytically soluble systems. For the sake of illustration, we consider explicitly the case of $f(R) = R^{1+\delta}$. We demonstrate that the formulation of[22,23] is recovered in the isotropic matter limit. Moreover, in a simpler and more direct way, we re-derive some uniqueness and stability properties of the Starobinsky's isotropic inflationary scenario in R^2 gravity,[24–26] which is consistent with the Planck 2018 results.[27,28]

The article is organized as follows. In section 2, we describe the dynamical equations for a Bianchi-I cosmology in $f(R)$ gravity in the presence of an anisotropic fluid. We discuss the isotropic fluid limit and introduce the new expansion-normalized variables for the system. In Section 3, we present cosmological applications. Finally, we summarize our results in Section 4.

2. Bianchi-I cosmology in $f(R)$ gravity with anisotropic fluid

The action describing $f(R)$ gravity is expressed as

$$S_{=}\frac{1}{2\kappa}\int d^4x\sqrt{-g}f(R) + S_M, \tag{1}$$

where $\kappa = 8\pi G$, $c = \hbar = 1$, and S_M stands for the usual matter contributions to the totalaction.

We consider the homogeneous and anisotropic Bianchi-I metric, which can be conveniently cast for our purposes in the following form[29–31]

$$ds^2 = -dt^2 + a^2(t)\sum_{i=1}^{3} e^{2\beta_i(t)}(dx^i)^2, \tag{2}$$

where $a(t)$ is the average scale factor and the three functions β_i, which characterize the anisotropies, are such that $\beta_1 + \beta_2 + \beta_3 = 0$. It is more convenient to employ the variables

$$\beta_{\pm} = \beta_1 \pm \beta_2. \tag{3}$$

The total amount of anisotropy in the metric (2) is given by the quantity

$$\sigma^2 = \dot{\beta}_1^2 + \dot{\beta}_2^2 + \dot{\beta}_3^2 = \frac{3}{2}\dot{\beta}_+^2 + \frac{1}{2}\dot{\beta}_-^2. \tag{4}$$

For $\sigma = 0$, one can show that the spatial coordinates x^i can be suitably rescaled to recast the Bianchi-I metric in the standard Friedmann-Lemaitre-Robertson-Walker

(FLRW) form. The Ricci scalar for the metric (2) reads

$$R = 6\dot{H} + 12H^2 + \sigma^2, \tag{5}$$

where the average Hubble parameter H is given by the standard expression

$$H = \frac{\dot{a}}{a}. \tag{6}$$

We assume the presence of an anisotropic barotropic fluid with energy momentum tensor parametrized as[32]

$$T^{\nu}_{\mu} = \mathrm{diag}\left(-\rho, p_1, p_2, p_3\right) = \mathrm{diag}\left(-\rho, \omega_1\rho, \omega_2\rho, \omega_3\rho\right), \tag{7}$$

and we define the anisotropic equation of state as

$$p_i = (\omega + \mu_i)\rho, \tag{8}$$

with $i = 1, 2, 3$, where ω is the average barotropic parameter and $\omega_i = \omega + \mu_i$, with $\mu_1 + \mu_2 + \mu_3 = 0$ by construction. We parameterize our fluid by the constants ω and $\mu_{\pm} = \mu_1 \pm \mu_2$.[31]

The dynamics of the Bianchi-I metric (2) under $f(R)$ gravity action (1), in the presence of and anisotropic barotropic fluid with energy-momentum tensor (7), can be described by the following set of equations,[31]

$$3H^2 = \frac{\kappa}{f'}\left(\rho + \frac{Rf' - f}{2\kappa} - \frac{3Hf''\dot{R}}{\kappa}\right) + \frac{\sigma^2}{2} \quad , \tag{9}$$

$$2\dot{H} + 3H^2 = -\frac{\kappa}{f'}\left(\omega\rho + \frac{\dot{R}^2 f''' + \left(2H\dot{R} + \ddot{R}\right) f''}{\kappa} - \frac{Rf' - f}{2\kappa}\right) - \frac{\sigma^2}{2}, \tag{10}$$

$$\ddot{\beta}_{\pm} + \left(3H + \frac{\dot{R}f''}{f'}\right)\dot{\beta}_{\pm} = \frac{\kappa\rho}{F}\mu_{\pm}, \tag{11}$$

$$\dot{\rho} + \left(3H\left(1 + \omega\right) + \boldsymbol{\delta}\cdot\dot{\boldsymbol{\beta}}\right)\rho = 0, \tag{12}$$

where $i = 1, 2, 3$, and

$$\boldsymbol{\delta}\cdot\dot{\boldsymbol{\beta}} = \mu_1\dot{\beta}_1 + \mu_2\dot{\beta}_2 + \mu_3\dot{\beta}_3 = \frac{3}{2}\mu_+\dot{\beta}_+ + \frac{1}{2}\mu_-\dot{\beta}_-. \tag{13}$$

Notice that in the presence of a perfect fluid, we have $\mu_+ = \mu_- = 0$ and the two equations (11) for β_+ and β_- can be substituted with

$$\dot{\sigma} + \left(3H + \frac{\dot{R}f''}{f'}\right)\sigma = 0. \tag{14}$$

In this case, there is no anisotropy in the matter sector and the single variable σ is sufficient to describe the total amount of metric anisotropy in the system.

In general, we have four functions of time $H(t)$, $\rho(t)$, $\beta_{\pm}(t)$ governing the dynamics. The existence of the constraint equation (9) implies that only three of them are indeed independent. Without loss of generality, we can choose them to be, for instance, $H(t)$ and $\beta_{\pm}(t)$. Given some specific form of the function $f(R)$, they can be determined by solving equations (10) and (11). The fluid energy density $\rho(t)$ can then be found using the energy constraint (9).

The traditional expansion-normalized variables were initially introduced for a better dynamical analysis of the standard FLRW model, see, e.g., Ref.[21]. Here, we expand the variables already introduced in[22,23] to include the case of the anisotropic barotropic fluid (7). In this regard, let us introduce the monotonically increasing variable

$$N = \epsilon \ln a, \tag{15}$$

known as the logarithmic time, where ϵ is defined to be $+1$ for expanding universe and -1 for a contracting one. Without loss of generality, we choose the scale factor at $t = 0$ to be $a_0 = 1$. Therefore, as time progresses in the forward (positive) direction, the logarithmic time N becomes positive and goes towards $+\infty$ in case of both expanding and contracting universes. One can notice that

$$\dot{N} = \epsilon H, \tag{16}$$

so that $\dot{N}$ is effectively always positive, justifying the use of N as the dimensionless evolution variable for both expanding and contracting universes. On the other hand, around a bounce or a turnaround point, this argument is not valid though and the expanding and contracting branches must be considered separately.

The expansion-normalized dynamical variables suitable for the equations (9) - (12) are the following dimensionless combinations

$$\begin{gathered} u_1 = \frac{\dot{R} f''}{f' H}, \; u_2 = \frac{R}{6H^2}, \; u_3 = \frac{f}{6 f' H^2}, \\ u_4^+ = \frac{\dot{\beta_+}^2}{4H^2}, \; u_4^- = \frac{\dot{\beta_-}^2}{12H^2}, \; u_5 = \frac{\kappa \rho}{3 f' H^2}. \end{gathered} \tag{17}$$

in terms of which the energy constraint (9) reads simply

$$g = 1 + u_1 - u_2 + u_3 - u_4^+ - u_4^- - u_5 = 0, \tag{18}$$

from where we have that one of the expansion-normalized variables can always be eliminated. Unless otherwise stated, we always choose the matter content variable u_5 to be expressed in terms of the others dynamical variables. The variable

$$u_4 = u_4^+ + u_4^- = \frac{\sigma^2}{6H^2} \tag{19}$$

is also relevant for our purposes. It is important to stress that the variables u_4^+ and u_4^- are both non-negative by construction. Now, let us introduce the quantity

$$\gamma(R) = \frac{f'}{R f''}, \tag{20}$$

which contains the information about the form of $f(R)$. Knowing the form of $f(R)$, γ can be determined in terms of the dynamical variables u_2, u_3 by inverting the relation

$$\frac{u_2}{u_3} = \frac{Rf'}{f}. \tag{21}$$

We return to the question of the invertibility of (21) in the last section. The 5-dimensional system of autonomous first order differential equations fully equivalent to (10) - (12) is given by

$$\begin{aligned}
\epsilon\frac{du_1}{dN} &= 1 + u_2 - 3u_3 - u_4 - 3\omega u_5 \\
&\quad -u_1\left(u_1 + u_2 - u_4\right), && (22)\\
\epsilon\frac{du_2}{dN} &= u_1u_2\gamma\left(\frac{u_2}{u_3}\right) - 2u_2\left(u_2 - u_4 - 2\right), && (23)\\
\epsilon\frac{du_3}{dN} &= u_1u_2\gamma\left(\frac{u_2}{u_3}\right) - u_3\left(u_1 + 2u_2 - 2u_4 - 4\right), && (24)\\
\epsilon\frac{du_4^+}{dN} &= -2u_4^+\left(1 + u_1 + u_2 - u_4\right) + 3\mu_+\sqrt{u_4^+}u_5, && (25)\\
\epsilon\frac{du_4^-}{dN} &= -2u_4^-\left(1 + u_1 + u_2 - u_4\right) + \mu_-\sqrt{3u_4^-}u_5, && (26)\\
\epsilon\frac{du_5}{dN} &= -u_5\Big(3\omega - 1 + u_1 + 2u_2 - 2u_4 && (27)\\
&\quad +3\mu_+\sqrt{u_4^+} + \mu_-\sqrt{3u_4^-}\Big).
\end{aligned}$$

Notice that differentiating (18) with respect to N and using the equations (22)-(27), we have

$$\epsilon\frac{dg}{dN} = -(u_1 + 2u_2 - 2u_4^+ - 2u_4^- - 1)g, \tag{28}$$

showing that the constraint $g = 0$ is indeed conserved along the solutions of our equations and the system (22) - (27) is effectively 5-dimensional.

The case of $f(R) = R^{1+\delta}$, with $\delta \neq 0$, is particularly important in our next examples. For this choice of $f(R)$, one has simply

$$\gamma = \delta^{-1}, \tag{29}$$

and the equations (23) and (24) can be considerably simplified. In this case, the right-handed side of the equations (22) - (27) involves only second degree polynomials in u_1, u_2, and u_3, and forth degree in $\sqrt{u_4^-}$ and $\sqrt{u_4^+}$. Hence, the task of finding the fixed points of our system reduce to finding polynomial roots, which may be performed in general with good accuracy. Notice that there are other relevant choices for $f(R)$ leading to polynomial fixed points. Besides of the trivial

extension $f(R) = \alpha R^{1+\delta} + \Lambda$, with α and Λ constants, for which (29) also holds. For $f(R) = R^a + \alpha R^b$, with $a \neq b$ constants, we have

$$\gamma = \frac{u_2}{(b+a-1)u_2 - abu_3}. \tag{30}$$

Notice that, as in the exponential case, the function γ does not depend on the parameter α. This, of course, does not mean that the dynamics in insensitive to the value of α, since the expansion-normalized variables (17) depend explicitly on α. The case $a = 1$ and $b = 2$ is the original Starobinsky inflationary scenario,[4] and for the vacuum case our approach reduces to that one considered recently in.[33]

3. Applications to cosmology

In the following, we consider the expanding universes ($\epsilon = 1$). We investigate the case $f(R) = R^{1+\delta}$, whose main motivations from a cosmological perspective can be found in,[22,23,34,35] for instance. The case with $\delta = 0$ is obviously pure GR, for which the corresponding system is lower-dimensional, and our approach simply does not apply. The case logarithmic case $f(R) = \ln R$ must be treated separately. Hence, we start considering $\delta \neq 0$ and $\delta \neq -1$. Since we will deal with vacuum solutions, we set $u_5 = 0$ in the equations (18) and (22) - (27). In this case, notice that (25) and (26) can be combined in only one equation for u_4. We can use (18) to write u_3 as

$$u_3 = u_2 - u_1 + u_4 - 1, \tag{31}$$

and we are left with only three dynamical variables u_1, u_2, and u_4. Now, there is an interesting point to notice[36] about the specific choice $f(R) = R^{1+\delta}$, with $\delta \neq -1$, namely that

$$\frac{u_2}{u_3} = \frac{Rf'}{f} = 1 + \delta, \tag{32}$$

which combined with the constraint (31) implies

$$\delta u_2 = (1+\delta)(u_1 - u_4 + 1), \tag{33}$$

and we are left in fact with a two-dimensional phase space spanned by the variables u_1 and u_4. The corresponding dynamical equations in this case are

$$\begin{aligned} \frac{du_1}{dN} &= \phi_1(u_1, u_4) \qquad (34)\\ &= -\delta^{-1}(1+2\delta)(u_1 - u_1^*)(u_1 - u_4 + 1), \\ \frac{du_4}{dN} &= \phi_4(u_1, u_4) \qquad (35)\\ &= -2\delta^{-1}(1+2\delta)u_4\,(u_1 - u_4 + 1), \end{aligned}$$

where

$$u_1^* = \frac{2(\delta - 1)}{1 + 2\delta}. \tag{36}$$

The phase space (u_1, u_4) associated with the system (34) - (35) has some interesting features. For instance, it has an one-dimensional invariant subspace (a continuous line of fixed points) corresponding to the straight line $u_1 - u_4 = -1$. However, from (31) we have that $u_3 = u_2$ on this line, which implies from (17) and (32) that $R = 0$ on $u_1 - u_4 = -1$. Besides of this invariant straight line, we find the isolated fixed $(u_1^*, 0)$, for $\delta \neq -\frac{1}{2}$. The case $\delta = -\frac{1}{2}$ is also discussed separately.

The stability of the isolated fixed point can be inferred from the linearization of (34) - (35). The Jacobian matrix of (34) - (35) at the point $(u_1^*, 0)$ reads

$$\left(\frac{\partial(\phi_1, \phi_4)}{\partial(u_1, u_4)}\right) = -\delta^{-1}(4\delta - 1)\begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}, \tag{37}$$

from where we see that such fixed point is stable for $\delta > \frac{1}{4}$ or for $\delta < 0$. For the stability of the invariant straight line, we can consider the divergence of the vector field (ϕ_1, ϕ_2). One has

$$\nabla \cdot \boldsymbol{\phi} = \frac{\partial \phi_1}{\partial u_1} + \frac{\partial \phi_4}{\partial u_4} = \delta^{-1}((1 + 2\delta)u_4 + 4\delta - 1) \tag{38}$$

on the invariant line. Recalling that $u_4 \geq 0$, we find that the invariant line is entirely repulsive (positive divergence) for $\delta > \frac{1}{4}$ or for $\delta \leq -\frac{1}{2}$. For $-\frac{1}{2} < \delta \leq \frac{1}{4}$, we can obtain some attractive segments, depending on the value of u_4. We return to the physical interpretation of this $R = 0$ invariant line in a following sub-section. The case $\delta = -\frac{1}{2}$ is particularly curious, since the isolated fixed point is absent and we get a second one-dimensional invariant line, namely $u_1 = 0$, which is also entirely repulsive. On the other hand, the case $f(R) = \ln R$ cannot be incorporated in the present analysis since (32) is not valid for $\delta \to -1$, and in fact we have a three-dimensional phase space for such case.

The solutions of (34) and (35) are curves on the plane (u_1, u_4), and it turns out that such curves can be determined analytically. Notice that the solutions are such that

$$\frac{u_4'}{u_1'} = \frac{2u_4}{u_1 - u_1^*}, \tag{39}$$

which can be integrated as

$$u_4 = c\,(u_1 - u_1^*)^2\,, \tag{40}$$

with arbitrary c. Thus, the phase space trajectories of all solutions of (34) and (35) are simply parabolas centered in the isolated fixed point, irrespective of the value of δ, provided the fixed point exists. Since we know the trajectories graphs, one can infer the dynamics direction and, consequently, the dynamical properties of the fixed point and the invariant line, directly form the equations (34) and (35) as follows. Consider the phase space function $L = u_1 - u_4 + 1$. It is clear that $L = 0$ is the invariant line. On the other hand, $L = c$ constant is a parallel line located below the invariant line if $c > 0$, or above if $c < 0$. The invariant line is the boundary between two semiplanes with reverse dynamics direction, and the dynamical properties of the

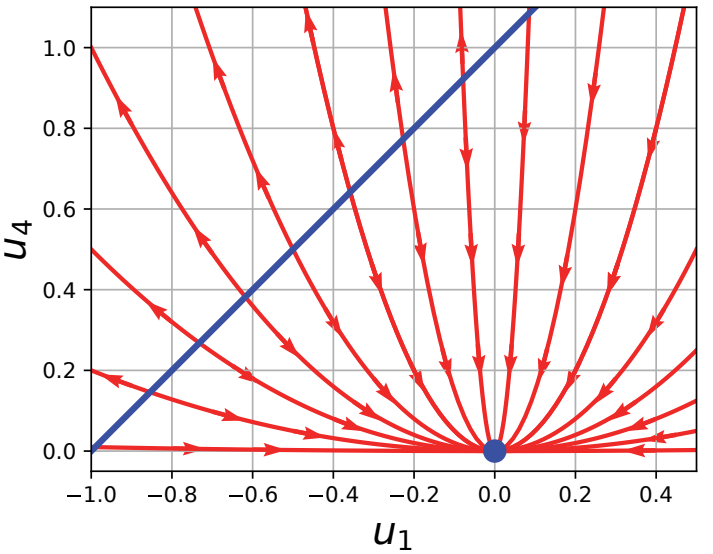

Fig. 1. Phase space for the system (34) - (35), for $\delta = 1$. The fixed point $(0, 0)$ is located in the semiplane below the critical line. The solutions are restricted to parabolas centered in the attractive fixed point. The region below the invariant line corresponds to the attraction basin of the fixed point. Any solution starting there tends to the fixed point asymptotically. All solutions starting in the region above the critical line will diverge to infinity. Notice that the critical line is entirely repulsive. Such phase space is rather generic, it is essentially the same for all theories of the type $f(R) = R^{1+\delta}$ such that the fixed point is attractive and is located below the invariant line.

fixed point and of the invariant line depend on the relative position between then, see Figs 1 and 2, which correspond, respectively, to the cases $\delta = 1$ and $\delta = \frac{1}{10}$. The former is the important case of the Starobinsky's inflationary scenario with $f(R) = R^2$.

We note that the solutions are constrained to the parabolas (40), the exact solutions of (34) and (35) boils down to a simple quadrature of a rational function

$$\frac{d\bar{u}_1}{c\bar{u}_1^3 - \bar{u}_1^2 - (u_1^* + 1)\bar{u}_1} = -\delta^{-1}(1 + 2\delta)dN, \tag{41}$$

with $u_1 = \bar{u}_1 + u_1^*$. For the case $\delta = -\frac{1}{2}$, u_4 is a constant and (34) also reduces to a simple rational quadrature. It has been shown that the vacuum solutions for the $f(R) = R^{1+\delta}$ case, for $\delta \neq -1$, are exactly soluble.

Since the stable fixed points of a cosmological model correspond to the cosmological histories which dominate the asymptotic evolution of the system, it worth to look more closely on them. By using (31) and (32), we see that the isolated fixed points are given by

$$u_3 = \frac{4\delta - 1}{\delta(1 + 2\delta)}, \tag{42}$$

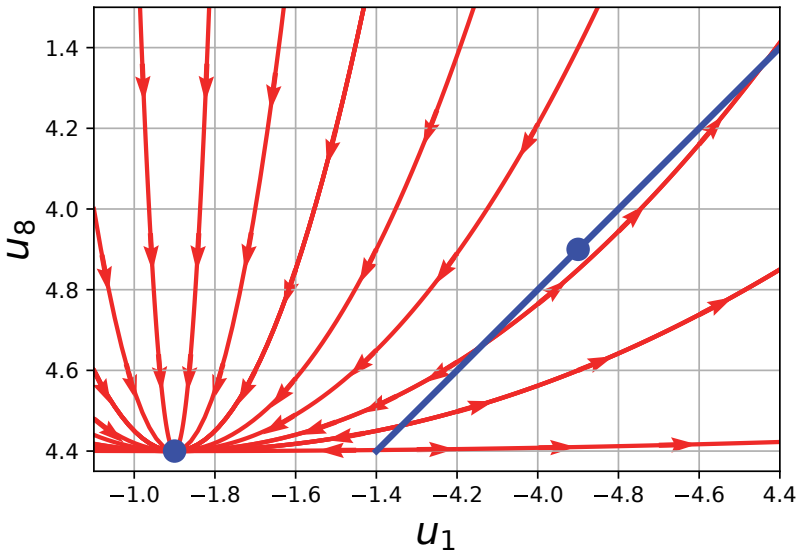

Fig. 2. Phase space for the system (34) - (35), for $\delta = \frac{1}{10}$. The fixed point $\left(-\frac{3}{2}, 0\right)$ is now located in the semiplane above the critical line. The solutions are also restricted to parabolas centered in the attractive fixed point. However, the attraction basin of the fixed point is now in the region above the critical line. Notice that the invariant line in this case has an attractive and a repulsive segment located, respectively, above and below the depicted point $\left(-\frac{1}{2}, \frac{1}{2}\right)$. The divergence (38) always vanishes in limit points between attractive and repulsive segments like this one.

with $\delta > \frac{1}{4}$ or $\delta < 0$. From the definition of u_3 and (5), we have that (42) implies that

$$\dot{H} = \Delta H^2, \tag{43}$$

where

$$\Delta = \frac{\delta - 1}{\delta(1 + 2\delta)}. \tag{44}$$

It is clear that for $\delta = 1$, the stable fixed point corresponds to de Sitter solution with $a(t) = e^{Ht}$, with constant H. (The case $H = 0$ corresponds to the flat Minkowski spacetime). This is namely the well known Starobinsky's inflationary solution. For $\delta \neq 1$, the solutions are

$$H(t) = \frac{H_0}{1 - \Delta H_0 (t - t_0)}, \tag{45}$$

where $H(t_0) = H_0$, which interpretation is straightforward. For $\Delta > 0$, which corresponds to $-\frac{1}{2} < \delta < 0$ or $\delta > 1$, we have a future finite time big rip singularity, while for $\Delta < 0$ ($\delta < -\frac{1}{2}$ or $0 < \delta < 1$), the Hubble parameter H decreases as t^{-1} for large t, *i.e.*, the solution asymptotically tends to a power law expansion.

The Starobinsky's R^2 inflationary scenario is unique among the $F(R) = R^{1+\delta}$ theories of gravity, since only for $\delta = 1$ the stable de Sitter fixed point $(0, 0)$ is available, a result indeed known for a long time, see,[24–26] for example. We can, however, easily prove a stronger result for generic $f(R)$ theories. The de Sitter solution $a(t) = e^{Ht}$, with constant and arbitrary H, implies $u_1 = u_4 = 0$, and also

$$R = 12H^2, \tag{46}$$

which, on the other hand, determine that $u_2 = 2$ and $u_3 = \frac{2f}{Rf'}$ and, hence, the constraint (18) reads

$$Rf'(R) = 2f(R). \tag{47}$$

Since we assume that de Sitter solution exists for arbitrary H, we have from (46) that it should exist for any $R > 0$, and hence equation (47) can be seen as a ordinary differential equation for $f(R)$, which unique solution is $f(R) = \alpha R^2$, establishing in this way a stronger result: the case R^2 is unique among all vacuum $f(R)$ theories with respect to the existence of a de Sitter solution with arbitrary H. The condition (47) was first obtained by Barrow and Ottewill in[24] by using a more intricate approach, but here we see that it appears from a very simple analysis of fixed points.

It is noted that in the case with anisotropic fluids, all isotropic fixed points are unstable (there is no asymptotically stable isotropic solutions in the presence of anisotropic matter). It is also mentioned that several known results as the existence of vacuum Kasner-like solutions for $-\frac{1}{2} \leq \delta \leq \frac{1}{4}$[34,35] are found. Moreover, for the case of exponential gravity,[37–40] $f(R) = e^{\alpha R}$, all isotropic fixed points in the presence of an anisotropic barotropic fluid are unstable.

4. Summary

In this article, we have introduced a new set of expansion-normalized variables for homogeneous and anisotropic Bianchi-I spacetimes in $f(R)$ gravity in the presence of anisotropic matter. In terms of these new dynamical variables, the full set of Einstein's equations boils down to a 5-dimensional phase space. As applications of the proposed dynamical approach, we have explicitly explored the $f(R) = R^{1+\delta}$ modified theory of gravity, and shown that its vacuum dynamics is exactly solvable. Furthermore, in a easier and more direct way, we have re-obtained several well known results for this particular choice of $f(R)$ such as Bleyer and Schmidt isotropic solutions.[41–43] We have also extended a uniqueness result for Starobisnki inflationary scenario, namely that the case R^2 is unique among all vacuum $f(R)$ theories with respect to the existence of a de Sitter solution with arbitrary H, a result obtained previously by Barrow and Ottewill by using a more intricate approach.[24]

We imvestigate the cosmological implications for the Sharma-Mittal holographic dark energy such as some cosmological parameters and thermodynamic analysis. Taking into account the apparent horizon with interacting scenario of dark energy and dark matter, the framework of deformed Hořava-Lifshitz gravity is considered. The cosmological parameters include the Hubble parameter, equation of state parameter for the accelerating/deceleratng phases, deceleration parameter to explore the expansion rate and squared speed of sound for stability analysis.

Keywords: Modified gravity theories; autonomous system analysis

1. Introduction

Observational data reveals that the expansion of our cosmos is currently accelerating.[1,2] If Einstein's law of gravity is valid on cosmological scales, this acceleration indicates that our cosmos is governed by a mystery type of energy. This unknown energy component known as dark energy (DE) which has some peculiar characteristics, such as the fact that it is not concentrated on massive distances and that its pressure must be negative in order to cause the universe's current acceleration. DE has appeared among the most major challenges in modern cosmology and in theoretical physics. Dark energy makes up 68 percent of the entire content of the universe, whereas mass energies in the form of dark matter (DM) and ordinary matter make up 27 percent and 5%, respectively, according to the standard model of cosmology. Cosmological investigations of thermodynamics in modified gravity theories have been executed in Refs.[4–10] (for a recent review on thermodynamic properties of modified gravity theories, see, e.g.,[11]).

The accelerated expansion is currently under the limelight of modern research. One of the most challenging problems in modern physics is to find a physical

mechanism that may explain this accelerating universe. This acceleration can be easily accommodated within the scope of general relativity (GR) by adding DE. One of the most significant obstacles to achieving this goal is that GR is not a renormalizable theory in the high-energy limit, the ultraviolet (UV) limit and so there is no control over the theory along with its predictions.[12] Hořava-Lifshitz gravity is a new class of UV-complete gravity theories that attempts to solve this major issue. In the high-energy limit, the Hořava-Lifshitz theory of gravity is derived by rejecting the Lorentz symmetry using a Lifshitz-type re-scaling[13]

$$t \to b^z t^i, \quad x^i \to b x^i, \quad (i = 1, 2, 3, \ldots, d), \tag{1}$$

here z represents the exponent of dynamical scaling, d is a spacetime dimension that expresses a spatial dimension and b is any constant term. The Lorentz symmetry broken when $z \neq 1$ and recovered only when $z = 1$. Hořava-Lifshitz gravity[14] is nonrelativistic at high energies and it's expected that in the low-energy limit, the four-dimensional general covariance may be reconstituted. A lot of research has been done in the literature on modified Hořava-Lifshitz gravity. The deformed Hořava-Lifshitz[15] gravity model has been studied to investigate black hole quasinormal modes.

In this paper, we discuss some cosmological parameters in the framework of deformed Hořava-Lifshitz gravity with Sharma-Mittal holographic DE (SMHDE) model. We discuss the basic equations of SMHDE and deformed Hořava-Lifshitz gravity in the section **2**. In section **3**, we evaluate the cosmological parameters such as Hubble parameter, EoS parameter, deceleration parameter and squared speed of sound parameter. In the last, we discuss the final results.

2. The Deformed Hořava-Lifshitz Modified Gravity and SMHDE Model

The deformed Hořava-Lifshitz theory is a power-counting, renormalizable and ultraviolet total gravity theory. The total action of this gravity can be described as[12]

$$I = \int (\mathcal{L}_0 + \mathcal{L}_1 + \mathcal{L}_m) dt dx^3. \tag{2}$$

From the above expression $\mathcal{L}_m$ is a matter Lagrangian and $\mathcal{L}_1,\ \mathcal{L}_0$ are given by

$$\mathcal{L}_1 = \sqrt{g} N \left[\frac{k^2 \mu^2 (1 - 4\lambda)}{32(1 - 3\lambda)} R^2 - \frac{k^2}{2E^2} (C_{ij} - \frac{\mu E^2}{2} R_{ij})(C^{ij} - \frac{\mu E^2}{2} R^{ij}) \right], \tag{3}$$

$$\mathcal{L}_0 = \sqrt{g} N \left[\frac{k^2 \mu^2 (\Lambda_E R - 3\Lambda_E^2)}{8(1 - 3\lambda)} + \frac{2}{k^2} (K_{ij} K^{ij} - \lambda K^2) \right], \tag{4}$$

where g and N are the determinant of metric tensor and Lapse function respectively, $\mu,\ \Lambda_E$ are mass dimension parameters whereas dimensionless parameters are $E,\ \lambda,\ k^2$. In aditios, $R,\ R_{ij}$ are Ricci scalar and Ricci tensor respectively while the

extrinsic curvature K_{ij} and the Cotton tensor C^{ij} are defined as

$$K_{ij} = \frac{1}{2N}(\partial_t g_{ij} - \nabla_i N_j - \nabla_j N_i), C^{ij} = \frac{\nabla_k}{\sqrt{g}}\epsilon^{ikl}\bigg(- \frac{1}{4}R\delta^j_l + R^j_l\bigg). \tag{5}$$

here ϵ^{ikl} is the antisymmetric unit tensor. The total action of Hořava-Liftshitz gravity takes the form[12]

$$I = \int \bigg[\frac{k^2\mu^2(1-4\lambda)}{32(1-3\lambda)\mu^4 R + R^2} + \frac{k^2\mu}{2E^2}\epsilon^{ijk}R_{il}\nabla_j R^l_k - \frac{\mu^2 k^2}{8}R^{ij}R_{ij} - \frac{k^2}{2E^4}C_{ij}C^{ij} + \frac{2}{8\pi G}(K^{ij}K_{ij} - K^2\lambda)\bigg]dtdx^3. \tag{6}$$

If $c^2 = \frac{k^2\mu^2}{2}$, $G = \frac{k^2}{32\pi C}$ and $\lambda = 1$, the Einstein-Hilbert action in anti de Sitter form can be constructed from the aforementioned action. For the flat FRW universe model, the Friedmann equation of deformed Hořava-Lifshitz gravity can be written as

$$H^2 + \frac{H^4}{2E} = \frac{\rho_{_D} + \rho_{_m}}{3M_p^2}. \tag{7}$$

In the above equation, we can define $\frac{H^2}{2E} = \gamma$, $\frac{\rho_m}{3M_p^2} = \Omega_{_m}$ and $\frac{\rho_D}{3M_p^2} = \Omega_{_D}$. Therefore, the above equation can be re-written as

$$1 + \gamma = \Omega_{_D} + \Omega_{_m}. \tag{8}$$

Also, $\dot{\rho} + 3H(p + \rho) = 0$ is the equation of continuity where ρ and p represent the total energy density and pressure respectively. Interacting of DE and cold DM leads to the following conservation equation

$$\dot{\rho}_{_D} + 3H\rho_{_D}(1 + \omega_{_D}) = -\Gamma, \tag{9}$$

$$\dot{\rho}_{_m} + 3H\rho_{_m} = \Gamma. \tag{10}$$

The coupling parameter Γ shows the mutual exchange rate between DM and DE. The energy exchange from DM to DE when $\Gamma < 0$ and corresponds to reverse scenario for $\Gamma > 0$. In the literature the various models have been proposed for parameter interaction to understand the universe's dynamics. We consider following expression for Γ as

$$\Gamma = 3Hd^2\rho_m, \tag{11}$$

here the coupling constant d exchange the energy between cold DM and DE. Inserting the value of Γ in Eq. (10), we get

$$\rho_m = a^{3(d^2-1)}\rho_{m0}, \tag{12}$$

where ρ_{m0} is an integration constant.

Now we will discuss the SMHDE model. SMHDE model is the new form of HDE model which is proposed due to the inspiration of holographic principle.[16] The Renyi and Tsallis entropies are formulations in which probability distributions are

replaced with power-law distributions, yielding generalized entropies. Tsallis and Renyi entropies are combined in the Sharma-Mittal (SM) entropy. This entropy[17] leads to useful conclusions in cosmological scenarios, such as a description of the present accelerating universe that makes use of vacuum energy. The energy density of SMHDE is given by

$$\rho_{_D} = \frac{3c^2H^4}{8\pi R}\left[\left(1+\frac{\delta\pi}{H^2}\right)^{\frac{R}{\delta}}-1\right], \tag{13}$$

where c^2 is the unknown free parameter, $R,\ \delta$ are constants which provide Renyi and Tsallis HDE models under appropriate limits and IR cutoff is taken as Hubble horizon. We attain the following expression by taking the derivative of Eq. (13) w.r.t to t as

$$\dot{\rho}_{_D} = 4\frac{\dot{H}}{H}\rho_{_D} - \frac{3}{4}c^2H\dot{H}\left(1+\frac{\delta\pi}{H^2}\right)^{\frac{R}{\delta}-1}. \tag{14}$$

3. Cosmological Parameters

In this section, we discuss the cosmological parameters in the frame work of SMHDE with apparent horizon, such that the Hubble, EoS, deceleration and squared speed of sound parameters.

3.1. *Hubble Parameter*

Taking into account Eqs. (7), (10), (11), (12) and (14), we obtain

$$\dot{H} = \left(9(d^2-1)HH_0^2\Omega_{m0}M_{p0}^2a^{3(d^2-1)} * E\right)\left[6M_p^2H^2(E+H^2)-E\right.$$
$$\left.\times\left(\frac{3c^2H^3}{2\pi R}\left[\left(\frac{\delta\pi}{H^2}+1\right)^{\frac{R}{\delta}}-1\right]-\frac{3c^2H}{4}\left(\frac{\delta\pi}{H^2}+1\right)^{\frac{R}{\delta}-1}\right)\right]^{-1} \tag{15}$$

The Hubble parameter H versus redshift function $(1+z)$ trajectories are shown in **Figure 1** for different values of $d^2 = 0.4, 0.6, 0.8$ and $M_{p0}^2 = 1,\ E = 80,\ \delta = 0.5,\ c = 1,\ R = 0.1,\ \Omega_{m0} = 0.5,\ H_0 = 74.$ are the other constant parameters. The values of Hubble parameter lie within the range 74.010^{+10}_{-10} for all epochs.

3.2. *Equation of State Parameter*

For the identification of universe at different phases of acceleration and deceleration, we examine the EoS parameter. It is ratio of pressure to density i.e $\omega = \frac{p}{\rho}$. If we take $\omega = 0$, it is a non-relativistic matter while radiation period as decelerated phase of the universe corresponds to $0 < \omega < \frac{1}{3}$ and stiff fluid is for $(\omega = 1)$. During acceleration phase, it represents the phantom epoch for $(\omega < -1)$, quintessence epoch for $(-1 < \omega < \frac{-1}{3})$, and cosmological constant for $(\omega = -1)$. For SMHDE

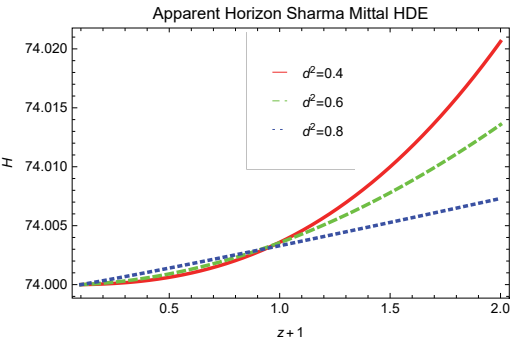

Fig. 1. (Color online) Plot of Hubble parameter H versus $1+z$ for Hubble horizon by choosing $d^2 = 0.4$ (solid red), 0.6 (dashed green), 0.8 (dotted blue).

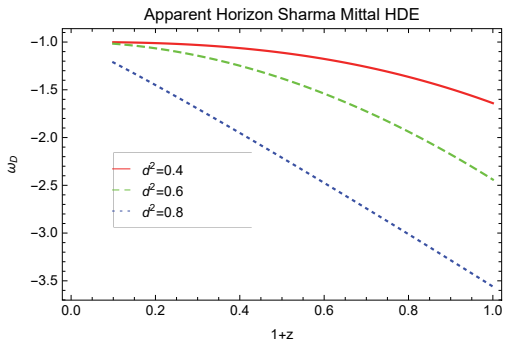

Fig. 2. (Color online) Plot of ω_{DE} versus $1+z$ for Hubble horizon by choosing $d^2 = 0.4$ (solid red), 0.6 (dashed green), 0.8 (dotted blue).

model we check the behavior of EoS parameter by using Eqs. (9), (11), (12) and (14), we get

$$\omega_{_D} = \frac{-3d^2H_0^2M_{p0}^2\Omega_{m0}a^{3(d^2-1)}}{\frac{3c^2H^4}{8\pi R}[(1+\frac{\delta\pi}{H^2})^{\frac{R}{\delta}}-1]} - 1 - \left[\frac{4}{3H^2} - \frac{c^2(1+\frac{\delta\pi}{H^2})^{\frac{R}{\delta}-1}}{\frac{3c^2H^2}{2\pi R}\left((1+\frac{\delta\pi}{H^2})^{\frac{R}{\delta}}-1\right)}\right]$$
$$\times\left(9(d^2-1)HH_0^2\Omega_{m0}M_{p0}^2a^{3(d^2-1)}E\right)\left[6M_p^2H^2(E+H^2)-E\right.$$
$$\left.\times\left(\frac{3c^2H^3}{2\pi R}\left[\left(\frac{\delta\pi}{H^2}+1\right)^{\frac{R}{\delta}}-1\right]-\frac{3c^2H}{4}\left(\frac{\delta\pi}{H^2}+1\right)^{\frac{R}{\delta}-1}\right)\right]^{-1}. \qquad (16)$$

In **Figure 2**, we plot $\omega_{_D}$ versus $1+z$ by taking same values of constants. The EoS parameter ($\omega_{_D}$) trajectories lie in the phantom regime which follow the cosmological constant behavior at $z=-1$.

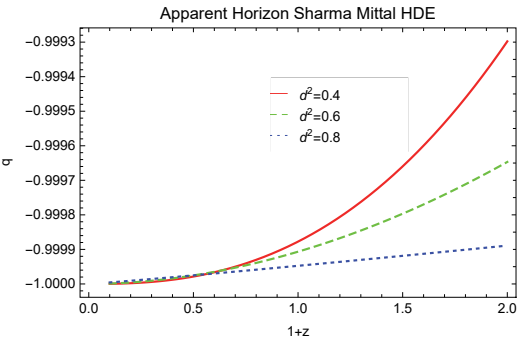

Fig. 3. Plot of q versus $1+z$ for Hubble horizon by choosing $d^2 = 0.4$ (solid red), 0.6 (dashed green), 0.8 (dotted blue).

3.3. *Deceleration Parameter*

We can analyze the accelerating and decelerating rate in different phases of the universe by using deceleration parameter. In terms of Hubble parameter, it is given by

$$q = -\frac{\ddot{a}}{aH^2} = -1 - \frac{\dot{H}}{H^2}. \tag{17}$$

The positive values of this parameter represent decelerated phase and expansion rate as constant when this parameter vanishes. The region described by $q < (-1, 0)$ is accelerating phase with power law expansion, $q = -1$ shows exponential expansion while and $q < -1$ describe super-exponential expansion of the accelerated phase of the expanding universe. In the underlying case, it takes the form

$$q = -1 - \frac{1}{H^2}\left[\left(9(d^2-1)HH_0^2\Omega_{m0}M_{p0}^2a^{3(d^2-1)}E\right)\left(6M_p^2H^2(E+H^2)\right.\right.$$
$$\left.\left. - E\left(\frac{3c^2H^3}{2\pi R}\left[\left(\frac{\delta\pi}{H^2}+1\right)^{\frac{R}{\delta}} - 1\right] - \frac{3c^2H}{4}\left(\frac{\delta\pi}{H^2}+1\right)^{\frac{R}{\delta}-1}\right)\right)^{-1}\right]. \tag{18}$$

Considering same values of constants, we plot q versus redshift $(1+z)$ as shown in **Figure 3**. The plot shows the expansion rate at power law level of the accelerating universe for all values of redshift parameter as well as d^2.

3.4. *Squared Speed of Sound Parameter*

In order to check the stability of model, we use squared speed of sound parameter for the underlying case. It is given by

$$v_s^2 == \frac{\dot{p}_D}{\dot{\rho}_D}, \tag{19}$$

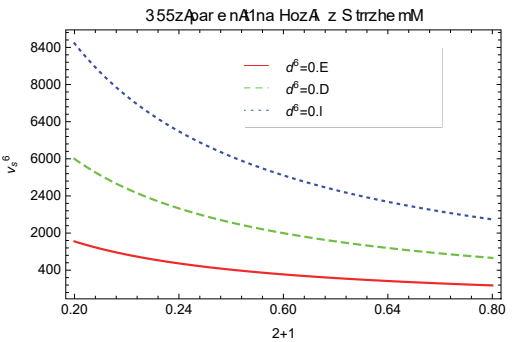

Fig. 4. Plot of υ_s^2 versus $1+z$ for Hubble horizon by choosing $d^2 = 0.4$ (solid red), 0.6 (dashed green), 0.8 (dotted blue).

If υ_s^2 is greater than zero then model is stable, otherwise unstable. For SMHDE model, υ_s^2 becomes

$$\begin{aligned}\upsilon_s^2 = &\Bigg(8RH_0^2\Omega_{m0}M_{p0}^2a^{3(d^2-1)\pi}(2(\delta\pi+H^2)(4d^2M_{p0}^2ER\pi+Ec^2H\\&+4d^2M_{p0}^2H^2R\pi)-c^2\left(1+\frac{\delta\pi}{H^2}\right)^{\frac{R}{\delta}}H(-ER\pi+d^2R\pi(1+E)\\&+2E\delta\pi+2EH^2))\Bigg)\Bigg(c^2\Bigg(-1+\left(1+\frac{\delta\pi}{H^2}\right)^{\frac{R}{\delta}}H^4(-2(\delta\pi+H^2)\\&\times(4M_{p0}^2ER\pi+Ec^2H+4M_{p0}^2H^2R\pi)+c^2\left(1+\frac{\delta\pi}{H^2}\right)^{\frac{R}{\delta}}H\\&\times(R\pi+2E\delta\pi+2EH^2))\Bigg)\Bigg)^{-1}+\dot{\omega}_D\left(\frac{4\dot{H}}{H}-\frac{3c^2H\dot{H}}{4\rho_D}\right.\\&\left.\times\left(1+\frac{\delta\pi}{H^2}\right)^{\frac{R}{\delta}-1}\right)^{-1}-1\end{aligned}\tag{20}$$

Figure 4 describes the plot of $\upsilon_s^2 > 0$ versus redshift parameter for same constant values as in previous cases. The plot expresses positive behavior for all the trajectories which lead to the stable behavior of the model.

4. Conclusions

In this paper, we have considered deformed Hořava-Lifshitz gravity with interaction of dark sector constituents of the universe. The SMHDE model with Hubble horizon is taken into account in order to discuss some cosmological parameters. These parameters are Hubble, EoS, deceleration and squared speed of sound. For different values of interaction parameter, we have investigated the behavior of these parameters graphically for some arbitrary values of model constants. The Hubble

parameter represents consistent results as 74.010^{+10}_{-10} for all trajectories while EoS parameter expresses phantom behavior of the universe. The deceleration parameter indicates the accelerating universe with power law expansion which leads to exponential expansion and squared speed of sound parameter gives the stable behavior of SMHDE models in the framework of deformed Hořava-Lifshitz gravity for all values of interaction parameter.

In this work, we elaborate on the finite action for wormholes in higher derivative theories as well as for wormholes. Both non-traversable and traversable wormholes in theories with higher curvature invariants posses finite action.

Keywords: Horava gravity; Wormholes; finite action

1. Introduction

The Finite Action Principle (FAP) proposes that the physical spacetimes are those for which the action is finite. This reasoning comes from the fact that in Euclidian path integral the weighting factor is $e^{-S[\Phi]}$. Hence lesser the action the more it contributes to the path integral. On the other hand, in the Lorentztian signature the more varying actions contribute less. For an infinitely varying action, one expects a distructive interference with the neighboring fields in such a configuration, see.[1]

This notion has recently received significant attention in the literature, see[2–4] for the cosmological considerations and[1,4] for the investigation of the black holes. Since it is expected that the quantum gravity should resolve the black-hole singularity problem, one may ask which of the microscopic actions remain finite for non-singular black holes and conversely interfere destructively for the singular ones. This we shall call the finite action selection principle. Only after the inclusion of higher-curvature operators, beyond the Einstein-Hilbert term, such selection principle can be satisfied.[1] Furthermore, in asymptotic safety, the quantum corrections to the Newtonian potential eliminate the classical-singularity.[5]

These findings suggest that by taking into account the higher curvatures one can resolve the singularities in black holes. Yet, an issue with the higher-curvature theory of quantum gravity is the existence of the particles with the negative mass-squared spectrum, known as *ghosts*, which makes the theory non-unitary. In this article, we explore possible resolution, namely, we investigate Horava-Lifshitz (H-L) gravity,[6] where the Lorentz Invariance (LI) is broken at the fundamental level (see[7] for a comprehensive progress report on this subject). Kinetic terms are first order in the time derivatives, while higher spatial curvature scalars regulate the UV behavior of the gravity. In our investigation we follow Horava[6] and assume that Wick

rotation is well defined. This can be motivated by the lack of the higher time-like curvature invariants. In the usual higher derivative constructions the existence of massive poles in the propagator makes the Wick rotation troublesome.[8] Conversely to the latter, the new poles are massless and non-tachyonic for suitable choice of parameters.[9] Furthermore, the existence of the foliation supports that claim. For the discussion of Minkowski path integral and FAP, see.[1]

In the previous article, we discussed the possibility that the Finite Action arguments applied to the projectable H-L gravity result in a flat, homogeneous, UV-complete, and ghost-free beginning of the universe.[4] However there is no known regular black hole solutions in HL gravity. Here we discuss the wormholes solutions in the context of the Finite Action Principle in HL gravity, as well as in the $f(R)$ theories. Interestingly the stable and traversable wormholes solutions are known only in the higher derivative gravities[10] (without exotic matter), so there seems to be a wormhole/non-singular BH trade-off after taking into account the Finite Action Principle.

2. Horava-Lifshitz gravity

In the Horava-Lifshitz gravity, space and time are scaled in a non-equivalent way. Diffeomorphism invariance is broken by the foliation of the 4-dimensional spacetime into 3-dimensional hypersurfaces of constant time, called leaves, making the theory power-counting renormalizable (see also the renormalization group studies of the subject[11–13]). The remaining symmetry respects transformations:

$$t \to \xi_0(t), \quad x^i \to \xi^i(t, x^k), \tag{1}$$

and is often referred to as the foliation-preserving diffeomorphism, denoted by $\mathrm{Diff}(M, \mathcal{F})$. The diffeomorphism invariance is still present on the leaves. The four-dimensional metric may be expressed in the Arnowitt-Deser-Misner (ADM)[14] variables:

$$(N, N^i, {}^{(3)}g_{ij}), \tag{2}$$

where N, N^i, ${}^{(3)}g_{ij}$ denote respectively the lapse function, shift vector, and 3-dimensional induced metric on the leaves. The theory is constructed from the following quantities:

$${}^{(3)}R_{ij}, \quad K_{ij}, \quad a_i, \quad {}^{(3)}\nabla_i, \tag{3}$$

where ${}^{(3)}R_{ij}$ is the 3-dimensional Ricci curvature tensor, ${}^{(3)}\nabla_i$ is the covariant derivative constructed from the 3-dimensional metric ${}^{(3)}g_{ij}$, and $a_i := \frac{N_{,i}}{N}$. Extrinsic curvature K_{ij} is the only object, invariant under general spatial diffeomorphisms containing exactly one time derivative of the metric tensor ${}^{(3)}g_{ij}$:

$$K_{ij} = \frac{1}{2N}\left(\frac{\partial\, {}^{(3)}g_{ij}}{\partial t} - {}^{(3)}\nabla_i N_j - {}^{(3)}\nabla_j N_i\right). \tag{4}$$

Quantities (2) are tensor/vectors with respect to Diff$(M, \mathcal{F})$ possessing the following mass dimensions:

$$[\,{}^{(3)}R_{ij}] = 2, \quad [K_{ij}] = 3, \quad [a_i] = 1, \quad [\,{}^{(3)}\nabla_i] = 1. \tag{5}$$

One may use (2) to construct, order by order, scalar terms appearing in the Lagrangian of the theory. Following[7,15] the action of the Horava gravity takes the form:

$$S_g = \zeta^2 \int dt dx^3 N \sqrt{{}^{(3)}g}\,(\mathcal{K} - V)\,, \tag{6}$$

where $\mathcal{K} = K_{ij}K^{ij} - \lambda K^2$ with $K = K_{ij}\,{}^{(3)}g^{ij}$, ${}^{(3)}g$ denotes the determinant of the 3-dimensional metric and $\zeta^2 = 1/16\pi G$. It may be expressed as the difference of the kinetic and potential part $\mathcal{L} = \mathcal{K} - V$ with $\mathcal{K} = \left(K_{ij}K^{ij} - \lambda K^2\right)$. At the 6th order, the potential part of the lagrangian contains over 100 terms.[7] The immense number of invariants is limited by imposing further symmetries. One possible restriction for the potential comes from the projectability condition $N = N(t)$, then terms proportional to $a_i \equiv 0$ vanish. Up to the sixth order (compatible with power counting renormalizability), the potential V restricted by the projectability condition is given by:

$$\begin{aligned} V = 2\Lambda\zeta^2 - {}^{(3)}R + \frac{1}{\zeta^2}\left(g_2\,{}^{(3)}R^2 + g_3\,{}^{(3)}R^{ij}\,{}^{(3)}R_{ij}\right) \\ + \frac{1}{\zeta^4}\left(g_4{}^{(3)}R^3 + g_5\,{}^{(3)}R\,{}^{(3)}R^{ij}\,{}^{(3)}R_{ij} + g_6\,{}^{(3)}R^i_j\,{}^{(3)}R^j_k\,{}^{(3)}R^k_i\right), \\ + \frac{1}{\zeta^4}\left(g_7{}^{(3)}R\nabla^2{}^{(3)}R + g_8(\nabla_i{}^{(3)}R_{jk})(\nabla^i{}^{(3)}R^{jk})\right), \end{aligned} \tag{7}$$

where Λ is the cosmological constant and α_{ij} are the coupling constants. For our purposes, we drop terms containing covariant derivatives ${}^{(3)}\nabla_i$. One should also mention that this *minimal theory*[16] suffers from the existence of spin 0 graviton, which is unstable in the IR. Various solutions to this problem have been proposed. One can add the additional local $U(1)$ symmetry.[7,17] Then by the introduction of new fields prevents the zero-mode from propagating. On the other hand, one can drop the projectability condition $a_i = 0$ and include the terms containing a_i in the potential term:

$$V = 2\Lambda\zeta^2 - {}^{(3)}R - \beta_0 a_i a^i + \sum_{n=3}^{6} \mathcal{L}_V^{(n)}, \tag{8}$$

then for the spin-0 mode to be stable one requires $0 < \beta_0 < 2$.[18,19]

3. Wormholes and finite action principle

Here, we take the first step in the direction of the investigations of the consequences of the Finite Action Principle in the context of wormholes (WH). The wormholes may be characterized in two classes: traversable and non-traversable.

The traversable WH, colloquially speaking, are such that one can go through it to the other side, see[20] for specific conditions. The pioneering Einstein-Rosen bridge has been found originally as a non-static, non-traversable solution to GR. The traversable solutions are unstable, however, they might be stabilized by an exotic matter or inclusion of the higher curvature scalar gravity.[10] This is important in the context of finite action since usually the divergences of black holes do appear in the curvature squared terms. Hence, due to the inclusion of the higher-order terms in the actions, the traversable wormholes are solutions to the equations of motions without the exotic matter. The exemplary wormhole spacetimes investigated here are the Einstein-Rosen bridge proposed in,[21] the Morris-Thorne (MT) wormhole,[20] the traversable exponential metric wormhole[22] and the wormhole solution discussed in the H-L gravity.[23] All of them have a finite action. Here, we shall discuss the exponential metric WH. For the exponential metric WH, the line element is given by:

$$ds^2 = -e^{-\frac{2M}{r}}dt^2 + e^{\frac{2M}{r}}\left(dr^2 + r^2 d\Omega^2\right). \tag{9}$$

This spacetime consists two regions: "our universe" with $r > M$ and the "other universe" with $r < M$. $r = M$ corresponds to the wormhole's throat. The spacial volume of the "other universe" is infinite when $r \to 0$. Such volume divergence is irrelevant to our discussion since it describes large distances in the "other universe". Hence, we further consider only $r \geq M$. The resulting Ricci and Kretschmann scalars have been calculated in[22] and the measure are non-singular everywhere:

$$\begin{aligned} R &= -\frac{2M^2}{r^4}e^{\frac{-2M}{r}}, \\ R_{\mu\nu\sigma\rho}R^{\mu\nu\sigma\rho} &= \frac{4M^2(12r^2 - 16Mr + 7M^2)}{r^8}e^{-4\frac{M}{r}}, \end{aligned} \tag{10}$$

resulting in the finite action for the Stelle gravity. Similarly for the H-L gravity:

$$\begin{aligned} {}^{(3)}R = R, \quad K^2 = K_{ij}K^{ij} = 0, \\ {}^{(3)}R_{ij}{}^{(3)}R^{ij} = \frac{2M^2(M^2 - 2Mr + 3r^2)}{r^8}e^{-\frac{4M}{r}}. \end{aligned} \tag{11}$$

Einstein-Rosen bridge The Einstein-Rosen (E-R) bridge smoothly glues together two copies of the Schwarzschild spacetime: the black hole and the white hole solutions corresponding to the positive and negative coordinate u. The metric tensor of the Einstein-Rosen wormhole proposed in[21] and discussed in e.g.[24] is given by:

$$ds^2 = \frac{-u^2}{u^2 + 4M}dt^2 + (u^2 + 4M)du^2 + \frac{1}{4}(u^2 + 4M)d\Omega^2. \tag{12}$$

The E-R bridge is non-traversable and geodesically incomplete in $u = 0$. This fact, however, does not impact the regularity of the curvature scalars. The 4-dimensional

Ricci scalar is:

$$R = \frac{2\left(64M^2 + 32Mu^2 + 4u^4 + u^2\right)}{\left(4M + u^2\right)^3}. \tag{13}$$

The second order curvature scalar $R_{\mu\nu}R^{\mu\nu}$ is:

$$\frac{4\left(48M^2 + 8\left(4M + u^2\right)^4 + (32M - 1)\left(4M + u^2\right)^2\right)}{\left(4M + u^2\right)^6}. \tag{14}$$

Both of which integrated with the measure are non-singular:

$$\sqrt{g} = \frac{1}{4}u(4M + u^2). \tag{15}$$

The wormhole solutions analyzed in this paper generally yield the finite action in both GR and H-L. The finite Action Principle suggests, that in the quantum UV regime, singular black-hole spacetimes may be replaced with the regular wormhole solutions.

Morris-Thorne wormhole The MT wormhole is defined in the spherically symmetric, Lorentzian spacetime by the line element:

$$ds^2 = -e^{2\Phi(r)}dt^2 + \frac{dr^2}{1 - \frac{b(r)}{r}} + r^2 d\Omega^2 \tag{16}$$

where $\Phi(r)$ is known as the redshift and there are no horizons if it is finite. Function $b(r)$ determines the wormhole's shape. We choose $\Phi(r)$, $b(r)$ to be:

$$\Phi(r) = 0, \quad b(r) = 2M\left(1 - e^{r_0 - r}\right) + r_0 e^{r_0 - r}, \tag{17}$$

where r_0 is the radius of the throat of the wormhole, such that $b(r_0) = r_0$. 4-dimensional curvature scalars for this spacetime have been calculated in.[25] The Ricci curvature scalar is singular at $r = 0$, however, the radial coordinate r varies between $r_0 > 0$ and infinity:

$$R = -2\left(2M - r_0\right)\frac{e^{r_0 - r}}{r^2}. \tag{18}$$

The resulting $S_s = \int_{r_{UV}=r_0}^{r_{IR}} \sqrt{g}R$ function is divergent as $r_{UV} \to r_0$ and cannot be expressed in terms of simple functions:

$$2(2M - r_0)\int_{r_{UV}=r_0}^{r_{IR}} \sqrt{\frac{r}{r - 2M(1 - e^{r_0 - r}) + r_0 e^{r_0 - r}}}\, e^{r_0 - r} dr. \tag{19}$$

However, this is only a coordinate singularity and one may get rid of it with a proper transformation.

Higher-order curvature scalars for Morris-Thorne wormhole are:

$$
\begin{aligned}
{}^{(3)}R &= \frac{2b'(r)}{r^2} \\
{}^{(3)}R_{ij}\,{}^{(3)}R^{ij} &= \frac{3r^2b'(r)^2 - 2rb(r)b'(r) + 3b(r)^2}{2r^6}, \\
{}^{(3)}R^i_j\,{}^{(3)}R^j_k\,{}^{(3)}R^k_i &= \frac{-9r^2b(r)b'(r)^2 + 5r^3b'(r)^3 + 15rb(r)^2b'(r) - 3b(r)^3}{4r^9},
\end{aligned} \tag{20}
$$

and integrated give action that is finite.

H-L wormhole Static spherically traversable symmetric wormholes have been constructed in[23] in the H-L theory through the modification of the Rosen-Einstein spacetime:

$$
ds^2 = -N^2(\rho)dt^2 + \frac{1}{f(\rho)}d\rho^2 + (r_0+\rho^2)^2d\Omega^2, \tag{21}
$$

with additional $\mathbf{Z}_2$ symmetry with respect to the wormhole's throat. There are solutions with $\lambda = 1$ asymptotically corresponding to the Minkowski vacuum. Explicitly we have:

$$
\begin{aligned}
f = N^2 &= 1 + \omega(r_0+\rho^2)^2 \\
&\quad - \sqrt{(r_0+\rho^2)\left(\omega^2(r_0+\rho^2)^3 + 4\omega M\right)}.
\end{aligned} \tag{22}
$$

The radius of the wormhole's throat is given by r_0. The parameters ω, and M are connected to the coupling constants in H-L action. See[23] for their explicit form. Ricci scalar of the H-L wormhole invariants are given by

$$
\begin{aligned}
{}^{(3)}R = &-\frac{1}{(\rho^2+r_0)^2}\Big[2(-10\rho^2\sqrt{\omega(\rho^2+r_0)(4M+\omega(r_0+\omega^2)^3)} \\
&- 4r_0\sqrt{\omega(\rho^2+r_0)(4M+\omega(r_0+\omega^2)^3)} + 16\rho^6\omega + 8\rho^2 \\
&+ 36\rho^4r_0\omega + 24\rho^2r_0^2\omega + 4r_0^3\omega + 4r_0 - 1)\Big], \\
{}^{(3)}R_{ij}\,{}^{(3)}R^{ij} = &\frac{1}{(\rho^2+r_0)^4}\Big\{2(-7\rho^2\sqrt{\omega(\rho^2+r_0)(4M+\omega(r_0+\omega^2)^3)} \\
&-2r_0\sqrt{\omega(\rho^2+r_0)(4M+\omega(r_0+\omega^2)^3)} \\
&+ 10\rho^6\omega + 6\rho^2 + 22\rho^4r_0\omega + 14\rho^2r_0^2\omega + 2r_0^3\omega + 2r_0 - 1)^2 + 4M \\
&+ \frac{4(\rho^2+r_0)}{\omega(4M+\omega(r_0+\omega^2)^3)}\Big[\rho^2\omega(-4(\rho^2+r_0) \\
&\times\sqrt{\omega(\rho^2+r_0)(4M+\omega(r_0+\omega^2)^3)} + \omega(r_0+\omega^2)^3)\Big] \\
&-2\sqrt{\omega(\rho^2+r_0)(4M+\omega(r_0+\omega^2)^3)} \\
&\times\left[-\sqrt{\omega(\rho^2+r_0)(4M+\omega(r_0+\omega^2)^3)} + \omega(\rho^2+r_0)^2+1)\right]^2\Big\}
\end{aligned} \tag{23}
$$

The kinetic terms with $K_{ij} = 0$ are vanishing, while the spacial Ricci scalar and higher curvature terms are finite.

From the point of view of the Finite Action Principle, all of the investigated wormhole spacetimes are included in the gravitational path integral.

4. Conclusions and discussion

The Finite Action Principle is a powerful tool to study quantum gravity theories and also QFTs in general. From the point of view of finite action selection principle[1,4] they are equally good theories, resolving the black holes singularities, assuming that ghost issue is resolved in the latter case. Yet none of the regular B-H solutions have been found in the context of H-L gravity[26] and the ones found for $f(R)$ suffer from mass inflation issue.[27–29] Hence, it is a strong suggestion that wormholes may appear in the UV regime of H-L gravity and can serve as a "cure" for singularities.[30–32]

Moreover, both the traversable and the non-traversable wormholes are on equal footing in the case of the Finite Action Principle, yet maybe the finite amplitude principle could distinguish between those,[3] since the amplitude to cross non-traversable wormhole should be different than the traversable one. However, this principle suggests that there is a trade-off between the resolution of black-hole singularities and the appearance of wormhole spacetimes due to higher curvature invariants. The wormhole solutions will remain in both the LI and H-L path integrals. The higher-order curvature scalars, generically present in the quantum gravity, stabilise the wormhole solutions without the need for an exotic matter.

Strange quark stars in Hořava gravity

Grigoris Panotopoulos

Departamento de Ciencias Físicas, Universidad de la Frontera, Casilla 54-D, 4811186 Temuco, Chile

grigorios.panotopoulos@ufrontera.cl

Non-rotating strange quark stars made of isotropic matter in Lorentz-violating theories of gravity are studied. In particular, Hořava gravity and Einstein-æther theory are considered. For quark matter we adopt both linear and non-linear equations-of-state, corresponding to the MIT bag model and color flavor locked phase, respectively. The new, modified structure equations generalize the usual Tolman-Oppenheimer-Volkoff equations valid in Einstein's General Relativity. A dimensionless parameter ν measures the deviation from the standard TOV equations, which are recovered in the appropriate limit. We compute some properties, such as masses, radii as well as the factor of compactness of the stars, and we show pictorially the impact of the parameter ν on the mass-to-radius relationships for several different equations-of-state. Other physical considerations, such as stability criteria, causality and energy conditions, are also considered, and they are all found to be fulfilled.

Keywords: Relativistic stars; Composition of astronomical objects; Theories of gravity other than GR.

1. Introduction

Einstein's General Relativity (GR)[1] is a relativistic, geometric theory of gravitation, which not only is beautiful but also very successful.[2,3] The classical tests and solar system tests,[4] and recently the direct detection of gravitational waves by the LIGO/VIRGO Collaborations[5] have confirmed a series of remarkable predictions of GR.

Despite its success, however, it it believed that GR must be somehow extended for several different reasons. One may mention, for example, the current cosmic acceleration,[6,7] one of the most dramatic discoveries in Cosmology in the end of the 90's. If a modified theory of gravity is assumed, correction terms to GR on cosmological scales are expected to appear, and those terms of geometrical origin could play the role of dark energy,[8] the fluid component that dominates the expansion of the Universe at late time. In this class of models one finds for instance $f(R)$ theories of gravity,[9–12] brane models[13–15] and scalar-tensor theories of gravity.[16–18]

Moreover, it has been known for a long time that GR is a classical, non-renormalizable theory of gravitation. A theory of gravity incorporating quantum mechanics in a consistent way is still one of the biggest challenges in Modern Theoretical Physics. In 2009 Hořava gravity[19,20] was proposed as a new candidate

theory for quantum gravity which explicitly breaks Lorentz invariance at any energy scale by introducing a preferred foliation of spacetime. Since then a lot of work has been done to prove, very successfully, its renormalizability by means of both power-counting arguments[21–26] and quantum field theory approaches.[27–30] Besides, a lot of effort has been made in order to investigate its phenomenological implications, e.g. concerning late-time Cosmology,[31,32] black hole physics,[33–39] binary systems,[40–42] and interior solutions of anisotropic stars.[43–45] In particular, after the multiple detections of gravitational waves by the LIGO-VIRGO Collaboration, and in particular the first merger observed from a binary of neutron stars,[46] a new era for gravitational astronomy get started. Very interestingly, Hořava gravity passes with flying colors all the theoretical and observational constraints which are available to date.[47] It is worth noticing that in the low-energy limit of Hořava gravity, its action written in a covariant form becomes equivalent to Einstein-æther theory[48] once the æther vector is restricted to be hypersurface-orthogonal at the level of the action.[49] In spherical symmetry it can be shown that the two theories share the same solutions.[50]

Therefore, it has become even more urgent to investigate the astrophysical implications and predictions of viable alternative theories of gravity, in order to explore non-standard scenarios and the possible signatures of deviations from GR to be observed in the forthcoming missions/space-based detectors. In this respect, compact objects,[51–53] such as neutron stars and white dwarfs, are relativistic stars of astrophysical and astronomical interest, which are characterized by ultra dense matter content and strong gravitational fields. Thanks to their properties, naturally they serve as ideal cosmic laboratories to study, test and constrain non-standard physics as well as non-conventional theories of gravity.

A new class of theoritized compact objects, that may be an alternative to neutron stars, are some as of today hypothetical objects which are supposed to be made of quark matter, and for that reason they are called strange quark stars.[54–59] Quark matter is by assumption absolutely stable,[60,61] and so it could be the true ground state of hadrons. That property provides us with a plausible explanation of some puzzling super-luminous supernovae,[62,63] which occur in about one out of every 1000 supernovae explosions, and which are more than 100 times more luminous than regular supernovae.

Our work is organized as follows. In Sec. 2 we briefly review the basics of Hořava gravity, and its connection to Einstein-æther theory, while in Sec. 3 we present the field equations as well as the structure equations describing hydrostatic equilibrium of static, spherically symmetric relativistic stars made of isotropic matter. In Sec. 4 we obtain and discuss our numerical results for quark stars. Finally, we finish our work with some concluding remarks in Sec. 5. We adopt the mostly negative metric signature $+,-,-,-$, and we work in natural units where $\hbar = 1 = c$. In those units all dimensionful quantities are measured in GeV $= 10^3$ MeV, and we make use of the conversion rules: 1 m $= 5.068 \times 10^{15}$ GeV^{-1} and 1 kg $= 5.610 \times 10^{26}$ GeV.[64]

2. Hořava gravity and Einstein-æther theory

The action of Hořava gravity[19,20] can be written in the preferred foliation as

$$\mathcal{S}_H = \frac{1}{16\pi G_H}\int dTd^3x\sqrt{-g}\left(K_{ij}K^{ij} - \lambda K^2 + \xi\mathcal{R} + \eta a_i a^i + \frac{L_4}{M_*^2} + \frac{L_6}{M_*^4}\right) + S_m[g_{\mu\nu},\psi]\,, \tag{1}$$

where G_H is the effective gravitational constant; g is the determinant of the metric $g_{\mu\nu}$; $\mathcal{R}$ is the Ricci scalar of the three-dimensional constant-T hypersurfaces; K_{ij} is the extrinsic curvature and K is its trace; and $a_i = \partial_i \ln N$, where N is the lapse function and S_m is the matter action where ψ collectively denotes the matter fields. The constant couplings $\{\lambda,\xi,\eta\}$ are dimensionless, and GR is identically recovered when they take the values $\{1,1,0\}$, respectively. Furthermore, L_4 and L_6 stand for the fourth-order and sixth-order operators respectively, which are suppressed by a characteristic mass scale M_*.

In the following, we consider the covariantized version of the low-energy limit of Hořava gravity, named the *khronometric* model, that is obtained by keeping only the operators up to second-order derivatives, which amounts to discarding L_4 and L_6 which instead contain the higher-order operators.

In order to write the action covariantly, let us first take the action of Einstein-æther theory:[48]

$$\mathcal{S}_{æ} = \frac{1}{16\pi G_{æ}}\int d^4x\sqrt{-g}\,(-R + L_{æ}) + S_m[g_{\mu\nu},\psi]\,, \tag{2}$$

where $G_{æ}$ is the "bare" gravitational constant; R is the four-dimensional Ricci scalar; u^a is a timelike vector field of unit norm, *i.e.*, $g_{\mu\nu}u^\mu u^\nu = 1$, from now on referred to as the "æther"; and

$$L_{æ} = -M^{\alpha\beta}{}_{\mu\nu}\nabla_\alpha u^\mu \nabla_\beta u^\nu\,, \tag{3}$$

with $M^{\alpha\beta}{}_{\mu\nu}$ defined as

$$M^{\alpha\beta}{}_{\mu\nu} = c_1 g^{\alpha\beta}g_{\mu\nu} + c_2\delta^\alpha_\mu\delta^\beta_\nu + c_3\delta^\alpha_\nu\delta^\beta_\mu + c_4 u^\alpha u^\beta g_{\mu\nu}\,, \tag{4}$$

where c_i's are dimensionless coupling constants.

Once the æther vector is taken to be hypersurface-orthogonal at the level of the action, that is

$$u_\alpha = \frac{\partial_\alpha T}{\sqrt{g^{\mu\nu}\partial_\mu T\partial_\nu T}}\,, \tag{5}$$

where the preferred time T is a scalar field (the *khronon*) which defines the preferred foliation, then the two actions in Eqs. (1) and (2) become equivalent if the parameters of the two theories are mapped into each other as[49]

$$\frac{G_H}{G_{æ}} = \xi = \frac{1}{1-c_{13}}\,, \qquad \frac{\lambda}{\xi} = 1 + c_2\,, \qquad \frac{\eta}{\xi} = c_{14}\,, \tag{6}$$

where $c_{ij} = c_i + c_j$. Moreover $G_{æ} = G_N\,(1 - \eta/2\xi)$, where G_N is the Newton's constant, which is needed to recover the Newtonian limit.[20,65] In what follows, we will thus consider the covariant formulation of the low-energy limit of Hořava gravity.

The variation of the action in Eq. (2) with respect to $g^{\alpha\beta}$ and T yields, respectively,[42]

$$G_{\alpha\beta} - T^{æ}_{\alpha\beta} = 8\pi G_{æ} T^{m}_{\alpha\beta}\,, \tag{7}$$

$$\partial_\mu \left(\frac{1}{\sqrt{\nabla^\alpha T \nabla_\alpha T}} \sqrt{-g} Æ^\mu \right) = 0\,, \tag{8}$$

where $G_{\alpha\beta} = R_{\alpha\beta} - R g_{\alpha\beta}/2$ is the Einstein tensor,

$$T^{æ}_{\alpha\beta} = \nabla_\mu \left(J_{(\alpha}{}^{\mu} u_{\beta)} - J^{\mu}{}_{(\alpha} u_{\beta)} - J_{(\alpha\beta)} u^\mu \right) + c_1 \left[(\nabla_\mu u_\alpha)(\nabla^\mu u_\beta) - (\nabla_\alpha u_\mu)(\nabla_\beta u^\mu) \right] + \left[u_\nu (\nabla_\mu J^{\mu\nu}) - c_4 \dot{u}^2 \right] u_\alpha u_\beta + c_4 \dot{u}_\alpha \dot{u}_\beta - \frac{1}{2} L_{æ} g_{\alpha\beta} + 2Æ_{(\alpha} u_{\beta)} \tag{9}$$

is the khronon stress-energy tensor,

$$J^{\alpha}{}_{\mu} = M^{\alpha\beta}{}_{\mu\nu} \nabla_\beta u^\nu\,, \quad \dot{u}_\nu = u^\mu \nabla_\mu u_\nu\,, \quad Æ_\mu = \left(\nabla_\alpha J^{\alpha\nu} - c_4 \dot{u}_\alpha \nabla^\nu u^\alpha \right) \left(g_{\mu\nu} - u_\mu u_\nu \right)\,, \tag{10}$$

and $T^{m}_{\alpha\beta}$ is the matter stress-energy tensor, defined as

$$T^{m}_{\alpha\beta} = \frac{2}{\sqrt{-g}} \frac{\delta S_m}{\delta g^{\alpha\beta}}\,. \tag{11}$$

3. Field equations

The most general static, spherically symmetric geometry, in Schwarzschild-like coordinates, may be written down as follows

$$ds^2 = e^{A(r)} dt^2 - B(r) dr^2 - r^2 \left(d\theta^2 + \sin^2\theta d\phi^2 \right)\,. \tag{12}$$

In addition, let us consider an interior spacetime filled by an isotropic fluid whose stress-energy tensor is

$$T^{m}_{\alpha\beta} = (\rho + p)\, v_\alpha v_\beta - p g_{\alpha\beta}\,, \tag{13}$$

where ρ is the density and p is the pressure of the fluid, and its 4-velocity v^α is given by

$$v^\alpha = \left(e^{-A(r)/2}, 0, 0, 0 \right)\,. \tag{14}$$

The æther vector field, which is by definition a unit timelike vector, in spherical symmetry is always hypersurface-orthogonal and takes the following general form:

$$u^\alpha = \left(F(r), \sqrt{\frac{e^{A(r)} F(r)^2 - 1}{B(r)}}, 0, 0 \right)\,. \tag{15}$$

However, in the following we will consider the case of a static aether which is aligned with the interior matter fluid 4-velocity v^α, *i.e.* when $F(r) = e^{-A(r)/2}$, which leads to

$$u^\alpha = \left(e^{-A(r)/2}, 0, 0, 0\right). \tag{16}$$

The field equations that we have to consider are the modified Einstein equations (0-0), (1-1) and (2-2) in Eq. (7), which can be written respectively as:

$$-\nu\left[4r^2A''(r) - \frac{2r^2A'(r)B'(r)}{B(r)} + r^2A'(r)^2 + 8rA'(r)\right] + \frac{rB'(r)}{B(r)} + B(r) - 1$$
$$= 8\pi G_{æ} r^2 B(r)\rho(r)\,, \tag{17}$$

$$\nu r^2 A'(r)^2 + rA'(r) - B(r) + 1 = 8\pi G_{æ} r^2 B(r) p(r)\,, \tag{18}$$

$$\frac{1}{2}r^2A''(r) - \frac{r^2A'(r)B'(r)}{4B(r)} - \nu r^2 A'(r)^2 + \frac{1}{4}r^2A'(r)^2 + \frac{1}{2}rA'(r) - \frac{rB'(r)}{2B(r)}$$
$$= 8\pi G_{æ} r^2 B(r) p(r)\,, \tag{19}$$

where $\nu = \frac{\eta}{8\xi}$. Furthermore, Eq. (8) is identically satisfied. In the following we shall set $8\pi G_{æ} = 1$. Finally, the conservation equation for the energy-momentum tensor takes the form

$$p'(r) + \frac{1}{2}A'(r)\left[\rho(r) + p(r)\right] = 0\,. \tag{20}$$

Notice that the standard Tolman-Oppenheimmer-Volkoff (TOV) equations,[66–69] which hold in GR,[1] are recovered setting $\nu = 0$ in the equations above.

Despite the fact that there are four equations in total, it turns out that only three of them are independent. Furthermore, since spherically symmetric solutions in Hořava gravity are identical to those of Einstein-æther theory, all of our conclusions will hold for both theories.[50]

In order to derive the modified TOV equations that will be used for the numerical integration, one can obtain $A'(r)$ from Eq. (18):

$$A'(r) = -\frac{r - r\sqrt{4\nu r^2 B(r)p(r) + 4\nu B(r) - 4\nu + 1}}{2\nu r^2}\,, \tag{21}$$

which corresponds to the only branch which admits the proper GR limit when $\nu \to 0$. Then, one has to substitute the latter in Eq. (17) and Eq. (20), that for brevity we do not show here. However, one can immediately notice the difference with respect to GR, since here the parameter ν (which in GR is identically zero) enters non-linearly in the resulting equations.

4. Properties of strange quark stars: Numerical treatment

In this section we investigate the properties of strange quark stars within the Lorentz-violating theories of gravity at hand. We integrate numerically the generalized structure equations, and after that we present and discuss the results.

4.1. *Vacuum solution*

In order to compute the radius and the mass of the objects, we need to match the solutions at the surface of the stars. For that we need to know the exterior (vacuum) solution first, and so we set the stress-energy tensor (i.e. both the pressure and the energy density of the matter content) to zero.

In order to calculate the total gravitational mass M of the fluid star appearing in the Newtonian potential, we will make use of the general vacuum solution found in Ref. 70 and summarized below:

$$e^A = \left(\frac{1 - Y/Y_-}{1 - Y/Y_+}\right)^{\frac{-Y_+}{2+Y_+}} , \tag{22}$$

$$B = \nu(Y - Y_-)(Y - Y_+) , \tag{23}$$

$$\frac{r_{\min}}{r} = \left(\frac{Y}{Y - Y_-}\right)\left(\frac{Y - Y_-}{Y - Y_+}\right)^{\frac{1}{2+Y_+}} , \tag{24}$$

where $Y = rA'$, $Y_\pm = (-1 \pm \sqrt{1 - 4\nu})/(2\nu)$, and $r_{\min}$ is an integration constant which is related to the gravitational radius $r_g = 2G_N M$ by

$$r_{\min}/r_g = (-Y_+)^{-1}(-1 - Y_+)^{(1+Y_+)/(2+Y_+)} . \tag{25}$$

The above solution agrees with the Schwarzschild solution[71] of GR to leading order in $1/r$.

4.2. *Equation-of-state*

Before we start integrating the structure equations, we must specify the matter content first, or in other words pick up a certain equation-of-state. Quark matter inside stars is commobly described by the MIT bag model.[72,73] In the simplest version there is a linear analytic function relating the energy density to the pressure of the fluid, which reads

$$p = k(\rho - \rho_s) , \tag{26}$$

where k is a dimensionless numerical factor, while ρ_s is the surface energy density. The MIT bag model is characterized by 3 parameters, namely i) the QCD coupling constant, α_c, ii) the mass of the strange (s) quark, m_s, and iii) the bag constant, B_0. In this work we shall consider the following 3 models:[74]

- The extreme model SQSB40 where $m_s = 100$ MeV, $\alpha_c = 0.6$ and $B_0 = 40$ MeV fm^{-3}. In this model $k = 0.324$ and $\rho_s = 3.0563 \times 10^{14}$ g cm^{-3}.

- The standard model SQSB56 where $m_s = 200$ MeV, $\alpha_c = 0.2$ and $B_0 = 56$ MeV fm^{-3}. In this model $k = 0.301$ and $\rho_s = 4.4997 \times 10^{14}$ g cm^{-3}.
- The simplified model SQSB60 where $m_s = 0 = \alpha_c$ and $B_0 = 60$ MeV fm^{-3}. In this model $k = 1/3$ and $\rho_s = 4.2785 \times 10^{14}$ g cm^{-3}.

Furthermore, at asymptotically large densities color superconductivity effects[75,76] become important. Quark matter is found to be in the so called color flavor locked (CFL) state,[77,78] in which quarks form Cooper pairs of different color and flavor, and where all quarks have the same Fermi momentum and electrons cannot be present. That quark state is described by a slightly more complicated equation of state (EoS), although still an analytic function, and it is given by the following non-linear relation[79–81]

$$\rho = 3p + 4B_0 - \frac{9\gamma\mu^2}{\pi^2}\,, \tag{27}$$

where γ and μ^2 are given by

$$\gamma = \frac{2\Delta^2}{3} - \frac{m_s^2}{6}\,, \tag{28}$$

and

$$\mu^2 = -3\gamma + \left(9\gamma^2 + \frac{4}{3}\pi^2(B_0 + p)\right)^{1/2}\,, \tag{29}$$

with Δ being the non-vanishing energy gap.

In the CFL state there are 19 viable models, but here we shall consider two, namely CFL4 and CFL10, characterized by the following parameters (look at table I in Ref. 81):

$$\Delta = 100 \text{ MeV}\,, \tag{30}$$
$$m_s = 150 \text{ MeV}\,, \tag{31}$$
$$B_0 = 60 \text{ MeV fm}^{-3}\,, \tag{32}$$

for CFL4, and

$$\Delta = 150 \text{ MeV}\,, \tag{33}$$
$$m_s = 150 \text{ MeV}\,, \tag{34}$$
$$B_0 = 80 \text{ MeV fm}^{-3}\,, \tag{35}$$

for CFL10.

4.3. *Numerical solution of structure equations*

The radius of the stars, R, is determined from the requirement that $p(r = R) = 0$, while the mass of the stars, M, is computed numerically using the vacuum solution presented before, and requiring that $B_{int}(r = R) = B_{ext}(r = R)$. Finally, the compactness of the object is computed by $C = G_N M/R$.

Our main numerical results are summarized in the figures below. At this point it should be mentioned that the 3 observed super-massive pulsars J1614-2230 ($(1.928 \pm 0.017)\ M_\odot$),[82,83] J0348+0432 ($(2.01 \pm 0.04)\ M_\odot$)[84] and J0740+6620 ($(2.14^{+0.20}_{-0.18})\ M_\odot$),[85] with masses $M \sim 2M_\odot$ have put stringent constraints on compact object modelling, since any EoS that does not cross the 2 solar mass strip must be ruled out. Furthermore, the recent observation of the highly massive pulsar in the binary J2215 + 5135 ($(2.27^{+0.17}_{-0.15})\ M_\odot$)[86] has put an even more tight constraint to be satisfied. However, our results will also depend on the assumed EoS, as the predicted mass-to-radius profiles are affected. For that reason, our goal is not to show that the models discussed here are able to pass all current tests, but just to study the general features of quark stars in the framework of Hořava gravity and Einstein-æther theory, and the impact of the modifications that they induce on the resulting mass-radius relationships. Moreover, the reader should also keep in mind that electrically charged stars or compact objects with anisotropic matter can have higher masses compared to their isotropic neutral counterparts, see e.g. Refs. 87, 88 and references therein.

In Fig. 1 we show the mass-to-radius (M_R) relations (left panel) and the compactness (right panel) of the quark stars with a linear EoS. Similarly, Fig. 2 shows the same properties of the stars with a non-linear EoS. We see that the M_R profiles are shifted downwards as the parameter ν increases. Therefore, if the highest star mass that a given EoS can support is lower than the 2 solar mass limit in GR, it will become even worse in Hořava gravity and Einstein-æther theory.

The speed of sound, defined by $c_s^2 \equiv dp/d\rho$, is shown in Fig. 3 for the models CFL4 and CFL10, while when the EoS is linear the sound speed is just a constant, $c_s^2 = k$. We have considered the cases where $\nu = 0.01, 0.02$, while for GR the speed of sound for the 19 CFL viable models can be seen in Fig. 2 (panel (b)) of Ref. 81. Clearly, throughout the object the speed of sound takes values in the range $0 < c_s^2 < 1$, as it should, and therefore causality is not violated. It should be stated that for each model the 2 curves corresponding to a different value of the parameter ν are indistinguishable.

The solutions obtained here should be able to describe realistic astrophysical configurations. Therefore, as a final check we investigate i) stability criteria, and ii) if the energy conditions are fulfilled or not. For the latter, we require that[89–93]

$$\rho \geq 0\,, \tag{36}$$

$$\rho - p \geq 0\,, \tag{37}$$

$$\rho - 3p \geq 0\,. \tag{38}$$

In Fig. 4 we show the normalized pressure, $\bar{p} \equiv p/B_0$, $3\bar{p}$, and normalized energy density, $\bar{\rho} \equiv \rho/B_0$ (from bottom to top) versus the normalized radial coordinate r/R for $\nu = 0.01, 0.02$ and $p_c(0) = 1.5\ B_0$ for the models CFL4 and CFL10. Notice that the lower curves corresponding to $\bar{p}$ and $3\bar{p}$ are indistinguishable for all four

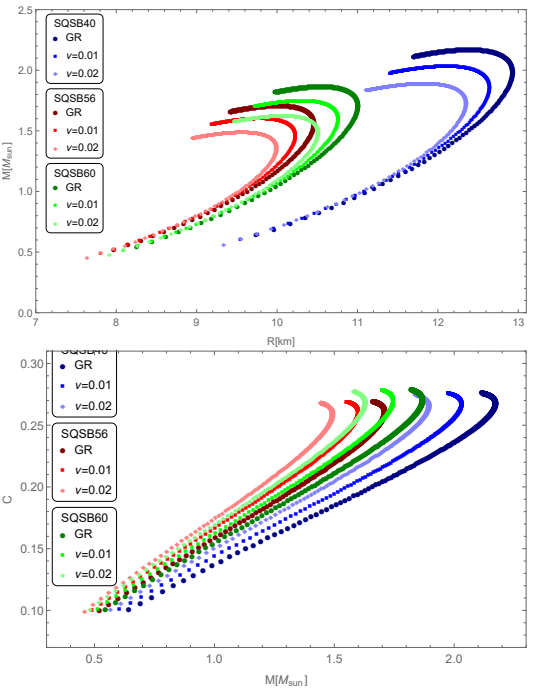

Fig. 1. Properties of strange quark stars with linear EoS. We have considered 3 MIT bag models, SQSB40 (in black), SQSB56 (in blue) and SQSB60 (in red) (see text) and $\nu = 0.01, 0.02$. The curves corresponding to GR ($\nu = 0$) are also shown for comparison reasons. **TOP:** M_R profiles (mass in solar masses and radius in km). **BOTTOM:** Compactness $C = G_N M/R$ vs mass (in solar masses).

cases, while the upper curves corresponding to the normalized energy density are clearly different for the two models. However, within each model the two curves corresponding to the two values of ν cannot be told apart. Regarding the models with a linear EoS we have obtained qualitatively very similar curves, which we do not show here. Clearly, all energy conditions are fulfilled throughout the star, and therefore we conclude that the solutions obtained here are realistic one, capable of describing realistic astrophysical configurations.

Regarding stability criteria, Bondi[94] suggested that for a stable Newtonian sphere the adiabatic index defined by

$$\Gamma \equiv c_s^2 \left[1 + \frac{\rho}{p}\right] \tag{39}$$

should be larger than 4/3. Moreover, the Harrison-Zeldovich-Novikov criterion requires that[95,96]

$$\frac{dM}{d\rho_c} > 0 \tag{40}$$

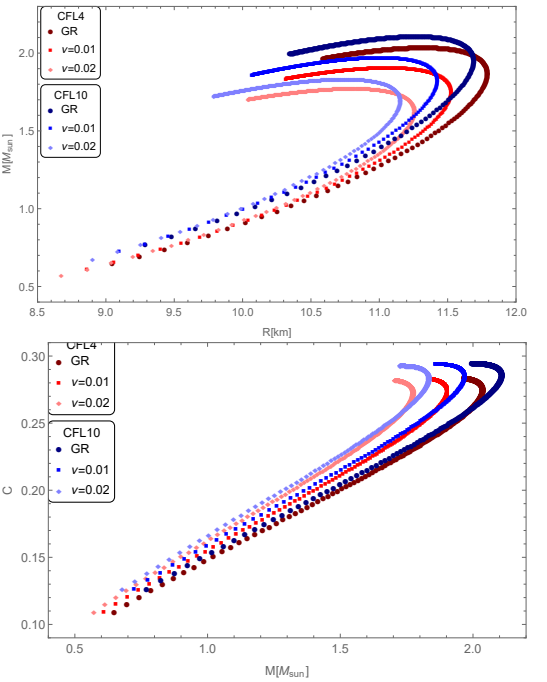

Fig. 2. Properties of strange quark stars with a non-linear EoS. We have considered 2 CFL models, CFL4 (in blue) and CFL10 (in black) (see text) and $\nu = 0.01, 0.02$. The curves corresponding to GR ($\nu = 0$) are also shown for comparison reasons. **TOP:** M_R profiles (mass in solar masses and radius in km). **BOTTOM:** Compactness $C = G_N M/R$ vs mass (in solar masses).

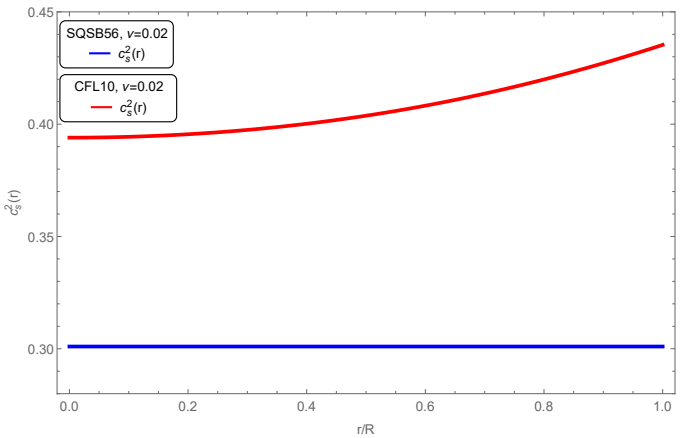

Fig. 3. Speed of sound, $c_s^2 = dp/d\rho$, vs normalized radial coordinate r/R for $\nu = 0.01, 0.02$ and for 2 color flavor locked states, CFL4 model (lower curves) and CFL10 model (upper curves) and for $\nu = 0.01, 0.02$.

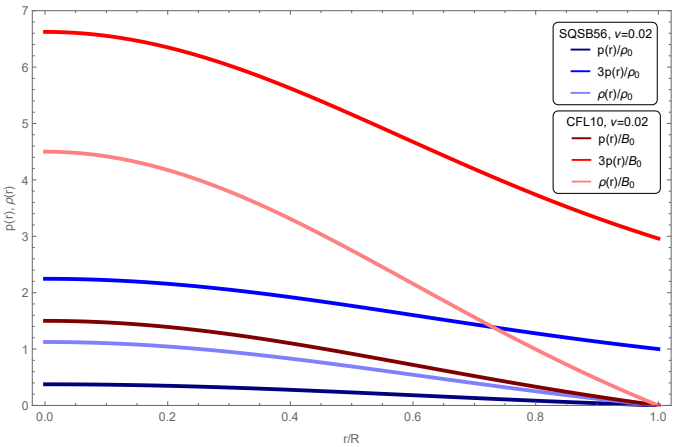

Fig. 4. Normalized pressure $\bar{p} \equiv p/B_0$, $3\bar{p}$ and energy density $\bar{\rho} \equiv \rho/B_0$ vs normalized radial coordinate r/R for $p_c = 1.5\ B_0$, $\nu = 0.01, 0.02$ and for 2 color flavor locked states, CFL4 model and CFL10 model. Shown are from bottom to top: i) Pressure (blue), ii) 3 times pressure (green), and iii) energy density (orange) for CFL 4 (upper) and for CFL10 (lower).

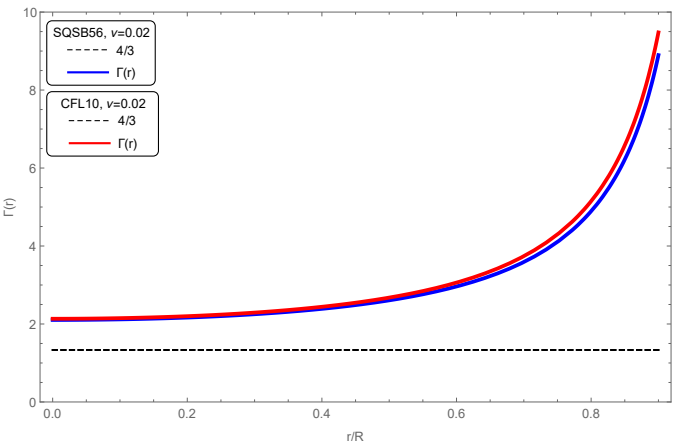

Fig. 5. Adiabatic index Γ vs normalized radial coordinate r/R for the model SQSB56 (linear EoS) and $\nu = 0.02$. The dashed horizontal line represents the Newtonian bound corresponding to $4/3$.

Fig. 5 shows that $\Gamma > 4/3$, as it should be. In Fig. 5 we have shown the adiabatic index only for one particular case, but we have checked that we have obtained almost identical figures for all the cases considered in the present work.

5. Conclusions

In summary, we have investigated in detail the properties of non-rotating, isotropic strange quark stars in Lorentz-violating theories of gravity. To be more precise, we have studied quark stars both in Hořava gravity and Einstein-æther theory, where a single dimensionless parameter ν measures the deviations from GR. As far as the EoS for the matter content is concerned, we adopted analytic functions, both linear and non-linear. The former corresponds to simple versions of the MIT bag model, while the latter corresponds to the CFL phase, where color superconductivity effects become important at very high densities. We numerically integrated the generalized structure equations, and we computed the factor of compactness, the radii and the masses of the objects upon matching the interior and the exterior solutions at the surface of the stars. We have presented graphically the mass-to-radius profiles for several different EoSs as well as for two distinct values of the parameter ν. The case $\nu = 0$ corresponding to GR is shown as well for comparison reasons. Our results show that the $M - R$ relationships are shifted downwards as ν increases, which implies a lower highest mass supported by a given EoS in comparison with the one obtained in GR for the same EoS. Finally, we have checked that causality is not violated, stability criteria are met, and energy conditions are fulfilled. Therefore we conclude that within the framework of the gravitational theories considered here, we have obtained well behaved solutions capable of describing realistic astrophysical configurations.

Acknowledgements

I wish to thank professor A. Wang for inviting me to MG-16, and the organizers for an excellent organization. I thank my colleagues I. Lopes and D. Vernieri for a fruitful collaboration. The work was financially supported by the Fundação para a Ciência e Tecnologia (FCT), Portugal, through the Project No. UIDB/FIS/00099/2020 and grant No. PTDC/FIS-AST/28920/2017.

The M87* black hole shadow observation by the Event Horizon Telescope (EHT) has enabled us to test the modified gravity theories in the extreme-field regime and estimating the black hole parameters. Having this assertion, we investigate the Kerr-like rotating black holes in 4*D* Einstein-Gauss-Bonnet (EGB) gravity and deduce their shadows. Considering the inclination angle $\theta_0 = 17^o$, we show that the EGB black hole shadows are smaller and more distorted than for the Kerr black holes. Modelling the M87* black hole as the EGB black hole, we predict the shadow angular size $35.7888\mu as \leq \theta_d \leq 39.6192\mu as$. The M87* black hole shadow angular size $\theta_d = 42\pm3\mu as$, within the 1σ region, constrains the GB coupling parameter and the black hole spin parameter. Interestingly, the circularity deviation of the EGB black hole shadows is smaller than the bounded deduced for the M87* black hole.

Keywords: EGB gravity, Shadows, Astrophysical black holes, Parameter Estimation, EHT, M87* black hole shadow

1. Introduction

The uniqueness of the Einstein tensor to describe gravity in the four-dimensional ($4D$) spacetime is dictated by the Lovelock theorem.[1] However, if one or more conditions in the Lovelock theorem are relaxed, then modifications to the Einstein-Hilbert action exist that lead to covariant, conserved, and second-order field equations and propagate only gravitational degrees of freedom and thus are free from the ghost instabilities. One such Lagrangian-based theory of gravity is Einstein-Gauss-Bonnet (EGB) gravity that exists in the $D \geq 5$ and is motivated by the heterotic string theory.[2,3] EGB gravity supplements the Einstein-Hilbert action with quadratic corrections terms constructed from the curvature tensors invariants and reads as follows

$$\mathcal{I}_{\rm EGB} = \frac{1}{16\pi G_D}\int d^Dx\,\sqrt{-g}(\mathcal{L}_{\rm EH} + \alpha\,\mathcal{L}_{\rm GB}), \tag{1}$$

with

$$\mathcal{L}_{\rm EH} = R, \quad \mathcal{L}_{\rm GB} = R^{\mu\nu\rho\sigma}R_{\mu\nu\rho\sigma} - 4R^{\mu\nu}R_{\mu\nu} + R^2. \tag{2}$$

Here, α is identified as the GB coupling constant and is related to the inverse string tension, making it positive-definite. The GB Lagrangian is a unique quadratic combination of the Riemann tensor that naturally emerges as a leading-order correction term in low-energy effective actions of heterotic string theory and $10D$ gauged supergravity. Boulware and Deser, in their seminal paper,[4] obtained the first spherically symmetric and static black hole solution for the EGB theory, afterward several intriguing black hole solutions are obtained.[5–7] It is worth mentioning that for $D < 5$ GB Lagrangian $\mathcal{L}_{\rm GB}$ turns into a total derivative, and thereby its contribution to the gravitational dynamics vanishes, rendering the theory indistinguishable from general relativity. However, in the presence of an additional non-minimally coupled scalar field dilaton with the canonical kinetic term, $\mathcal{L}_{\rm GB}$ leads to the non-trivial gravitational dynamics[8–11] and the resulting theory is Horndeski or Galilean.

Ever since the formulation of the EGB gravity theory, its $4D$ regularization has been a topic of great interest. In this line of research, Tomozawa[12] showed for the first time that the quantum corrections to gravity in a conformally flat metric in $4D$ appears as GB quadratic curvature forms, and the $4D$ black hole solution shows repulsive nature at $r \to 0$. In another attempt of regularization procedure, Cognolo *et al.*[13] used an "entropic" dimensional reduction of EGB gravity to $D \to 4$ within the classical Lagrangian formulation. Lately, the interest in the $4D$ EGB gravity theory is re-surged due to the regularization approach proposed by Glavan and Lin;[14] the GB coupling is re-scaled as $\alpha \to \alpha/(D-4)$ and the $4D$ EGB theory was obtained as the limit $D \to 4$ at the level of field equations. The aim for introducing this re-scaling is to generate a divergence that exactly cancels the vanishing contribution that the GB term makes to the field equations in $4D$. The extension to higher-order Lovelock gravity is presented in Refs.[15,16] Likewise, EGB theory is obtained in lower dimensions.[17,18] Interestingly, the Glavan and Lin's static and spherically symmetric black hole solution[14] matched with that obtained using the quantum correction by Tomozawa,[12] and Cognolo *et al.*[13]

However, Glavan and Lin's claim[14] that the resulting theory is of pure graviton was later proven to be spurious on several grounds. The covariant approach proposed in Ref.[14] is largely speculated to be valid only for specific higher-dimensional spacetimes with high degrees of symmetries, particularly maximally symmetric or spherically symmetric spacetimes. Recently, some studies have called into question the Glavan and Lin[14] regularization procedure for the less-symmetric spacetimes and also reported several other inconsistencies Refs.[17,19–22] Following that, the GB contribution arising in higher dimensions could be renormalized in such a way as to yield a non-trivial contribution also in $4D$, even without re-scaling the GB coupling.[16–18,23–26] Hennigar *et al.*[17] proposed another well defined $D \to 4$ limit of EGB gravity generalizing the previous work of Mann and Ross[27] in establishing the $D \to 2$ limit of general relativity and this regularization is applicable not only in $4D$ but also to $D < 4$. These alternate regularization procedures of EGB theory, leading to a divergence-free $4D$ action, describe the scalar-tensor theory of

gravity of the Horndeski type. These scalar-tensor models propagate the supplementary scalar mode in addition to the gravitational degree of freedom. Thus these alternate regularized theories are in line with Lovelock's theorem, as they introduce another dynamical field. Nevertheless, the spherically symmetric $4D$ black hole solution obtained in Ref.[14] remains valid for these regularised scalar-tensor theories.[16–18,23,28] This means that $4D$ EGB gravity can be viewed as both a dimensionally reduced theory and as a gravitational theory that displays known quantum corrections. As a result, both the Glavan and Lin theory[14] and scalar-tensor regularizations have received remarkable attention and more then 100 papers have been reported on $4D$ EGB gravity and its various solutions including their charged extension,[29,30] rotating counterparts,[31,32] Vaidya-like radiating black holes,[33,34] regular black holes.[35,36] The gravitational lensing of $4D$ EGB black holes have also been studied.[37–40]

The black hole shadow observations by the Event Horizon Telescope (EHT) Collaboration have unprecedentedly opened up an exciting arena to make a precision test of the gravitational theory in the strong and relativistic field regimes (in the vicinity of the unstable bound orbits around black holes).[41,42] The EHT analysis suggested that, based on *a priori* known estimates for the mass and distance from stellar dynamics, the M87* shadow size is consistent within 17% for a 68% confidence interval of the size predicted from the Kerr black hole general-relativistic-magneto-hydrodynamics (GRMHD) image.[43] However, several other studies altogether have not entirely precluded the possibility of non-Kerr black holes.[44–46] Using the M87* shadow angular size, constraints are placed on the second post-Newtonian metric coefficients, which were inaccessible in the earlier weak-field tests at the Solar-scale.[43] Therefore, it is both legitimate and timely to test the viability of the $4D$ EGB gravity theory using the M87* black hole shadow observations. This paper aims to present the detailed study of the rotating $4D$ EGB black hole shadow, parameter estimation of the black hole using the shadow observables, and constraining them using the M87* black hole shadow observed by the Event Horizon Telescope (EHT).

2. Rotating $4D$ EGB black hole shadows

Finding an exact analytic and rotating axially symmetric black hole solution of the EGB gravity is a notorious task due to the non-linearity involved in the field equations. However, there exists the rotating solution generating mechanisms such as the Newman-Janis algorithm[47] and the gravitational-decoupling method,[48] which have been widely used to construct rotating black hole solutions from their non-rotating counterparts. The Azreg-Aïnou's non-complexification procedure[49,50] for the modified Newman-Janis algorithm generates a unique imperfect fluid rotating solution from the seed spherically symmetric static solution. It has been applied to generate rotating solutions in several modified gravity theories.[32,51–56] The rotating

$4D$ EGB black hole metric, in Boyer-Lindquist coordinates, reads[31,32]

$$ds^2 = -\frac{\Delta}{\Sigma}\left(dt - a\sin^2\theta\, d\phi\right)^2 + \frac{\Sigma}{\Delta}dr^2 + \Sigma\, d\theta^2 + \frac{\sin^2\theta}{\Sigma}\left((r^2+a^2)\, d\phi - a\, dt\right)^2 \tag{3}$$

with

$$\Delta = r^2 + a^2 + \frac{r^4}{32\pi\alpha}\left[1 - \sqrt{1 + \frac{128\pi\alpha M}{r^3}}\right], \quad \Sigma = r^2 + a^2\cos^2\theta. \tag{4}$$

Thus rotating $4D$ EGB black holes are characterized by three parameters, mass (M), spin (a), and GB coupling parameter α, which also gives potential deviation from the Kerr solution. In the limit $\alpha \to 0$ or large r, the metric Eq. (3) smoothly recovers the Kerr black hole.[57] Because the static black hole solution of Ref.[14] is identical to that of regularized scalar-tensor theories and other quantum-corrected theories of gravity,[12–17,58,59] the rotating black hole metric (3) also corresponds to these theories. The rotating black hole admits up to two distinct horizons whose radii $r_- \leq r_+$ can be identified as real positive roots of the $\Delta = 0$. The variation of both horizon radii with GB coupling is shown in Fig. 1, it is evident that the event horizon radius decreases and Cauchy horizon radius increase with α. For a given value of spin a, there exists a extremal value of GB coupling $\alpha = \alpha_E$ for which degenerate horizons $r_- = r_+$ exists, such that for $\alpha > \alpha_E$ horizons disappear and the central singularity becomes globally naked. Similarly, for a given value of α, one can find the extremal value of spin $a = a_E$ which leads to degenerate horizons $r_- = r_+$. In this paper, we will only consider the black hole case viz., $\alpha \leq \alpha_E$.

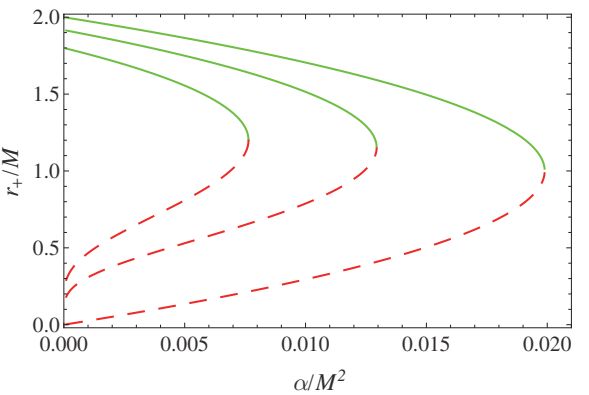

Fig. 1. Event horizon (solid green) and Cauchy horizon (dashed red) radii variation with α for different values of $a = 0, 0.40M, 0.60M$ (from outside to inside).

The optical appearance of the black hole in the presence of a bright background or the illuminated matter accretion flow is known as the shadow. The light from

the source gets strongly lensed by the black hole in the vicinity of the horizon and receive by a faraway observer on the opposite side of the source. Synge,[60] and Luminet[61] led the study of black hole shadow and calculated the capturing angle of the Schwarzschild black hole. For the first time, the shadow of the Kerr black hole was reported by Bardeen[62] in his pioneering work in 1973. The rotating EGB metric (3) belongs to Petrov type-D spacetimes, and thus the geodesics equations are completely integrable. The metric (3) carries two Killing vectors ∂_t and ∂_ϕ, associated with the time translational and rotational invariance of the spacetime geometry. The components of photon four-momentum p^μ projected along these Killing vectors are constant of motion, which in this case can be identified as the energy E and axial angular momentum magnitude L_z. We follow the Hamilton-Jacobi formalism to determine the null geodesics equations of motion around the rotating black hole, which read as follows[32,63]

$$\Sigma\frac{dt}{d\tau} = \frac{r^2+a^2}{\Delta}\left(E(r^2+a^2) - aL_z\right) - a(aE\sin^2\theta - L_z), \tag{5}$$

$$\Sigma\frac{dr}{d\tau} = \pm\sqrt{\mathcal{R}(r)}, \tag{6}$$

$$\Sigma\frac{d\theta}{d\tau} = \pm\sqrt{\Theta(\theta)}, \tag{7}$$

$$\Sigma\frac{d\phi}{d\tau} = \frac{a}{\Delta}\left(E(r^2+a^2) - aL_z\right) - \left(aE - \frac{L_z}{\sin^2\theta}\right), \tag{8}$$

where τ is the affine parameter along the null geodesics and

$$\mathcal{R}(r) = \left((r^2+a^2)E - aL_z\right)^2 - \Delta((aE-L_z)^2 + K), \tag{9}$$

$$\Theta(\theta) = K - \left(\frac{{L_z}^2}{\sin^2\theta} - a^2E^2\right)\cos^2\theta. \tag{10}$$

The constant K is the separability constant related to the Carter constant $\mathcal{Q}$ through $\mathcal{Q} = K + (aE - L_z)^2$. Carter constant appears as a conserved quantity associated with the hidden symmetry described by the second-rank Killing tensor. We introduce the impact parameters for the photons geodesics, which are constant along geodesics and defined in dimensionless form as follows[63]

$$\xi = \frac{L_z}{E} \ , \ \eta = \frac{K}{E^2}. \tag{11}$$

Photons may get scattered, captured, or follow bound orbits around the black hole depending on the values of (xi, eta). Because of the black hole rotation, photons can either co-rotate or counter-rotate along with the black hole, whose radii vary differently with black hole spin. At $\theta = \pi/2$, Carter's constant vanishes, and the photons follow the circular orbits with radii $r_p^\pm$, which can be determined by solving $Y = 0$. Whereas for $\theta \neq \pi/2$ the Carter constant is positive definite and the photons follow the non-planar orbits with radii $r_p^- < r_p < r_p^+$. The photons following the spherical orbits of constant coordinate radii r_p around the black hole are characterized by $\dot{r} = 0$ and $\ddot{r} = 0$. This results into the critical values of impact parameters

$(\xi_{crit}, \eta_{crit})$ for the unstable orbits[32]

$$\xi_{crit} = \frac{\left(a^2 + r^2\right)\Delta'(r) - 4r\Delta(r)}{a\Delta'(r)},$$
$$\eta_{crit} = \frac{r^2\left(8\Delta(r)\left(2a^2 + r\Delta'(r)\right) - r^2\Delta'(r)^2 - 16\Delta(r)^2\right)}{a^2\Delta'(r)^2}, \tag{12}$$

where $'$ stands for the derivative with the radial coordinate r. Furthermore, these spherical photons orbits are the non-planar orbits that periodically cross the equatorial plane and construct a photon region around the black hole. As a result, the photons following the spherical orbits, beside having a motion along the ϕ direction also move along the θ-direction. For visualizing the black hole shadow, we consider a distant observer at position (r_0, θ_0). The coordinates (X, Y) define the observer image plane, such that the stereographic projection of the shadow from the celestial sphere to the image plane is defined as follow

$$X = \lim_{r_0 \to \infty}\left(-r_0^2 \sin\theta_0 \frac{d\phi}{dr}\right),$$
$$Y = \lim_{r_0 \to \infty}\left(r_0^2 \frac{d\theta}{dr}\right). \tag{13}$$

For an asymptotically far observer, Eq. (13) leads to

$$X = -\xi_{crit}\csc\theta_0,$$
$$Y = \pm\sqrt{\eta_{crit} + a^2\cos^2\theta_0 - \xi_{crit}^2\cot^2\theta_0}\,. \tag{14}$$

and satisfy

$$X^2 + Y^2 = \eta_{crit} + \xi_{crit}^2 + a^2\cos^2\theta_0. \tag{15}$$

The parametric curve Y vs X delineates the shadow's boundary of the rotating EGB black hole. It is clear that the non-rotating black hole ($a = 0$) cast a perfectly circular shadow silhouette. For $\theta_0 \neq 0$ or π the rotating black hole shadow shifts in the direction perpendicular to the black hole rotation and appears distorted, whereas for $\theta_0 = 0, \pi$ shadows is centered at $(0, 0)$ and is perfectly circular for all values of a. The maximum off-center displacement of shadow appears for $\theta_0 = \pi/2$.

In April 2019, the EHT collaboration using the VLBI technology unveiled the first-ever horizon-scaled image of the supermassive black hole M87*.[41,42] The M87* image shows powerful relativistic jets, which could be emerged from magnetohydrodynamic interactions between the accretion disk and the rotating black hole. Considering the orientation of these jets in M87*, the inclination angle (angle between the rotational axis and the line of sight) is estimated to be 17^o.[64] Hereafter, for our analysis of EGB black hole shadows, we will consider the inclination angle $\theta_0 = 17^o$. The rotating EGB black holes shadows with varying a and α are depicted in Fig. 2. It is evident that the shadow size decreases with increasing α, such that

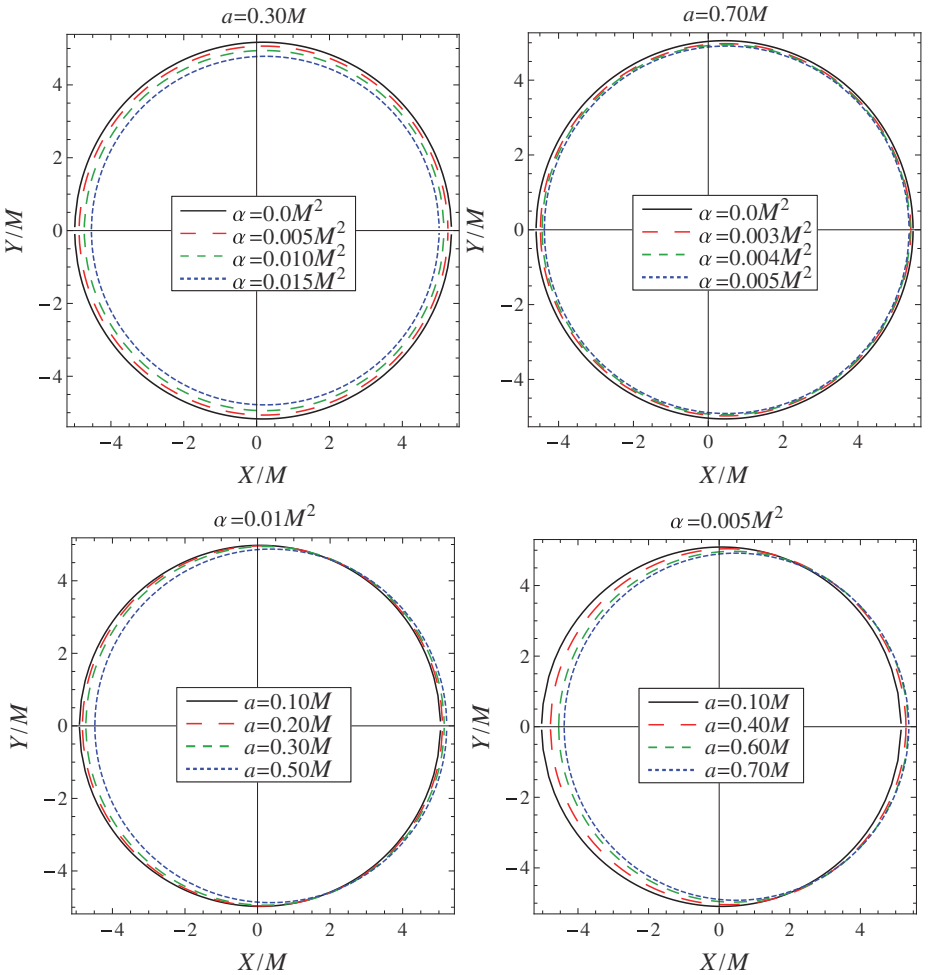

Fig. 2. Plot showing the rotating EGB black holes shadows with varying parameters a and α. Solid black curves in the upper panel are for the Kerr black holes.

the rotating EGB black hole shadows are smaller than the Kerr black hole shadows. Furthermore, the rotating black holes shadows are not perfectly circular. To characterize the shadow size and the deviation from the circularity, we introduce the shadow observables, namely, shadow area A and oblateness D as follows[65,66]

$$A = 2\int Y dX = 2\int_{r_p^-}^{r_p^+} \left(Y\frac{dX}{dr_p}\right) dr_p, \tag{16}$$

$$D = \frac{X_r - X_l}{Y_t - Y_b}, \tag{17}$$

where the points on the right, left, top, and bottom of the shadow boundary are designated by subscripts r, l, t and b. The shadow boundary, defined by (X, Y), is a function of spherical photon orbits radii r_p. Interestingly, photons with different orbit radii construct the different parts of the shadow boundary. Therefore, as one moves along the Y-axis in the shadow image, one sees deeper or far away from the black hole. The behavior of the shadow observables A and D with varying a and α is shown in Fig. 3. The shadow area monotonically decreases with α and a, and the oblateness increases with increasing a. To estimate the rotating EGB black hole parameters, we make a contour plot of observables A and D as functions of a and α in Fig. 4. Therein each solid red curve corresponds to constant values of A and dashed blue curve to D. The intersection point of observables A and D determines the unique and precise values of the black hole parameters a and α. Hence, from Fig. 4, it is clear that for a given set of $4D$ EGB black hole shadow observables, A and D, we can determine information about black hole spin and GB coupling parameter.

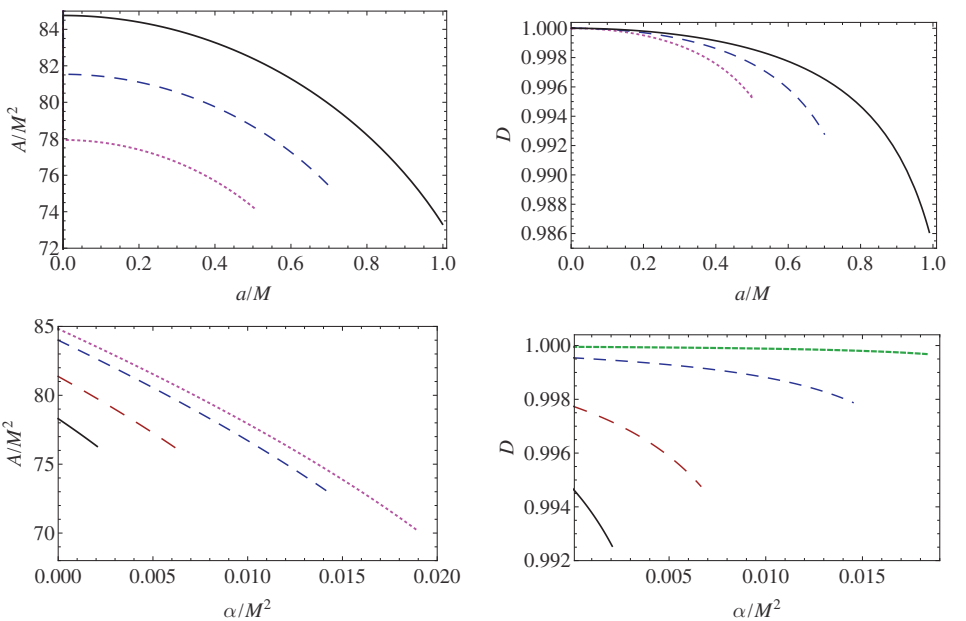

Fig. 3. *Upper*: The observables A and D vs a for $\alpha = 0.0M^2$ (solid black curve), for $\alpha = 0.005M^2$ (dashed blue curve), and for $\alpha = 0.01M^2$ (dotted magenta curve). *Bottom*: The observables A and D vs α for $a = 0.0M$ (dotted magenta curve), for $a = 0.1M$ (dotted green curve), for $a = 0.3M$ (dashed blue curve), for $a = 0.6M$ (long-dashed brown curve), and for $a = 0.8M$ (solid black curve).

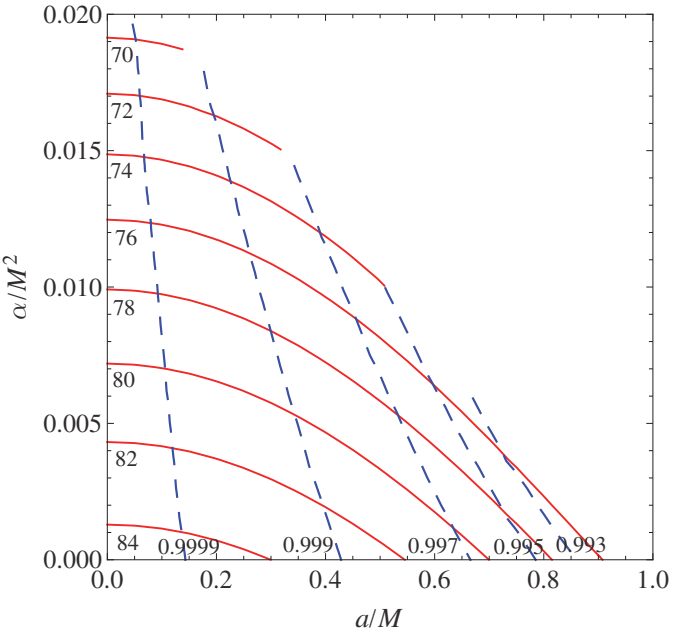

Fig. 4. Contour plots of the observables A and D in the plane (a, α) for the rotating EGB black holes. Each curve is labeled with the corresponding values of A and D. Solid red curves correspond to the A, and dashed blue curves are for the oblateness parameter D.

3. Constraints from the M87* shadow

Although the M87* black hole shadow is found to be consistent with the Kerr black hole image as predicted in the general relativity, the non-Kerr black holes are also not ruled out. Very recently, the EHT collaboration team has set stringent constraints on the physical charges of a large variety of modified gravity black holes by using the M87* shadow.[67] The M87* shadow is of crescent shape with the circularity deviation $\Delta C \leq 0.10$ (10%) in terms of root-mean-square deviation from average shadow radius, axis ratio $\lesssim 4/3$, whereas the angular diameter θ_d is $42 \pm 3\mu as$.[41,42] Here, we will model the M87* black hole as the rotating $4D$ EGB black hole and use the M87* shadow observables to place constraints on the black hole parameters.

For this, we define the shadow boundary with polar coordinates $(R(\varphi), \varphi)$ such that the origin is at the shadow center (X_O, Y_O). Figure (2) infers that the rotating black hole shadow is always $\mathcal{Z}_2$ symmetric around $Y = 0$. However, due to black hole rotation, the shadow center shifts from $X = 0$, and as a result, the shadow is asymmetric along the Y axis. It ascertains that the shadow center is $(X_O = |X_r + X_l|/2, Y_O = 0)$, where X_r and X_l are the maximum and minimum abscissas of

the shadow boundary in the image plane. The radial coordinate of shadow boundary from its center reads as

$$R(\varphi) = \sqrt{(X - X_O)^2 + (Y - Y_O)^2}, \quad \varphi \equiv \tan^{-1}\left(\frac{Y}{X - X_O}\right),$$

whereas shadow average radius $\bar{R}$ is defined as[68]

$$\bar{R}^2 = \frac{1}{2\pi}\int_0^{2\pi} R^2(\varphi) d\varphi. \tag{18}$$

We describe the circularity deviation ΔC to quantifies the shadow deviation from a perfect circle as a measure of the root-mean-square deviation of $R(\varphi)$ from the shadow average radius[68–70]

$$\Delta C = \frac{1}{\bar{R}}\sqrt{\frac{1}{2\pi}\int_0^{2\pi}\left(R(\varphi) - \bar{R}\right)^2 d\varphi}, \tag{19}$$

clearly, for a circular shadow of spherically symmetric black hole $\Delta C = 0$. Second observable is the shadow angular diameter θ_d, which for a far distant observer, at a distance r_0 from the black hole, is defined as

$$\theta_d = 2\frac{R_s}{r_0}, \quad R_s = \sqrt{A/\pi}, \tag{20}$$

and the third observable is the axis ratio

$$D_x = \frac{\Delta Y}{\Delta X}, \tag{21}$$

which is just the inverse of oblateness observable $D_x = 1/D$. We have calculated these three observable $\Delta C, \theta_d$, and D_x for the rotating $4D$ EGB black hole with $M = 6.5 \times 10^9 M_\odot$ and $r_0 = 16.8$ Mpc and plotted them in Fig. 5. The EHT bound for the M87* black hole shadow angular diameter $\theta_d = 39\,\mu$as within the 1σ region, shown as the black solid line, constrained the a and α. The shadow angular size for the non-rotating extremal EGB black hole with $a = 0, \alpha = 0.019894367M^2$ is $\theta_d = 35.7888\mu$as and for extremal Kerr black hole with $a = M, \alpha = 0$ is $\theta_d = 36.8632\mu$as. For comparison, at the inclination angle $\theta_o = 90^o$, the extremal Kerr black hole shadow angular size is 37.3534μas. The relative difference in shadow angular diameter $\delta\theta_d \equiv (\theta_d|_{Kerr} - \theta_d|_{EGB})/\theta_d|_{Kerr}$ is shown in Fig. 6. Clearly, $\delta\theta_d \leq 17\%$ and thus it is consistent with the Psaltis *et al.*[43] findings. Furthermore, the axis ratio and the circularity deviation for the M87* black hole shadow allow all parameter space of the EGB black hole.

4. Conclusions

The underlying theory of gravity in the extreme-field regime is currently unknown, and insights into it are likely to be gained through observations. In this paper, we have investigated the rotating $4D$ EGB black hole. The EGB gravity theory has been of great interest and importance due to second-order field equations and being

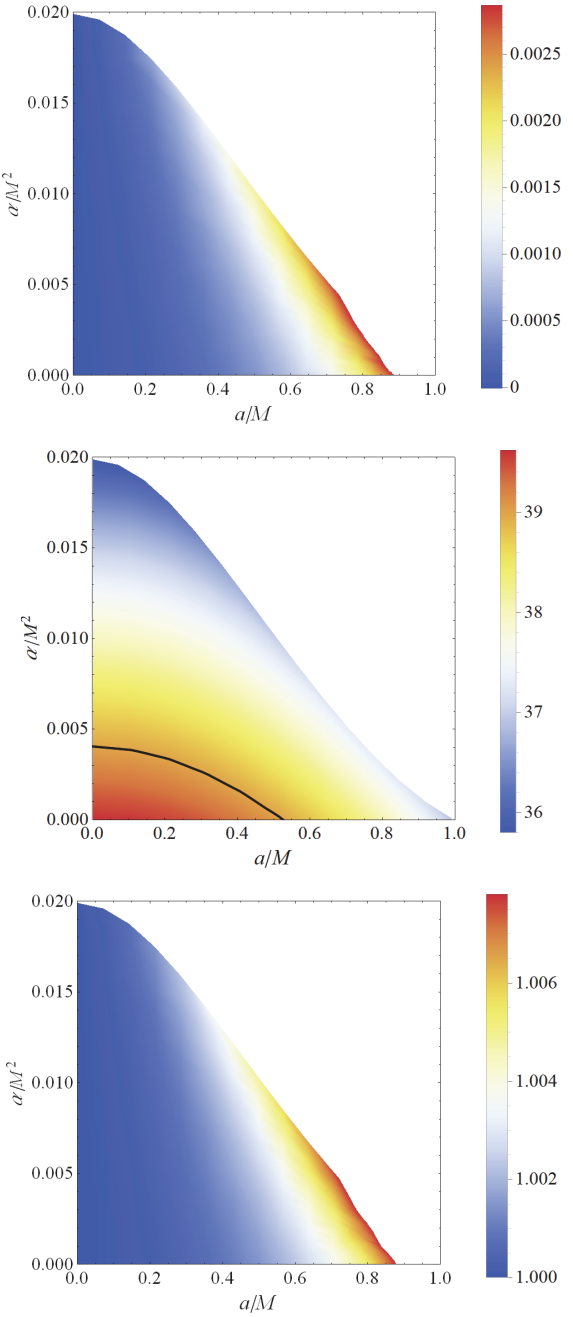

Fig. 5. Circularity deviation observable ΔC (*top*), the angular diameter θ_d (*middle*), and axis ratio D_x (*bottom*) as a function of (a, α) for the rotating EGB black holes. Black solid lines correspond to the M87* black hole shadow bounds $\theta_d = 39\mu$as within the 1σ region, such that the region above the black line is excluded by the EHT bounds.

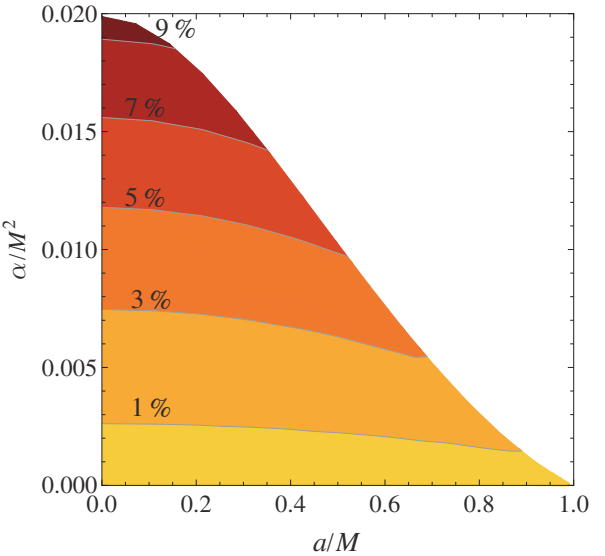

Fig. 6. Relative difference between the shadow angular diameter size of a rotating EGB black hole and a Kerr black hole with the same mass.

free from ghost instabilities. The rotating black holes possess two distinct horizons that eventually merge to form the degenerate horizon for the extremal values of the GB coupling parameter $\alpha = \alpha_E$. The null geodesics equations of motion were obtained in the first-order differential form, and the analytical expressions of the critical impact parameters for unstable spherical photon orbits are derived. The shadow contours are drawn for the rotating black hole for $\theta_0 = 17^o$ inclination angle and compared with those for the Kerr black hole. The rotating black hole shadows deviate from the circularity. The shadow observables A and D are calculated, and it is shown that the EGB black hole shadows are smaller and more distorted than those for the Kerr black hole. Furthermore, these observables are used to estimate the black hole parameters. We modeled the M87* black hole as the rotating $4D$ EGB black hole and used the deduced shadow observables ΔC, θ_d, and D_x for the M87* to constrain the EGB black hole parameters. We have found that only θ_d within 1σ region placed stringent bound the EGB parameters. Whereas ΔC and D_x allows all parameter space. The constraints deduced for $\theta_0 = 17^o$ are weaker than those deduced for $\theta_0 = 90^o$ in Ref.[32] However, it is important to account for systematic uncertainty when identifying observable shadow characteristics like the emission ring and center brightness depression, especially when using low-resolution data, to gravitational qualities like the size and shape of the critical curve. Future observations utilizing an improved ground or space-based array might significantly reduce these systematic errors, and we anticipate better constraints on the GB coupling parameter.

A lattice regularization for the 2d projectable Horăva-Lifshitz (HL) quantum gravity is known to be the 2d causal dynamical triangulations (CDT), and the 2d CDT can be generalized so as to include all possible genus contributions non-perturbatively. We show that in the context of HL gravity, effects coming from such a non-perturbative sum over topologies can be successfully taken into account, if we quantize the 2d projectable HL gravity with a simple bi-local wormhole interaction. This conference paper is based on the article, Phys. Lett. B **816** (2021), 136205.[1]

Keywords: Wormholes; Low dimensional quantum gravity; Canonical quantization

1. Introduction

Two-dimensional models of quantum gravity are useful for understanding some aspects of non-perturbative physics, since they can be examined beyond the framework of perturbation theory by analytic computations in many cases. One of such models is the two-dimensional causal dynamical triangulations (2d CDT),[2] which is a lattice toy model of quantum gravity with a global time foliation. Global hyperbolicity imposed at the quantum level do not allow for any topology change in the CDT model, and the continuum limit can be described by quantum mechanics of a 1d universe.[2]

Yet another toy model for quantum gravity that has a global time foliation is 2d Horăva-Lifshitz (HL) quantum gravity that was introduced first in higher dimensions to resolve the issue of perturbative renormalizability by breaking the diffeomorphisms down to the foliation-preserving diffeomorphisms,[3,4] and so the model has a preferred foliation structure. The projectable version of the 2d HL quantum

gravity was discussed in the articles,[5,6] and in particular it was shown that the canonical quantization of the model yields exactly the same quantum Hamiltonian as the one obtained by the continuum limit of 2d CDT.[5] Therefore, one can interpret 2d CDT as a lattice regularization for the 2d projectable HL quantum gravity.

Although the creation of baby universes and wormholes (handles) is not allowed to occur in the original setup of CDT, one can generalize the 2d model to include such configurations in a manner consistent with the scaling limit,[7] and such a generalized model can be fully described by a string field theory for CDT[8a]. Here the word "string" refers to the 1d spatial universe. Based on the string field theory, one can take into account all genera (handles) as well as all baby universes of the two-dimensional spacetime. In addition, as long as one only asks for the amplitude between the states describing connected spatial universes separated a proper time t, this sum over topologies and baby universes can effectively be described by a one-body Hamiltonian.[11,12]

Having the equivalence between the continuum limit of 2d CDT and the 2d projectable HL quantum gravity, we discussed in the article[1] what kind of effective interaction should be added to the classical Lagrangian of the 2d projectable HL gravity when canonically quantized, in order to obtain the above mentioned one-body quantum Hamiltonian that includes all wormholes and baby universes obtained in 2d CDT. The answer is that it is enough to include a simple bi-local and spatial wormhole interaction that is compatible with the foliation-preserving diffeomorphisms.

This article is organized as follows. In Section 2, we give a brief introduction to 2d CDT and 2d HL quantum gravity, and explain the relation between the two. In Section 3 the string field theory for CDT is described and we introduce the one-body quantum Hamiltonian that includes all possible topologies. In Section 4, we introduce a simple wormhole interaction to the 2d projectable HL gravity and show that one can precisely recover the one-body Hamiltonian when canonically quantizing the model. Section 5 is devoted to discussions.

2. CDT and Horăva-Lifshitz gravity in two dimensions

In this Section, we review causal dynamical triangulations (CDT) and Horăva-Lifshitz gravity (HL) in two dimension, and explain the relation between the two.

2.1. 2*d CDT*

The starting point is a globally hyperbolic manifold equipped with a global time foliation:

$$\mathcal{M} = \bigcup_{t\in\mathbb{R}} \Sigma_t \ , \tag{1}$$

[a]The time-independent amplitudes can be also computed by the matrix model for CDT[9] and by the new scaling limit of the Hermitian one-matrix model.[10]

where each leaf Σ_t is a Cauchy "surface". 2d CDT is a model which quantizes 2d geometries with such a proper-time foliation. The geometries in the path integral are regularized by piecewise linear geometries constructed by gluing together special kinds of triangles.[2] Each triangle consists of one space-like edge and two time-like edges such that a square of the space-like edge is positive, $a_s^2 = \varepsilon^2$, while it is negative for the time-like edge, $a_t^2 = -\alpha\varepsilon^2$ with positive α.

If we prohibit a creation of baby universes, a reasonable choice of the action is the cosmological constant term that is regularized as follows:

$$\begin{aligned} S[g_{ij}] &= -\lambda_0 \int d^2x \, \sqrt{-\det(g_{ij})} \ , \\ \rightarrow \quad S_R[T;\alpha] &= -\frac{\mu}{\varepsilon^2} \times \left(\frac{\sqrt{4\alpha+1}}{4} \varepsilon^2 \times n(T) \right) \ , \end{aligned} \tag{2}$$

where the bare cosmological constant λ_0 is replaced by the dimensionless cosmological constant μ, and the quantity in the parentheses is the discretized area of the triangulation T, i.e. the area of each triangle times the number of triangles $n(T)$. The lattice action S_R in eq. (2) is called the Regge action.[13]

For computational convenience we implement a rotation to the Euclidean signature which can be done by replacing α with $-\alpha$:

$$iS_R[T;\alpha] \rightarrow -S_R^{(e)}[-\alpha;T] = -\mu \frac{\sqrt{4\alpha-1}}{4} n(T) =: -\mu\, n(T) \ , \tag{3}$$

where we have absorbed a numerical factor into the dimensionless cosmological constant. Note that this map is a bijection between individual Lorentzian and Euclidean geometries.

In CDT, the integration over diffeomorphism equivalent classes of metric g keeping both initial and final geometries fixed can be regularized by the sum over "all" triangulations. Therefore, the 2d Euclidean path-integral regularized by CDT is

$$G^{(0)}_{\text{lattice}}(l_1, l_2; \tau) = \sum_{T \in \mathcal{T}(l_1, l_2; \tau)} e^{-\mu n(T)} \ , \tag{4}$$

where $\mathcal{T}(l_1, l_2; \tau)$ is a set of triangulations such that the initial and final boundaries whose lengths are kept fixed to l_1 and l_2 are separated by τ Euclidean time steps.

One can compute the amplitude (4) analytically through the use of the generating function for the numbers $G^{(0)}_{\text{lattice}}(l_1, l_2; \tau)$.[2] As in the case of lattice QCD, tuning the UV relevant coupling constant μ/ε^2 to its critical value μ_c/ε^2 and taking $\varepsilon \rightarrow 0$ in a correlated manner, one can transmute the dimension of the lattice spacing to the renormalized coupling constant:

$$\lambda := \lim_{\substack{\varepsilon \rightarrow 0 \\ \mu \rightarrow \mu_c}} \frac{\mu - \mu_c}{\varepsilon^2} \ , \tag{5}$$

where λ is the renormalized cosmological constant. Introducing the renormalized quantities, boundary lengths and a proper time such that

$$\ell_1 := \varepsilon l_1 \ , \quad \ell_2 := \varepsilon l_2 \ , \quad t := \varepsilon \tau \ , \tag{6}$$

one can obtain the renormalized amplitude $G^{(0)}(\ell_1, \ell_2; t)$ that is known to satisfy the differential equation:[2,5]

$$-\frac{\partial}{\partial t} G^{(0)}(\ell_1, \ell_2; t) = H_a^{(0)}(\ell_1) G^{(0)}(\ell_1, \ell_2; t) \ , \tag{7}$$

where $H_a^{(0)}$ is the quantum Hamiltonian defined as

$$H_0^{(0)}(\ell) = -\frac{\partial}{\partial \ell} \ell \frac{\partial}{\partial \ell} + \lambda \ell \ , \quad H_{-1}^{(0)}(\ell) = -\ell \frac{\partial^2}{\partial \ell^2} + \lambda \ell \ , \quad H_{+1}^{(0)}(\ell) = -\frac{\partial^2}{\partial \ell^2} \ell + \lambda \ell \ . \tag{8}$$

Here the label a in eq. (7) specifies the ordering of the Hamiltonian. If we define a quantum state of the one-dimensional universe whose length is ℓ as $|\ell\rangle$, the amplitude $G^{(0)}(\ell_1, \ell_2; t)$ can be rewritten as

$$G^{(0)}(\ell_1, \ell_2; t) = \langle \ell_2 | e^{-t H_a^{(0)}(\ell_1)} | \ell_1 \rangle \ . \tag{9}$$

In fact, each ordering specifies the geometry of the quantum state $|\ell\rangle$, i.e. if $a = 0, -1, +1$, then the geometry of the one-dimensional universe is open, closed with a mark, and closed, respectively.[2,5] Marking a point on a closed universe is analogous to introducing a coordinate. The Hamiltonian is hermitian with respect to the following inner product:

$$\langle \phi | H_a^{(0)} | \psi \rangle = \int_0^\infty \phi^*(\ell) H_a^{(0)}(\ell) \psi(\ell) \ d\mu_a(\ell) \ , \quad \text{with} \quad d\mu_a(\ell) = \ell^a d\ell \ . \tag{10}$$

As a result, the physics of 2d CDT can be described by the quantum mechanics of a one-dimensional universe.

2.2. *2d projectable HL gravity*

The starting point is the same as that of CDT, i.e. a globally hyperbolic manifold equipped with a global time foliation (1). A natural parametrization for the metric on such a geometry is given by the Arnowitt-Deser-Misner metric:

$$g = -N^2 ds^2 + h_{11}(dx + N^1 ds)(dx + N^1 ds) \ , \tag{11}$$

where h_{11} is the spatial metric on the leaf; N and N^1 called lapse and shift functions, quantify the normal and tangential directions of the proper time to the leaf, respectively.

The 2d HL gravity is introduced as a theory that keeps the foliation structure,[3] or in other words, it is invariant under the foliation preserving diffeomorphisms (FPD):

$$s \to s + \xi^0(s) \ , \quad x \to x + \xi^1(s, x) \ . \tag{12}$$

Under the FPD, the fields transform as

$$\delta_\xi h_{11} = \xi^0 \partial_0 h_{11} + \xi^1 \partial_1 h_{11} + 2h_{11}\partial_1 \xi^1 \ , \tag{13}$$

$$\delta_\xi N_1 = \xi^\mu \partial_\mu N_1 + N_1 \partial_\mu \xi^\mu + h_{11}\partial_0 \xi^1 \ , \tag{14}$$

$$\delta_\xi N = \xi^\mu \partial_\mu N + N\partial_0 \xi^0 \ , \tag{15}$$

where $N_1 = h_{11}N^1$.

Note that if the lapse function N is a function of time, $N = N(t)$, it stays as a function of time under the FPD. The 2d projectable HL gravity satisfies this condition on N, and it is defined by the following action:

$$I = \frac{1}{\kappa}\int dsdx\ N\sqrt{h}\left((1-\eta)K^2 - 2\tilde{\lambda}\right) \ , \tag{16}$$

where η, $\tilde{\lambda}$ and κ are a dimensionless parameter, the cosmological constant and the dimensionless gravitational coupling constant, respectively; h is the determinant of the metric h_{11}, i.e. $h = h_{11}$; K is the trace of the extrinsic curvature K_{11} defined as

$$K_{11} = \frac{1}{2N}\left(\partial_0 h_{11} - 2\nabla_1 N_1\right) \ , \quad \text{with} \quad \nabla_1 N_1 := \partial_1 N_1 - \Gamma^1_{11} N_1 \ . \tag{17}$$

Here Γ^1_{11} is the spatial Christoffel symbol:

$$\Gamma^1_{11} = \frac{1}{2}h^{11}\partial_1 h_{11} \ . \tag{18}$$

In principle, one can add higher spatial derivative terms to the action (16), but they are not needed since 2d gravity is renormalizable without such terms and we will omit such terms.

The quantization of 2d projectable HL gravity was discussed in,[5,6] and in particular, it was shown that the quantum Hamiltonian coincides with the continuum Hamiltonian of 2d CDT when the following identification of the parameters is made:[5]

$$\lambda = \frac{\tilde{\lambda}}{2(1-\eta)} \ , \quad \eta < 1 \ , \quad \tilde{\lambda} > 0 \ , \quad \kappa = 4(1-\eta) \ . \tag{19}$$

where λ is the renormalized cosmological constant in 2d CDT (5)[b].

Let us briefly explain how to recover the quantum Hamiltonian (8) from the quantization of 2d HL gravity. Introducing the conjugate momentum of $\sqrt{h}$ as π, we have in the canonical formalism the Poisson bracket

$$\left\{\sqrt{h(s,x)}, \pi(s,x')\right\} = \delta(x-x') \, , \tag{20}$$

and corresponding to the Lagrangian (16) we have the Hamiltonian

$$H = \int dx\ \left[N_1\left(-\frac{\partial_1 \pi}{\sqrt{h}}\right) + N\left(\frac{\kappa}{4(1-\eta)}\pi^2\sqrt{h} + \frac{2}{\kappa}\tilde{\lambda}\sqrt{h}\right)\right] \ . \tag{21}$$

[b]We have set unimportant dimensionless gravitational constant as $\kappa = 4(1-\eta)$.

If we solve the momentum constraint at the classical level, i.e.

$$-\frac{\partial_1 \pi}{\sqrt{h}} = 0 \ , \quad \Rightarrow \quad \pi = \pi(s) \ , \tag{22}$$

the system reduces to a one-dimensional model with the Hamiltonian

$$H = N(s) \left(\frac{\kappa}{4(1-\eta)} \pi^2(s) \ell(s) + \frac{2}{\kappa} \tilde{\lambda} \ell(s) \right) \ , \quad \text{with} \quad \ell(s) := \int dx \ \sqrt{h(s,x)} \ . \tag{23}$$

Hereafter choosing the correct sign for the kinetic term, i.e. $\eta < 1$, we use the parametrization (19) with positive λ in order to discuss the relation to 2d CDT.

The classical 1d system with the Hamiltonian (23) can be alternatively described by the following action:

$$S = \int_0^1 ds \left(\frac{\dot{\ell}^2}{4N\ell} - \lambda N \ell \right) \ , \tag{24}$$

where $\dot{\ell} := d\ell/ds$. This system is invariant under the time reparametrization, $s \to s + \xi^0(t)$, which is ensured by the lapse function. In fact, the proper time,

$$t := \int_0^1 ds \ N(s) \ , \tag{25}$$

and the length, $\ell = \ell(t)$, are invariant under the time reparametrization, and so it makes sense to discuss the probability amplitude for a 1d universe to propagate in the proper time $t(> 0)$, starting from the state with the length ℓ_1 and ending up in the one with length ℓ_2.[5] Such an amplitude can be computed based on the path-integral, and we evaluate it by a rotation to the Euclidean signature for convenience. In our foliated spacetime, for $\eta < 1$, we can implement this procedure by a formal rotation, $s \to is$, which yields the amplitude:

$$G^{(0)}(\ell_2, \ell_1; t) = \int \frac{\mathcal{D}N(s)}{\mathrm{Diff}[0,1]} \int_{\ell(0)=\ell_1}^{\ell(1)=\ell_2} \mathcal{D}\ell(s) e^{-S_E[N(s),\ell(s)]} \ , \tag{26}$$

where Diff$[0,1]$ is the volume of the time reparametrization; S_E is the Euclidean action given by

$$S_E = \int_0^1 ds \left(\frac{\dot{\ell}^2}{4N\ell} + \lambda N \ell \right) \ , \tag{27}$$

where $\dot{\ell} := d\ell/ds$.

We set $N = 1$ as a gauge choice. One can show that the corresponding Faddeev-Popov determinant only gives an overall constant, which we will omit in the following. The amplitude (26) then becomes

$$G^{(0)}(\ell_2, \ell_1; t) = \int_{\ell(0)=\ell_1}^{\ell(t)=\ell_2} \mathcal{D}\ell(s) \exp\left[- \int_0^t ds \left(\frac{\dot{\ell}^2}{4\ell} + \lambda \ell \right) \right] \ , \tag{28}$$

which can be expressed in terms of the quantum Hamiltonian H that is unknown at the moment:

$$G^{(0)}(\ell_2, \ell_1; t) = \langle \ell_2 | e^{-tH} | \ell_1 \rangle \ , \tag{29}$$

where $|\ell\rangle$ is a quantum state of the 1d universe with the length ℓ. By standard methods (see e.g. the article[5]), one can determine the quantum Hamiltonian from eq. (28) and eq. (29). One obtains precisely the 2d CDT quantum Hamiltonians given by eq. (8) if the integral measures are chosen as

$$\mathcal{D}\ell(s) = \prod_{s=0}^{s=t} \ell^a(s) d\ell(s) \ , \tag{30}$$

where $a = 0, \pm 1$. The measures (30) are consistent with eq. (10) introduced in 2d CDT.

Therefore, we can conclude that 2d CDT is a lattice regularization for the 2d projectable HL quantum gravity.

3. Sum over all genera in 2d CDT

One can generalize the 2d CDT model so as to include spatial topology changes (splitting and joining interactions of 1d universe) in keeping with the foliation structure, and this is described by promoting the 1d quantum mechanics to a field theory of 1d universes, which is called the string field theory for CDT.[8] Here the word "string" means a 1d closed spatial universe.

We introduce an operator that creates a marked closed string with the length ℓ, $\Psi^\dagger(\ell)$, and an operator that annihilates a length ℓ closed string without a mark, $\Psi(\ell)$. They satisfy the commutation relation:

$$[\Psi(\ell), \Psi^\dagger(\ell')] = \delta(\ell - \ell'), \quad [\Psi(\ell), \Psi(\ell')] = [\Psi^\dagger(\ell), \Psi^\dagger(\ell')] = 0. \tag{31}$$

The vacuum $|\text{vac}\rangle$ is defined by $0 = \Psi(\ell)|\text{vac}\rangle = \langle \text{vac}|\Psi^\dagger(\ell)$.

The CDT amplitude (9) can be written in terms of the string field Hamiltonian obtained by sandwiching the one-body Hamiltonian:

$$G^{(0)}(\ell_1, \ell_2; t) = \langle \text{vac}|\Psi(\ell_2)\ e^{-t\hat{H}^{(0)}}\ \Psi^\dagger(\ell_1)|\text{vac}\rangle \ , \tag{32}$$

where

$$\hat{H}^{(0)} = \int_0^\infty \frac{d\ell}{\ell} \Psi^\dagger(\ell) H^{(0)}_{-1} \Psi(\ell) \ . \tag{33}$$

In order to incorporate topology change, one has to include suitable interactions, and the full string field Hamiltonian is given by:[8]

$$\begin{aligned} \hat{H} = \hat{H}^{(0)} &- \int_0^\infty d\ell\ \delta(\ell)\Psi(\ell) - g_s \int_0^\infty d\ell_1 \int_0^\infty d\ell_2\ \Psi^\dagger(\ell_1)\Psi^\dagger(\ell_2)(\ell_1 + \ell_2)\Psi(\ell_1 + \ell_2) \\ &- \alpha g_s \int_0^\infty d\ell_1 \int_0^\infty d\ell_2\ \Psi^\dagger(\ell_1 + \ell_2)\ell_1\Psi(\ell_1)\ell_2\Psi(\ell_2) \ , \end{aligned} \tag{34}$$

where the second, third and fourth terms mean a string vanishing into the vacuum, the splitting interaction with the string coupling g_s, and the joining interaction with the coupling αg_s, respectively; α is a constant introduced for counting handles. In general one can compute the following amplitude:

$$A(\ell_1, \cdots, \ell_m; \ell'_1, \cdots, \ell'_n; t) = \langle \text{vac}|\Psi(\ell'_1)\cdots\Psi(\ell'_n)e^{-t\hat{H}}\Psi^\dagger(\ell_1)\cdots\Psi^\dagger(\ell_m)|\text{vac}\rangle \ . \tag{35}$$

From now on, we focus on the full propagator $G(\ell_1, \ell_2; t)(:= A(\ell_1; \ell_2; t))$ that includes the sum over all genera (handles) and baby universes, and so we simply set $\alpha = 1$. In this case, somewhat miraculously, the full propagator in the multi-body system can be described by an effective one-body system:[11, 12]

$$G(\ell_1, \ell_2; t) = \langle \ell_2|e^{-tH_{-1}}|\ell_1\rangle \ , \quad \text{with} \quad H_{-1} = -\ell\frac{\partial^2}{\partial\ell^2} + \lambda\ell - g_s\ell^2 \ . \tag{36}$$

All the contributions coming from the sum over all genera and baby universes can be effectively described by the last term $-g_s\ell^2$. Although the Hamiltonian (36) is not bounded from below, it belongs to a class of Hamiltonians which are called "classical incomplete", where the Hamiltonians have discrete energy spectra and square integrable eigenfunctions.

The effective one-body system given by eq. (36) can be also described by the path-integral:[1, 14]

$$G(\ell_1, \ell_2; t) = \int_{\ell(0)=\ell_1}^{\ell(t)=\ell_2} \mathcal{D}\ell(s) \ \exp\left[-\int_0^t ds \ \left(\frac{\dot{\ell}^2(s)}{4\ell(s)} + \lambda\ell(s) - g_s\ell^2(s)\right)\right] \ . \tag{37}$$

If we choose the integral measure such that

$$\mathcal{D}\ell(s) = \prod_{s=0}^{s=t} \ell^a(s)d\ell(s) \ , \tag{38}$$

where $a = 0, \pm 1$, all possible orderings of the full one-body Hamiltonian (36) can be realized. As explained in the article,[14] in order for the functional integral to be well defined, the boundary conditions on $\ell(s)$ at infinity have to be chosen such that the kinetic term counteracts the unboundedness of the potential. As we will see, the information about the boundary conditions also appears in the classical Hamiltonian constraint (42) of 2d projectable HL gravity with a wormhole interaction.

In the next section, we will show that the path-integral (37) can be obtained quantizing the 2d projectable HL gravity with a wormhole interaction.

4. Wormhole interaction in 2d projectable HL gravity

We consider 2d projectable HL gravity with a space-like wormhole interaction given by the action:

$$\begin{aligned} I_w = \frac{1}{\kappa}\int dsdxN(s)\sqrt{h(s,x)}\left((1-\eta)K^2(s,x) - 2\tilde{\lambda}\right) \\ + \beta\int dsN(s)\int dx_1dx_2\sqrt{h(s,x_1)}\sqrt{h(s,x_2)} \ , \end{aligned} \tag{39}$$

where β is a dimensionfull coupling constant. One can show that the action (39) is invariant under the FPD (12) with the projectable lapse function, $N = N(t)$. The bi-local interaction in eq. (39) relates two distinct points at an equal time. The action is a simplified version of the general bi-local action suggested in the article,[15] made possible because HL gravity is invariant only under the FPD (12) and not the full set of diffeomorphisms.

Following the same procedure explained in the section 2.2, we quantize the system with the action (39). Introducing a conjugate momentum of $\sqrt{h}$ as π as before, we move on to the canonical formalism, and the Hamiltonian is

$$H = \int dx \ \left[N_1 \mathcal{C}^1(s,x) + N\mathcal{C}(s,x) \right] \ , \tag{40}$$

where

$$\mathcal{C}^1(s,x) = -\frac{\partial_1 \pi(s,x)}{\sqrt{h(s,x)}} \ , \tag{41}$$

$$\mathcal{C}(s,x) = \frac{\kappa}{4(1-\eta)} \pi^2(s,x)\sqrt{h(s,x)} + \frac{2}{\kappa}\tilde{\lambda}\sqrt{h(s,x)} - \beta\sqrt{h(s,x)} \int dx_2 \sqrt{h(s,x_2)} \ . \tag{42}$$

If we solve the momentum constraint (41) at the classical level, the system again reduces to the 1d system with the Hamiltonian:

$$H = N(s) \left(\frac{\kappa}{4(1-\eta)} \pi^2(s)\ell(s) + \frac{2}{\kappa}\tilde{\lambda}\ell(s) - \beta\ell^2(s) \right) \ , \tag{43}$$

where $\ell(s) := \int dx \ \sqrt{h(s,x)}$. Hereafter choosing the correct sign for the kinetic term, i.e. $\eta < 1$, we use the parametrization (19) with positive λ as before.

The classical Hamiltonian constraint (42) can be solved as

$$\pi^2 = -\lambda + \beta\ell \geq 0 \ , \tag{44}$$

for $\sqrt{\lambda}\ell \geq 1/\xi$ with $\xi := \beta/\lambda^{3/2}$, and otherwise, the classical Hamiltonian constraint (42) requires $\ell = 0$ on the constraint surface. As in the $\beta = 0$ case, when quantizing the system based on the path-integral, we don't have any problem with respect to the quantization around $\ell(s) = 0$.

Simply repeating the procedure in the section 2.2, one can show that the amplitude (37) can be precisely recovered by quantizing the 2d projectable HL gravity with the bi-local interaction based on the path-integral, if $\beta = g_s$.

5. Discussions

We have canonically quantized the 2d projectable HL gravity with a simple space-like wormhole interaction, and shown that the quantum Hamiltonian is equivalent to the one-body quantum Hamiltonian that includes contributions coming from all wormholes and baby universes obtained in the string field theory for CDT, if $g_s = \beta$ and $\lambda = \tilde{\lambda}/(2(1-\eta))$ where $\beta > 0$, $\lambda > 0$ and $\eta < 1$.

Let us consider the classical Hamiltonian constraint $\mathcal{C}$ (42) in the parameter region above. When $\sqrt{\lambda}\ell \geq 1/\xi$ where ξ is a dimensionless quantity defined by $\xi := g_s/\lambda^{3/2}$, the constraint surface is given by $\pi^2 = -\lambda + g_s\ell \geq 0$. However, when $\sqrt{\lambda}\ell < 1/\xi$, the only allowed solution is $\ell = 0$. In the case of the 2d projectable HL gravity ($\beta = g_s = 0$), with the parameter region corresponding to 2d CDT, i.e. $\lambda > 0$, the only solution to the classical Hamiltonian constraint is $\ell = 0$. Therefore, when $\sqrt{\lambda}\ell < 1/\xi$, the classical solution of the 2d projectable HL with the wormhole interaction will be close to that of the 2d projectable HL gravity, if one sits in the parameter region above; they can be quite different when $\sqrt{\lambda}\ell \geq 1/\xi$. Such a relation also holds at the quantum level. As shown in the article,[14] when $\sqrt{\lambda}\ell < 1/\xi$ the eigenfunctions of the one-body quantum Hamiltonian including all wormholes and baby universes, H_{-1} (36), can be well approximated by the eigenfunctions of the quantum Hamiltonian of 2d CDT without wormholes and baby universes, $H^{(0)}_{-1}$ (8). On the other hand, when $\sqrt{\lambda}\ell \geq 1/\xi$, their behaviors are quite different, and in this case, in order for the theory to be well-defined, the unbounded nature of the potential in H_{-1} will be counteracted by the kinetic term. This balance between the kinetic and potential terms is precisely what is reflected in the classical Hamiltonian constraint (42). This is also consistent with the boundary conditions on ℓ at infinity in the path-integral (38).

The picture of creation and annihilation of baby universes and wormholes is conceptually straightforward in the string field theory for CDT.[8] Nevertheless it is somewhat surprising that one from this can derive an effective one-body Hamiltonian which can describe propagation of a single spatial universe, i.e. the propagation where the spatial universe starts with the topology of a circle and at a later time t has the same topology, but where it in the intermediate times is allowed to split in two and either one part disappears in the vacuum (a baby universe), or the two parts join again at a later time (then changing the spacetime topology). This process of joining and splitting can be iterated at intermediate times and using string field theory we can perform the summation of all iterations and derive the effective one-body Hamiltonian (36). From the point of view of unitary evolution (or using Euclidean time, semigroup evolution, to be more precise), as given in eq. (29), it is difficult to understand how a complete set of intermediate states can both be given by the one spatial universe states $|\ell\rangle$ and by the complete multi-universe Fock states of the string field theory (for a recent discussion of this issue see i.e.[16]). However, this seems to be the case by explicit calculation, and we find it even more surprising that the simplest wormhole interaction term added to the classical action as in eq. (39) leads to precisely the same single universe quantum Hamiltonian as found in the string field theory for CDT.

Nature of singularities in vector-tensor theories of gravity

V. H. Satheeshkumar

Departamento de Física, Universidade Federal do Estado do Rio de Janeiro (UNIRIO), Rio de Janeiro, RJ 22290-240, Brazil
vhsatheeshkumar@gmail.com

The Vector-Tensor (VT) theories of gravity are a class of alternative theories to General Relativity (GR) that are characterized by the presence of a dynamical vector field besides the metric. They are studied in attempts to understand spontaneous Lorentz violation, to generate massive gravitons, and as models of dark matter and dark energy. In this article, I outline how the nature of singularities and horizons in VT theories differ greatly from GR even under the same ordinary conditions. This is illustrated with Einstein-aether theory where vacuum black hole solutions have naked singularities and vacuum cosmological solutions have new singularities that are otherwise absent in GR. It would be interesting to explore these deviations using gravitational waves.

Keywords: Vector-tensor theories of gravity, Modified theories of gravity, Lorentz violation, Spacetime singularities, Naked singularities, Event horizon, Universal horizon

1. Introduction

In the 1960s and early 1970s Roger Penrose, Stephen Hawking and Robert Geroch proved, independently and often in collaboration, a series of theorems on global features of spacetimes in GR. These theorems implied that singularities are inevitable in physically important situations of gravitational collapse and cosmology. The unpreventable existence of singularities for wide classes of rather general models in GR (and other classical theories of gravitation) marks the breakdown of the theory. That is why understanding singularities is crucial for us to find a replacement of GR at very high energies. Even after decades of work, very little is known about the structure and properties of spacetime singularities. For the latest developments on these issues, I refer the reader to the recent reviews by Witten,[1] and Penrose,[2] and also an accessible introduction to the subject by Joshi.[3]

In this paper, we are interested in studying how the presence of a dynamical vector field present in VT theories affects the nature of singularities in comparison to GR. There are many VT theories, but of them the Einstein-aether (EA) theory has the most general diffeomorphism-invariant action involving a spacetime metric and a vector field with the field equations being the second-order differential equations in terms of not only the metric but also the aether field. We study both timelike and spacelike singularities in EA theory. To this end, we consider both black hole and cosmological singularities. In both cases, by computing the Kretschmann scalar, we guarantee that we are dealing with curvature singularities, not conical or caustic singularities.

The paper is organized as follows. The Section 2 presents a quick overview of VT theories. Section 3, briefly outlines the EA theory. In Section 4 and 5, we present future and past singularities respectively. We end with a short summary in Section 6.

2. Vector-Tensor Theories of Gravity

One simple and straightforward extension of GR involves an introduction of a dynamical, timelike four-vector field in addition to the dynamical metric. This class of theories is referred to as Vector-Tensor theories of gravity. In some models, the four-vector is unconstrained, while in others it is constrained to have unit norm. The examples of unconstrained theories are Will-Nordtvedt theory[4,5] (1972), Hellings-Nordtvedt theory[6] (1973) and General vector-tensor theory[7] (1981). The constrained theories include Kostelecky-Samuel theory[8] (1989), Einstein-Aether theory[9] (2001) and Khronometric theory[10] (2010).

The most general action for such a theory which is Lagrangian-based and whose equations of motion involving the vector-field are linear and at most of second order is given by,

$$S = \frac{1}{16\pi G}\int \Big[(1+\omega\, g_{ab}u^a u^b)R - K^{ab}{}_{mn}\nabla_a u^m \nabla_b u^n + \lambda(g_{ab}u^a u^b + 1)\Big]\sqrt{-g}\, d^4x, \quad (1)$$

where

$$K^{ab}{}_{mn} = c_1 g^{ab}g_{mn} + c_2\delta^a_m\delta^b_n + c_3\delta^a_n\delta^b_m - c_4 u^a u^b g_{mn}, \quad (2)$$

the c_i being dimensionless coupling constants, and λ is a Lagrange multiplier enforcing the unit timelike constraint on the aether. The parameter ω is taken to be zero in constrained theories, while λ is set to zero in unconstrained theories.[11] Below, we give the conditions under which different VT theories can be obtained from the general action given above.

- Will-Nordtvedt theory: $\lambda = 0$, $c_1 = -1$ and $c_2 = c_3 = c_4 = 0$
- Hellings-Nordtvedt theory: $\lambda = 0$, $c_1 = 2$, $c_2 = 2\omega$, $c_1 + c_2 + c_3 = 0$ and $c_4 = 0$
- General vector-tensor theory: $\lambda = 0$, $c_1 = 2\epsilon - \tau$, $c_2 = -\eta$, $c_1 + c_2 + c_3 = -\tau$ and $c_4 = 0$
- Kostelecky-Samuel theory: $\omega = 0$ and u^a is not necessarily timelike.
- Einstein-Aether theory: $\omega = 0$ and u^a is always timelike unit vector.
- Khronometric theory: $\omega = 0$, $c_1 = -\epsilon$, $c_2 = \lambda_K$, $c_3 = \beta_K + \epsilon$ and $c_4 = \alpha_K + \epsilon$ where the limit $\epsilon \to \infty$ is to be taken.

Although a lot of work is done on VT theories, there are few reviews on the subject.[12] From the latest phenomenological studies,[13–15] it is evident that EA theory is the most representative of the VT theories and observationally relevant. For this reason, we shall restrict our discussion to EA theory.

3. Einstein-Aether Theory

The general action[9] of the EA theory is given by

$$S = \frac{1}{16\pi G}\int \Big[R - K^{ab}{}_{mn}\nabla_a u^m \nabla_b u^n + \lambda(g_{ab}u^a u^b + 1)\Big]\sqrt{-g}\, d^4x + S_{matter}, \quad (3)$$

where

$$K^{ab}{}_{mn} = c_1 g^{ab}g_{mn} + c_2\delta^a_m\delta^b_n + c_3\delta^a_n\delta^b_m - c_4 u^a u^b g_{mn}, \quad (4)$$

the c_i being dimensionless coupling constants, and λ is a Lagrange multiplier enforcing the unit timelike constraint on the aether, and $\delta^a_m\delta^b_n = g^{a\alpha}g_{\alpha m}g^{b\beta}g_{\beta n}$. In the weak-field, slow-motion limit EA theory reduces to Newtonian gravity with a value of Newton's constant $G_{\rm N}$ related to the parameter G in the action (3) by,

$$G = G_N\left(1 - \frac{c_{14}}{2}\right). \quad (5)$$

Here, the constant c_{14} is defined as

$$c_{14} = c_1 + c_4. \quad (6)$$

Note that if $c_{14} = 0$ the EA coupling constant G becomes the Newtonian coupling constant G_N, without necessarily imposing $c_1 = c_4 = 0$. For $c_{14} > 2$ the coupling constant G becomes negative, implying that the gravity is repulsive. The coupling constant vanishes when $c_{14} = 2$ which renders the action undefined. Thus, physically interesting region is $0 \le c_{14} < 2$. These free parameters have been severely constrained using many observational/experimental tests, including gravitational waves.[16]

The field equations are obtained by extremizing the action with respect to independent variables of the system. The variation with respect to the Lagrange multiplier λ imposes the condition that u^a is a unit timelike vector, thus

$$g_{ab}u^a u^b = -1, \quad (7)$$

while the variation of the action with respect u^a, leads to

$$\nabla_a K^{am}_{bn}\nabla_m u^n + c_4 u^m \nabla_m u_a \nabla_b u^a + \lambda u_b = 0, \quad (8)$$

the variation of the action with respect to the metric g_{mn} gives the dynamical equations,

$$G^{Einstein}_{ab} = T^{aether}_{ab} + 8\pi G T^{matter}_{ab}, \quad (9)$$

where

$$\begin{aligned} G^{Einstein}_{ab} &= R_{ab} - \frac{1}{2}g_{ab}R, \\ T^{aether}_{ab} &= \nabla_c[J^c{}_{(a}u_{b)} + u^c J_{(ab)} - J_{(a}{}^c u_{b)}] - \frac{1}{2}g_{ab}J^c_d\nabla_c u^d + \lambda u_a u_b \\ &\quad + c_1[\nabla_a u_c \nabla_b u^c - \nabla^c u_a \nabla_c u_b] + c_4 u^c \nabla_c u_a u^d \nabla_d u_b, \\ T^{matter}_{ab} &= \frac{-2}{\sqrt{-g}}\frac{\delta\left(\sqrt{-g}L_{matter}\right)}{\delta g_{ab}}, \end{aligned} \quad (10)$$

with

$$J^a{}_m = K^{ab}{}_{mn}\nabla_b u^n. \tag{11}$$

In a more general situation, the Lagrangian of GR is recovered, if and only if, the coupling constants are identically zero, i.e., $c_1 = c_2 = c_3 = c_4 = 0$.

4. Naked Singularities in Einstein-Aether Theory

In this section, I show that naked singularities appear in EA theory which are otherwise covered by event (Killing) horizons in GR. For this, we start with the most general spherically symmetric static metric,

$$ds^2 = -e^{2A(r)}dt^2 + e^{2B(r)}dr^2 + r^2 d\theta^2 + r^2\sin^2\theta d\phi^2. \tag{12}$$

In accordance with equation (7), the aether vector is taken to be unitary and timelike,

$$u^a = (e^{-A(r)}, 0, 0, 0). \tag{13}$$

This choice is not the most general and is restricted to the scenario where aether is static. The aether must tip in a black hole solution as it cannot be timelike to be aligned with the null Killing vector on the horizon. As that is not the case with our choice, our solutions are valid only outside the Killing horizon. However, this is not going to be problematic for the solutions presented here.

The timelike Killing vector of the metric (12) is giving by

$$\chi^a = (-1, 0, 0, 0). \tag{14}$$

The Killing and the universal horizon[17] are obtained finding the largest root of

$$\chi^a\chi_a = 0, \tag{15}$$

and

$$\chi^a u_a = 0, \tag{16}$$

respectively, where χ^a is the timelike Killing vector. Thus

$$\chi^a\chi_a = -e^{2A(r)}, \tag{17}$$

$$\chi^a u_a = e^{A(r)}. \tag{18}$$

For the metric in Eq. (12), the tt, rr and $\theta\theta$ components of the vacuum field equations (10) are given by,

$$-\frac{e^{2(A-B)}}{2r^2}\left[c_{14}(-2r^2A'B' + r^2A'^2 + 2r^2A'' + 4rA') - 4rB' - 2e^{2B} + 2\right] = 0, \tag{19}$$

$$-\frac{1}{2r^2}\left(c_{14}r^2A'^2 + 4rA' - 2e^{2B} + 2\right) = 0, \tag{20}$$

$$\frac{r}{2e^{2B}}\left(2rA'' - 2rA'B' + 2A' - 2B' - (c_{14} - 2)rA'^2\right) = 0. \tag{21}$$

The Kretschmann scalar for the metric (12), is given by

$$K = \frac{4}{r^4 e^{4B}}\left(2B'^2r^2 + e^{4B} - 2e^{2B} + 1 + 2A'^2r^2 + r^4A''^2 + 2r^4A''A'^2 - 2r^4A''B'A' + r^4A'^4 - 2r^4A'^3B' + r^4B'^2A'^2\right). \quad (22)$$

It is not possible to solve these equations analytically for a general case. However, there exist closed form solutions for $c_{14} = 16/9$ and $c_{14} = 48/25$, both of which are within the permitted range. More details about the method employed to obtain these solutions are found in our papers.[18,19]

For $c_{14} = 16/9$, the metric functions and Kretschmann scalar are given by,

$$A = -\frac{3}{4}\ln(r) + \frac{3}{4}\ln\left[r + 4 + \sqrt{(r+8)r}\right], \quad (23)$$

$$B = -\frac{1}{2}\ln(2) + \frac{1}{2}\ln\left(\sqrt{\frac{r}{r+8}} + \frac{r}{r+8}\right), \quad (24)$$

$$K = \frac{768\sqrt{r+8}\left[2r(r+8)^2 + (384 + 104r + 7r^2)\sqrt{(r+8)r}\right]}{\left[r^{11/2}\left(r + 8 + \sqrt{(r+8)r}\right)^4\right]}. \quad (25)$$

From the above equation, we can see that there exists a curvature singularity at $r = 0$. The Killing and universal horizons for this case are obtained by finding the roots of the following,

$$\chi^a\chi_a = -r^{-\frac{3}{2}}\left(r + 4 + \sqrt{(r+8)r}\right)^{\frac{3}{2}} = 0, \quad (26)$$

$$\chi^a u_a = r^{-\frac{3}{4}}\left(r + 4 + \sqrt{(r+8)r}\right)^{\frac{3}{4}} = 0. \quad (27)$$

We can see easily that these equations do not have any real root. Thus, there exists neither Killing horizon nor universal horizon.

For $c_{14} = 48/25$, we see the same behavior as in the previous case, but the mathematical expressions are quite lengthy. So, instead of presenting them here, I refer the reader to our paper.[18]

5. Cosmological Singularities in Einstein-Aether Theory

In this section, I show that initial singularities appear in EA theory which are otherwise absent in GR. For this, we start with the most general isotropic and homogeneous universe is described by a Friedmann-Lemaître-Robertson-Walker (FLRW) metric,

$$ds^2 = -dt^2 + B(t)^2\left[\frac{dr^2}{1-kr^2} + r^2d\theta^2 + r^2\sin^2\theta d\phi^2\right], \quad (28)$$

where, $B(t)$ is the scale factor and k is a Gaussian curvature of the spacial slice at a given time. The appropriate aether vector for this metric is given by,

$$u^a = (1, 0, 0, 0). \tag{29}$$

The standard definitions of the Hubble parameter $H(t)$ and the deceleration parameter $q(t)$ are given by,

$$H(t) = \frac{\dot{B(t)}}{B(t)}, \tag{30}$$

$$q(t) = -\frac{\ddot{B(t)}B(t)}{\dot{B(t)}^2}, \tag{31}$$

where the symbol dot denotes the differentiation with respect to the time coordinate. The Friedmann-Lemaître equations are given by,

$$\left(1 + \frac{\beta}{2}\right)\left(\frac{\dot{B(t)}}{B(t)}\right)^2 = \frac{\Lambda}{3} - \frac{k}{B(t)^2}, \tag{32}$$

$$\left(1 + \frac{\beta}{2}\right)\frac{\ddot{B(t)}}{B(t)} = \frac{\Lambda}{3}, \tag{33}$$

where Λ is the cosmological constant. The Kretschmann scalar for FLRW metric is given by,

$$K = \frac{12}{B^4}\left[k^2 + 2k\dot{B}(t)^2 + \dot{B}(t)^4 + \ddot{B}(t)^2 B(t)^2\right]. \tag{34}$$

We can solve the above equations for nine different combinations of Λ and k. However, here I present only the three cases involving $k = -1$, because these solutions are non-singular in GR but are singular in EA theory. The theoretical consistency requires $\beta \equiv c_1 + 3c_2 + c_3 > -2$. A detailed discussion on other cases can be found in our article.[20]

For $\Lambda > 0, k = -1$, the Friedmann-Lemaître equations have two solutions that exist for $\beta + 2 > 0$,

$$B_1(t) = \frac{1}{2\sqrt{\Lambda}}\left[-\frac{3\, e^{\sqrt{\frac{2\Lambda}{3(\beta+2)}}(t_0 - t)}}{\epsilon\sqrt{\Lambda+3} + \sqrt{\Lambda}} + \frac{\epsilon\sqrt{\Lambda+3} + \sqrt{\Lambda}}{e^{\sqrt{\frac{2\Lambda}{3(\beta+2)}}(t_0 - t)}}\right], \tag{35}$$

$$B_2(t) = \frac{1}{2\sqrt{\Lambda}}\left[-\frac{3\, e^{\sqrt{\frac{2\Lambda}{3(\beta+2)}}(t - t_0)}}{\epsilon\sqrt{\Lambda+3} + \sqrt{\Lambda}} + \frac{\epsilon\sqrt{\Lambda+3} + \sqrt{\Lambda}}{e^{\sqrt{\frac{2\Lambda}{3(\beta+2)}}(t - t_0)}}\right]. \tag{36}$$

Both are singular at,

$$t_{sing}(B_1) \; = t_0 - \sqrt{\frac{3(\beta+2)}{8\Lambda}}\ln\left[\frac{2}{3}\Lambda + \frac{2}{3}\epsilon\sqrt{\Lambda(\Lambda+3)} + 1\right], \tag{37}$$

$$t_{sing}(B_2) \; = t_0 + \sqrt{\frac{3(\beta+2)}{8\Lambda}}\ln\left[\frac{2}{3}\Lambda + \frac{2}{3}\epsilon\sqrt{\Lambda(\Lambda+3)} + 1\right]. \tag{38}$$

The metric is not singular for $\beta = 0$ as the curvature invariant being $\frac{8\Lambda^2}{3}$. But, the metric is singular for $\beta + 2 > 0$ with $\beta \neq 0$. This means it exists only in EA theory but not in GR.

For $\Lambda = 0, k = -1$, we have two solutions satisfying $\beta + 2 > 0$,

$$B_1(t) = 1 + \sqrt{\frac{2}{2+\beta}}(t_0 - t) \tag{39}$$

$$B_2(t) = 1 + \sqrt{\frac{2}{2+\beta}}(t - t_0) \tag{40}$$

Both are singular at

$$t_{sing}(B_1) = t_0 + \sqrt{\frac{2+\beta}{2}}, \tag{41}$$

$$t_{sing}(B_2) = t_0 - \sqrt{\frac{2+\beta}{2}}. \tag{42}$$

For $\beta = 0$ which corresponds to GR, the solution exists and is never singular with the curvature invariant being zero. But, the metric is singular for $\beta + 2 > 0$ such that $\beta \neq 0$. This means it is a new singularity that exists only in EA theory but not GR.

For $\Lambda < 0, k = -1$, there exists two solutions satisfying $\beta + 2 > 0$,

$$B_1(t) = \sqrt{\frac{3}{|\Lambda|}} \sin\left(\sqrt{\frac{2|\Lambda|}{3(\beta+2)}}(t - t_0) + \sin^{-1}\sqrt{\frac{|\Lambda|}{3}}\right) \tag{43}$$

$$B_2(t) = \sqrt{\frac{3}{|\Lambda|}} \sin\left(\sqrt{\frac{2|\Lambda|}{3(\beta+2)}}(t_0 - t) + \sin^{-1}\sqrt{\frac{|\Lambda|}{3}}\right) \tag{44}$$

Both are singular at

$$t_{sing}(B_1) = t_0 - \sqrt{\frac{3(\beta+2)}{2|\Lambda|}} \sin^{-1}\sqrt{\frac{|\Lambda|}{3}} \tag{45}$$

$$t_{sing}(B_2) = t_0 + \sqrt{\frac{3(\beta+2)}{2|\Lambda|}} \sin^{-1}\sqrt{\frac{|\Lambda|}{3}} \tag{46}$$

For $\beta = 0$ the solution exists but is never singular with the curvature invariant being $\frac{8|\Lambda|^2}{3}$. But, the metric is singular for $\beta + 2 > 0$ with $\beta \neq 0$. This means it is a new singularity that exists only in EA theory.

The above results are independently confirmed by studying the focusing of congruence of timelike geodesics using the Raychaudhuri equation.[20]

6. Conclusions

Many of the deep conceptual issues related to gravity are closely connected with the very existence spacetime singularities. The singularity theorems predict only the existence of spacetime singularities under a set of physically reasonable conditions, but not say much else about them. In principle, spacetime singularities and event horizons are two totally different and independent concepts in gravitational physics. However, the Cosmic Censorship Conjecture (CCC) suggests that whenever a spacetime singularity occurs it always stays hidden within an event horizon. But, the mathematically rigorous formulation of the CCC, let alone its proof, is still an open problem. We have attempted to understand these issues in VT theories of gravity with the hope that we might look at GR from a fresh perspective.

In this paper, we investigated how the presence of timelike vector field in EA theory affects the nature of singularities in comparison to GR theory. Firstly, I have illustrated with two analytical solutions ($c_{14} = 16/9$ and $48/25$) that the Schwarzschild metric in EA theory is singular at $r = 0$ but it is not covered by neither Killing horizon nor universal horizon, whereas the corresponding case in GR has horizons. Thus we have naked singularities. Astrophysically, a naked singularity is distinguishable from a black hole of the same mass from the the luminosity of the accretion disk as it extends very close to the naked singularity.[21] Secondly, I have shown that for three different cases with $k = -1$, the FLRW vacuum solutions in EA theory are singular, but non-singular in GR. All these solutions are within the experimentally allowed parameter space. Initial singularity is in principle visible. However, from the data we know that our universe has $k = 0$, thus making this result observationally not viable. The important take away is that the new singular solutions show that GR and EA theories have different global structures even for the simple situations.

Acknowledgments

It is my pleasure to thank Roberto Chan and Maria de Fátima Alves da Silva for several useful discussions and collaboration on the works that produced some of the key results presented here. I am grateful to the organizers of MG16, especially Anzong Wang, for the invitation to give this talk. Finally, I would like to dedicate this article to T. Padmanabhan (1957–2021) who has significantly influenced me before and since I got to be in his orbit when I participated in the *IUCAA Vacation Students' Programme* during the summer of 2003.

Hořava-Lifshitz and Einstein-Æther gravity in the light of Event Horizon Telescope observations of M87*

Emmanuel N. Saridakis

National Observatory of Athens, Lofos Nymfon, 11852 Athens, Greece
E-mail: msaridak@noa.gr

We investigate Hořava-Lifshitz and Einstein-Æther gravity in light of the Event Horizon Telescope (EHT) observations of the M87*. We calculate the corresponding photon effective potential, the unstable photon sphere radius, and finally the induced angular size, which combined with the mass and the distance can lead to a single prediction that quantifies the black hole shadow, namely the diameter per unit mass d. Since d_{M87*} is observationally known from the EHT Probe, we extract the corresponding parameter regions in order to obtain consistency. We find that Einstein-Æther black hole solutions agree with the shadow size of EHT M87*, if the involved Æther parameters are restricted within specific ranges, along with an upper bound on the dimensionless spin parameter a, which is verified by a full scan of the parameter space within 1σ-error.

Keywords: M87* observations; Event Horizon Telescope; Einstein-Æther gravity; Hořava-Lifshitz gravity.

1. Introduction

In the light of recording the first stunning new radio images of the supermassive black hole (BH) that exists at the center of nearby galaxy M87* by *"Event Horizon Telescope"* (EHT),[1,2] the black-hole shadow has become one of the most exciting events in observational astronomy. Historically the concept of the black hole shadow comes from the 70's with the seminal works.[3] In these studies it was found that the non-rotating BH has a perfect circular shadow, while by taking the rotation into account the shape of shadow is elongated due to the dragging effect.[4]

The dark area over a brighter background in the center of the image is termed as *"BH's shadow"*, and it is predicted by general relativity as the null geodesics in the strong gravity area.[5,6] In particular, photons with some critical angular momentum, will swirl around the BH one ring by one ring which makes the unstable boundary of the shadow, which is the same as the shining halo observed in EHT image. Nevertheless, given that the shape and size of the shadow contains traces of the geometry vicinity of the BH, and similarly to the quasinormal modes approach, one can consider the shadow as a potential probe to investigate the BH structure within different gravitational theories.

Horava-Lifshitz[7–10] and Einstein-Æther (EA) theory[11–14] are generally covariant theories of gravity, which violate the Lorentz invariance locally, and the latter possesses a dynamical, unit-norm and timelike vector field, called *"æther field"*, which defines a preferred timelike direction at each spacetime point. EA gravity includes a number of coupling constants called æther parameters. In the present work we

are interested in investigating Horava-Lifshitz and Einstein-Æther theory using the EHT observations of the M87*, based on.[15] Throughout the manuscript we adopt natural units where $\hbar = k_B = c = 1$.

2. Rotating black-hole solutions in Einstein-Æther gravity

The action of the EA theory is[11]

$$S = S_{EH} + S_{AE} = \frac{1}{16\pi G_{AE}} \int d^4x\sqrt{-g}\Big(R + \mathcal{L}_{AE}\Big), \tag{1}$$

which includes the standard Einstein-Hilbert action S_{EH} plus the æther action S_{AE}. In the above action, R, G_{EA} and $\mathcal{L}_{AE}$ refer respectively to the Ricci scalar, the Æther gravitational constant and the Lagrangian of the Æther field u^μ, which is defined as

$$\mathcal{L}_{AE} \equiv -\left(c_1 g^{\alpha\beta} g_{\mu\nu} + c_2 \delta^\alpha_\mu \delta^\beta_\nu + c_3 \delta^\alpha_\nu \delta^\beta_\mu - c_4 u^\alpha u^\beta g_{\mu\nu}\right)(\nabla_\alpha u^\mu)(\nabla_\beta u^\nu) + \lambda_0(u^2 + 1). \tag{2}$$

Here, λ_0 is a Lagrangian multiplier, ensuring that the Æther four-velocity u^α is always timelike (i.e. $u^2 = -1$). All of four coupling constants (c_1, c_2, c_3, c_4) in the above expression are dimensionless, and thus G_{AE} is linked to the Newtonian constant G_N via two of them, namely $G_{AE} = \frac{2G_N}{2-c_1-c_4}$.[16] As usual, variations of the total action with respect to $g_{\mu\nu}$, u^α, λ_0 yield, respectively, the field equations.[15]

There exists a corresponding slowly rotating black hole solution, with a spherically symmetric æther field configuration ($\lambda(r) = 0$), namely[15]

$$ds^2 = -e(r)dt^2 + \frac{dr^2}{e(r)} + r^2(d\theta^2 + \sin^2\theta d\phi^2) - \frac{4Ma}{r}\sin^2\theta dt d\phi, \tag{3}$$

with

$$e(r) = 1 - \frac{2M}{r} - \frac{27c_{13}}{256(1-c_{13})}\left(\frac{2M}{r}\right)^4. \tag{4}$$

Note that for convenience we have replaced the angular momentum J by introducing the rotation parameter[17] a through $a \equiv \frac{J}{M}$.

3. Black hole shadow

As usual, in order to study the geodesics structure of the photon trajectories, we begin with the Hamilton-Jacobi equation

$$\frac{\partial S}{\partial \lambda} = -\frac{1}{2} g^{\mu\nu} \frac{\partial S}{\partial x^\mu} \frac{\partial S}{\partial x^\nu}\ , \tag{5}$$

where S and λ denote respectively the Jacobi action of the particle (here photon) moving in the black hole spacetime, and the affine parameter of the null geodesic. Concerning the massless photon propagating on the null geodesics, the Jacobi action S can be separated as

$$S = -Et + J\phi + S_r(r) + S_\theta(\theta)\ , \tag{6}$$

where E and J respectively address the energy and angular momentum of the photon in the direction of the rotation axis. Furthermore, the functions $S_r(r)$ and $S_\theta(\theta)$ have only r and θ dependencies, respectively.

By inserting the Jacobi action (6) into the Hamilton-Jacobi equation (5), using also the metric components (3), we find that the photon trajectories are expressed in terms of the radial geodesics and the effective potential $U_{eff}(r)$ as:[15]

$$\left(\frac{dr}{d\lambda}\right)^2 + U_{eff}(r) = 0 \tag{7}$$

with

$$U_{eff}(r) = -1 + \frac{e(r)}{r^2}(\xi^2 + \eta) + \frac{4M\eta a}{r^3}, \tag{8}$$

where $\xi = \frac{J}{E}, \quad \eta = \frac{\mathcal{K}}{E^2}$. The above two impact parameters ξ and η are actually the principle quantities for determining the photon motion. We can extract the geometric shape of the shadow via the allowed values of ξ and η that satisfy the above conditions. Thus, we arrive at

$$2(\eta + \xi^2)re(r) - (\eta + \xi^2)r^2e'(r) + 12M\xi a = 0\ . \tag{9}$$

By solving this equation one acquires the radius r_{ps} of the photon sphere, which since we have taken the rotation effect into account is expected to be between the two values $r_{ps}^{\mp}$.

For slowly rotating BHs we immediately find that for the spherical-orbit photon motion the two parameters ξ and η have the form

$$\xi(r) = \frac{r^3[re'(r) - 2\,e(r)]}{4Ma[e(r) + re'(r)]}\ , \tag{10}$$

$$\eta(r) = \frac{-r^6[-2e(r) + re'(r)]^2 + 48M^2a^2r^2\left[e(r) + re'(r)\right]}{16M^2a^2\left[e(r) + e'(r)\right]^2}\ . \tag{11}$$

As usual, to describe the shadow as seen by a distant observer, one introduces the following two celestial coordinates X and Y:[6]

$$X = \lim_{r_*\to\infty}\left(-r_*^2\sin\theta_0\frac{d\phi}{dr}\right), \tag{12}$$

$$Y = \lim_{r_*\to\infty} r_*^2\frac{d\theta}{dr}, \tag{13}$$

where r_* and θ_0 are respectively the distance between the observer and the black hole, and the inclination angle between the line of sight of the observer and the rotational axis of the black hole. By applying the geodesics equations along with the expressions $\frac{d\phi}{dr} = \frac{d\phi/d\lambda}{dr/d\lambda}$ and $\frac{d\theta}{dr} = \frac{d\theta/d\lambda}{dr/d\lambda}$ we obtain

$$X = -\xi(r_{ps})\csc\theta_0\ , \tag{14}$$

$$Y = \sqrt{\eta(r_{ps}) - \xi^2(r_{ps})\cot^2\theta_0}\ , \tag{15}$$

and therefore these two celestial coordinates fulfill

$$X^2 + Y^2 = \xi^2(r_{ps}) + \eta_{\mathbf{ps}}(r_{ps}) \ , \tag{16}$$

where r_{ps} is the aforementioned radius of the unstable photon sphere. This is the expression of the EA BHs shadow in the slow rotation limit. As a self-consistency check, we can see that in the Schwarzschild limit, namely $a \to 0$, the above equation becomes $X^2 + Y^2 = 27M^2$, as expected.

3.1. *Einstein-Æther black hole solution*

In order to draw the shadow of the BH solution we need to calculate two essential quantities, namely the event horizon radius r_e and the radius of the unstable photon sphere r_{ps}. In order to find the even horizon of metric (3) we have to solve

$$r^4 - 2Mr^3 - \frac{27c_{13}}{16(1-c_{13})}M^4 = 0 \ , \tag{17}$$

where $c_{13} \equiv c_1 + c_3$. This leads to

$$r_{e_{1,2}} = \frac{3M^2}{2} - s \pm \frac{1}{2}\sqrt{-4s^2 + 3M^2 - \frac{M^2}{s}}, \tag{18}$$

$$r_{e_{3,4}} = \frac{3M^2}{2} + s \pm \frac{1}{2}\sqrt{-4s^2 + 3M^2 + \frac{M^2}{s}}, \tag{19}$$

where

$$s = \sqrt{\frac{3M^2Q + Q^2 + \Delta_0}{12Q}}, \quad Q = \left(\frac{\Delta_1 + \sqrt{\Delta_1^2 - 4\Delta_0^3}}{2}\right)^{1/3}, \tag{20}$$

$$\Delta_0 = -\frac{81c_{13}}{4(1-c_{13})}M^4, \quad \Delta_1 = \frac{729c_{13}}{2(1-c_{13})}M^7. \tag{21}$$

Solutions $r_{1,2}$ are imaginary and thus not physically interesting. Nevertheless, by setting c_{13} to zero the third solution becomes $r_3 = 2M$, as expected from Schwarzschild background. Thus, we deduce that r_3 addresses the event horizon radius r_e of the Einstein-Æther BH solution.

We proceed by setting $\eta = 0$, and inserting the ξ_{ps} from $U_{eff} = 0$

$$\xi_{ps} = \frac{2Ma}{e(r_{ps})r_{ps}}\left[-1 + \sqrt{1 + \frac{r_{ps}^4 e(r_{ps})}{4M^2a^2}}\right] \ , \tag{22}$$

into (9). Then, using $e(r)$ from Eq. (4) we finally result to the following equation

$$\begin{aligned} a^2\,(\alpha_1 - 8)\,(c_{13} - 1)\,r_{ps}^3\,\big[&81\alpha_1 c_{13} + 16\,(\alpha_1 + 16)\,(c_{13} - 1)\,r_{ps}^4 \\ &-48\,(\alpha_1 + 8)\,(c_{13} - 1)\,r_{ps}^3\big] = 0 \ , \end{aligned} \tag{23}$$

with

$$\alpha_1 = \sqrt{\frac{64a^2\,(c_{13} - 1)\,(r_{ps} - 2)r_{ps}^3 + 16\,(c_{13} - 1) + 27c_{13}}{(c_{13} - 1)a^2}} \ . \tag{24}$$

The solution of Eq. (23) will provide the radius of the photon sphere r_{ps}.

4. Confrontation with and M87* observations

We can now proceed to the investigation of the constraints on the æther parameter c_{13} that arise from the EHT Observations of the shadow of M87*. In particular, the size of the resulting shadow is sensitive on the æther parameter c_{13}, and hence the image of M87* is able to impose bounds on them.

In light of the report released by EHT collaboration for the shadow of M87* in,[1,2] for the angular size of the shadow, the mass and the distance to M87* one respectively has the values

$$\delta = (42 \pm 3)\,\mu\text{arcsec}, \tag{25}$$

$$M = (6.5 \pm 0.9) \times 10^9\, M_\odot, \tag{26}$$

$$D = 16.8^{+0.8}_{-0.7}\ \text{Mpc}, \tag{27}$$

where $M_\odot$ is the Sun mass. One can merge this information by introducing the single number d_{M87*}, which quantifies the size of M87*'s shadow in unit mass, defined as[17]

$$d_{M87*} \equiv \frac{D\delta}{M} \approx 11.0 \pm 1.5\,. \tag{28}$$

This combination can be used in order to confront with the theoretically predicted shadows (e.g. the above number is in agreement within 1σ-error with what we theoretically expect for the Schwarzschild BH, namely $d_{Schw} \simeq 10.4$[6]).

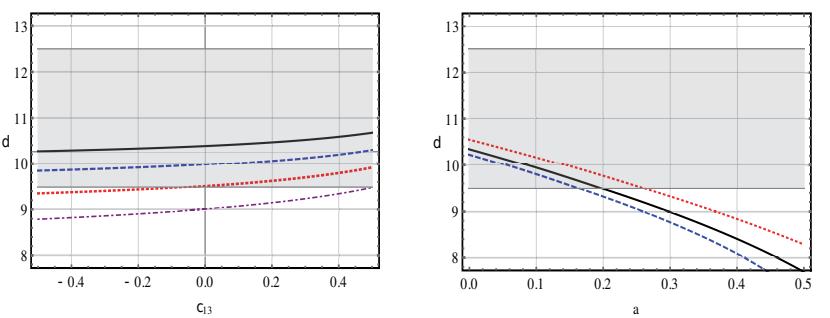

Fig. 1. **Left graph:** The predicted diameter per unit mass d for the Einstein-Æther black hole solution (3) with (4), as a function of the æther parameter c_{13}, for several values of the rotational parameter: $a = 0$ (black - solid), $a = 0.1$ (blue - dashed), $a = 0.2$ (red - dotted), $a = 0.3$ (purple - dashed-dotted). **Right graph:** d as a function of the rotational parameter a, for $c_{13} = -0.5$ (blue - dashed), $c_{13} = 0$ (black- solid), $c_{13} = 0.5$ (red- dotted). In both graphs the shaded area mark the observationally determined diameter per unit mass of M87*'s shadow, namely d_{M87*}, within 1σ-error.

In order to confront Einstein-Æther solutions with the above observational number, all we need is to calculate the angular size δ as a function of the Einstein-Æther parameters. The angular size can be immediately extracted from the profile (16), as long as we know the radius of the unstable photon sphere r_{ps} (as a function of

the Einstein-Æther parameter). Knowing δ can then easily lead to the predicted diameter per unit mass d. Note that in agreement with EHT, from now on we fix the value $\theta_0 = 17$ for the inclination angle.

In Fig. 1 we depict the diameter of the predicted shadow d as a function of c_{13} and a, on top of the observed one from M87* within 1σ. As we observe, the Æther BH solution is able to quantitatively describe the shadow size of M87*, provided that the dimensionless spin parameter a is constrained to specific values, dependent on c_{13}. Note that since our whole analysis has been restricted to the slow rotation case, the extracted upper bounds on a are perfectly consistent and justify our approximation. The curves in Fig. 1 imply that within these ranges of c_{13} it is possible to distinguish a naked singularity ($c_{13} < 0$) from BH ($c_{13} > 0$). Furthermore, in order to present the bounds on spin parameter a in a more transparent way, we perform a full scan of the two-dimensional parameter space and in Fig. 2 we depict the region which corresponds to a d in agreement with the observed value d_{M87*}. As it is clear from it as well as from the right panel in Fig. 1, by moving from negative to positive values of æther parameter c_{13}, the upper bound on the a grows. This may be useful in distinguishing between BH and naked singularity.

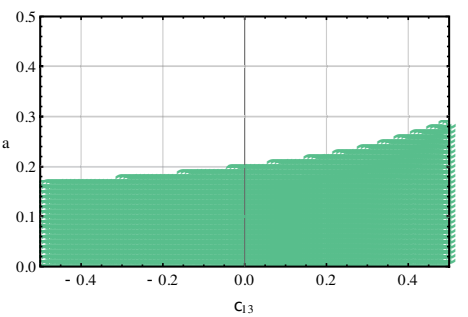

Fig. 2. The allowed parameter region (green) in the $c_{13} - a$ plane, for fixed BH mass ($M = 6 \times 10^9 M_\odot$), for the Einstein-Æther black hole solution (3) with (4), that leads to diameter per unit mass d in agreement with the observationally determined one d_{M87*} within 1σ-error.

We mention here that in order to create the allowed parameter space plots on the $c_{13} - a$ plane, we have fixed the BH mass to $M = 6 \times 10^9 M_\odot$. Nevertheless, one can also perform a similar parameter scan for the case of non-fixed BH mass, namely within the two-dimensional parameter space (c_{13}, M), for different fixed values of the rotation parameter a. In Fig. 3 we present such a graph. As we observe, for reasonable c_{13} values, the BH mass lies within the range we expect from EHT for M87*, i.e. $M = (6.5 \pm 0.9) \times 10^9\, M_\odot$. Furthermore, Fig. 3 shows the role of rotation on the allowed region of the $c_{13} - M$ plane, namely by increasing the rotation parameter we are led to larger region for the c_{13} parameter and still be consistent with EHT data within 1-σ error. In summary, Einstein-Æther BH solution is in agreement with M87* observation, and moreover we obtain a restriction to low rotational values.

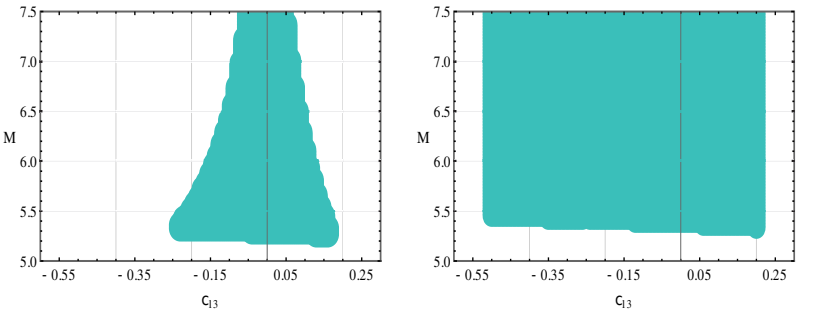

Fig. 3. The allowed parameter region (green) in the $c_{13} - M(10^9 M_{\odot})$ plane, for fixed rotation parameter values $a = 0$ (left graph) and $a = 0.2$ (right graph), for the Einstein-Æther black hole solution (3) with (4), that leads to diameter d in agreement with the observationally determined one d_{M87*} within 1σ-error.

5. Conclusions

In the present work we investigated Hořava-Lifshitz and Einstein-Æther gravity in light of the recent Event Horizon Telescope (EHT) observations of the M87*. In particular, the EHT provided the first visual evidence indicating directly the existence of a compact object such as a supermassive black hole candidate at the center of the M87* galaxy. Since the shape and size of the observed BH shadow contains information of the geometry in the vicinity of the BH, one can consider the shadow as a potential probe to investigate the BH structure within different gravitational theories, due to the fact that in modified gravity one obtain black holes which deviate from those of general relativity.[18] Hence, allowing for a modified gravity as the underlying theory enriches the calculation framework with different size-rotation features as well as with extra model parameters.

We first extracted the black hole solutions for EA gravity, and we calculated the corresponding effective potential $U_{eff}(r)$ for the photons, the resulting event horizon radius r_e and the radius of the unstable photon sphere r_{ps}. Then we straightforwardly calculated the induced angular size δ, which combined with the mass and the distance can lead to a single prediction that quantifies the black hole shadow size, namely the diameter per unit mass d. Since d_{M87*} is observationally known from the EHT Probe, we extracted the corresponding parameter regions of Einstein-Æther theory in order to obtain consistency.

Apart from the restriction of the æther parameter c_{13} to specific ranges, we found some constraints on the dimensionless spin parameter a in slow rotation limit, dependent on the values of æther parameters, which was verified by a full scan of the parameter space. Furthermore, our analysis has indicated that in the Einstein-Æther theory is possible to distinguish a naked singularity from BH. This is indeed a verification of the fact that in modified gravity one obtains different size-rotation features, depending on the extra model parameters, and hence the M87* observation can be in principle described in different ways comparing to general relativity,

especially in theories which possess various corrections on the Kerr-metric solutions, such is the case in Hořava-Lifshitz and Einstein-Æther gravity. In summary, Einstein-Æther black hole solutions are in agreement with EHT M87* observation.

This paper is a summary of a talk given in the proceedings of Sixteenth Marcel Grossmann Meeting (MG16). We study a (3+1)-dimensional Hořava-Lifshitz (HL) gravity which coupling with an anisotropic electromagnetic (EM) field which is obtained from a (4+1)-dimensional HL gravity. The model has a noticeable feature that gravitational and electromagnetic waves have the same velocity in the Minkowski background and the Friedman-Robertson-Walker (FRW) background. Based on this characteristic we put forward a new way to restrict the parameter of the HL gravity by considering the possible Lorentz violation effect of the GRB 170817A. It turns out that in this way we can place a stringent constraint on the parameter of (4+1)-dimensional HL gravity.

Keywords: Hořava-Lifshitz gravity; Lorentz violation effect; GRB 170817A.

1. Introduction

The first gravitational wave (GW) event from a binary neutron star merger, GW170817, was detected by LIGO and Virgo Collaboration,[1] opened the era of multi-messenger astronomy, which create an opportunity to study gravity and cosmology by multiple observations. At the same time, its EM counterpart—GRB 170817A— was observed by Fermi-GBM with a time delay $\Delta t = (1.74 \pm 0.05)s$.[2] Analyzing the time delay between GW170817 and GRB 170817A, one can impose a stringent constraint on the speed deviation between GWs and the GRBs. This in turn may put restrictions on certain models of modified gravity. However, due to the lack of more similar GW events and the way of direct detection of the speed of GWs, it is necessary to develop new methods to restrict the GWs velocity. In view of this, we turn to consider the GW's counterpart: the gamma ray bursts (GRBs). It is of great interest to investigate whether we can limit the velocity of GWs from the GRB data. If this is possible, it may provide an independent approach in restricting the parameter of some modified models of gravity.

On the other hand, Lorentz invariance has been confirmed rigorously in low energy and the light speed is a constancy in General Relativity (GR). However, the viewpoint that the possible Lorentz violation (LV) will happen at energies comparable with the Planck scale ($E_{pl} \approx 1.22 \times 10^{19}$ GeV) has been proposed in many

quantum gravity theories. This possible LV effect may have been observed in some high-energy astrophysical phenomena such as gamma-ray bursts, active galactic nuclei (AGN) and Crab pulsars, etc., and the LV energy scale can be estimated by analyzing the observed time delay or spectra delay of the gamma rays.[3] Then we wonder if the possible LV is common in these high-energy astrophysical phenomena, the GRB 170817A would have the similar LV behavior. It can be then used to study GWs and restrict the parameter of some modified theories of gravity.

For this reason, in this work we consider a special modified model of gravity: a (3+1)-dimensional HL gravity couple with the electromagnetic field which is obtained from a $(4+1)-$dimensions HL gravity through a Kaluza-Klein (KK) reduction. The wave equations for gravitational and EM fields can be obtained by linear perturbations. One of the most significant characteristics of this model is that the speeds of gravitational and EM waves are the same, no matter it is in the Minkowski background or the Friedman-Robertson-Walker (FRW) background. Based on this feature, we can impose restrictions on the propagation velocity of GWs by considering the possible LV effect of the accompanied GRB, which in turn can be applied to limit the parameter of some gravity theories.

2. The (4+1)-dimensional Hořava-Lifshitz gravity

We begin with a (4+1)-dimensional HL gravity. The action of the non-projectable HL gravity in (4+1) dimensions is,[4]

$$S(g_{\mu\nu}, N_\rho, N) = \int dt d^4x N\sqrt{g}\Big[K_{\mu\nu}K^{\mu\nu} - \lambda K^2 + \beta\,{}^{(4)}R + \alpha a_\mu a^\mu + V(g_{\mu\nu}, N)\Big], \quad (1)$$

where μ, ν=1, 2, 3, 4. $V(g_{\mu\nu}, N)$ expresses the higher terms, we can ignore these terms because the most energetic particles of the GRB events are much less than the HL energy scale.

The Hamiltonian density $\mathcal{H}$ can be expressed as

$$\mathcal{H} = \sqrt{g}N\left[\frac{\pi_{\mu\nu}\pi^{\mu\nu}}{g} + \frac{\lambda}{1-4\lambda}\frac{\pi^2}{g} - \beta\,{}^{(4)}R - \alpha a_\mu a^\mu\right] + 2\pi^{\mu\nu}\nabla_\mu N_\nu + \sigma P_N, \quad (2)$$

where $\pi^{\mu\nu}$ is the conjugate momentum to $g_{\mu\nu}$ and we have added the the primary constraints by multiplying the Lagrange multipliers σ and N_ν.

In Eq.(2), we notice that $\lambda = 1/4$ is a kinetic conformal point which will eliminate a scalar mode, but it has no influence on gravity and electromagnetic modes which we are interest. In order to analyze the couplings between gravity modes and electromagnetic modes, we can perform a KK reduction and reduce the theory to (3+1) dimensions. The specific approach is to decompose the 4-dimensional Riemannian metric $g_{\mu\nu}$ in the following way[4]

$$g_{\mu\nu} = \begin{pmatrix} \gamma_{ij} + \phi A_i A_j & \phi A_j \\ \phi A_i & \phi \end{pmatrix}, \quad (3)$$

where γ_{ij} is a 3-dimensional Riemannian metric, A_i, A_j are the anti-symmetric electromagnetism vectors, and ϕ is a scalar field. After a canonical transformation,

the Hamiltonian density (2) can be rewritten by γ_{ij}, A_i, ϕ and their conjugate momenta p_{ij}, p_i and p. Variations with respect to variables γ_{ij}, A_i, ϕ, p^{ij}, p^i, p generate the equations of motion.[4]

For the scalar field ϕ and its conjugate momenta p, we can get their solutions from the equations of motion and find they are constants, regardless of whether it is in the Minkowski background or in the FRW background. As a consequence, one can assume $\bar{\phi} = 1$ and $\bar{p} = 0$ without loss of generality. Under this condition, for the Minkowski background we have

$$\bar{\gamma}_{ij} = \delta_{ij}, \bar{p}_{ij} = 0, \bar{N} = 1, \bar{A}_i = \bar{p}_i = 0, \bar{N}_i = \bar{N}_4 = 0. \tag{4}$$

and for the FRW background it becomes

$$\bar{\gamma}_{ij} = a(t)^2\delta_{ij},\ \bar{p}_{ij} = 0,\ \bar{p} = -a(t)^2\dot{a}(t),\ \bar{N} = 1,\ \bar{A}_i = \bar{p}_i = 0,\ \bar{N}_i = \bar{N}_4 = 0,\ \bar{\phi} = 1. \tag{5}$$

In order to get the wave equations of gravitational tensor and electromagnetic vectors, we can perform perturbations in both two backgrounds. The perturbations of the Minkowski background are

$$\begin{aligned} &\gamma_{ij} = \delta_{ij} + \epsilon h_{ij},\ p_{ij} = \epsilon\Omega_{ij},\ N_i = \epsilon n_i,\ N_4 = \epsilon n_4, \\ &N = 1 + \epsilon n,\ A_i = \epsilon\xi_i,\ p_i = \epsilon\zeta_i,\ \phi = 1 + \epsilon\tau,\ p = \epsilon\chi, \end{aligned} \tag{6}$$

and for the FRW background we have

$$\begin{aligned} &\gamma_{ij} = a(t)^2(\delta_{ij} + \epsilon h_{ij}),\ p_{ij} = \epsilon\Omega_{ij},\ p = -a(t)^2\dot{a} + \epsilon\chi, \\ &N_i = \epsilon n_i,\ N_4 = \epsilon n_4,\ N = 1 + \epsilon n,\ A_i = \epsilon\xi_i,\ p_i = \epsilon\zeta_i,\ \phi = 1 + \epsilon\tau. \end{aligned} \tag{7}$$

where h_{ij}, Ω_{ij}, n_i, n_4, n, ξ_i, ζ_i, τ, χ are linear perturbations for each field.

Inputting these perturbations into the equations of motion, the equations of motion at the linear order of ϵ can be obtained. Imposing the transverse traceless (TT) gauge conditions of tensors and vectors, and combining the constraint conditions, the wave equations of the EM vectors and the gravitational tensors in the Minkowski background are

$$\ddot{\xi}_i^T - \beta c^2\Delta\xi_i^T = 0, \tag{8}$$

$$\ddot{h}_{ij}^{TT} - \beta c^2\Delta h_{ij}^{TT} = 0. \tag{9}$$

Similarly, the wave equations in the FRW background can be obtained in the same way, they are

$$\ddot{\xi}_i^T + H\dot{\xi}_i^T - \beta c^2\triangle\xi_i^T = 0, \tag{10}$$

$$\ddot{h}_{ij}^{TT} + 3H\dot{h}_{ij}^{TT} - \beta c^2\triangle h_{ij}^{TT} = 0, \tag{11}$$

where $H = \dot{a}(t)/a(t)$ is the Hubble parameter.

From these wave equations, we can find that the propagation velocity of the EM waves and the GWs are the same, that is, $\sqrt{\beta}c$, no matter whether it is in the Minkowski background or in the FRW spacetime. In other words, in this model the

speed of GWs is exactly identified with the one of the EM waves. This remarkable feature allows us to examine possible LV of the model (and in turn place possible constraints on the parameter of the model) by detecting the deviation of the speed of the EM waves from the usual speed of light. In what follows we will present how can one get the deviation of the speed of the EM waves by analyzing the observed GRBs data.

3. Lorentz violation from GRB photons

Considering possible LV, the dispersion relation of a particle with energy E can be phenomenologically written as[3]

$$E^2 = p^2c^2 + m^2c^4 - \Sigma_n s_n E^2 \Big(\frac{E}{E_{LV,n}}\Big)^n, \tag{12}$$

where n is an integer, which corresponds to linear or higher-order dependence of the energy in question. $s_n = \pm 1$ is the sign factor of the LV correction, which indicates that the high-energy photons spread slower than the low-energy photons or vice versa. All GRB data we adopt in this paper have the sign $s_n = 1$. $E_{LV,n}$ is the nth-order LV energy scale which can be obtained from the time delay or the spectra lag of the high-energy particles generated from astrophysical sources such as the GRBs, the active galactic nuclei(AGN) and the Crab pulsars, etc.

In this paper, the GRB 170817A is a photon event which has the mass $m = 0$. Consider only the linear effect $n = 1$, Eq. (12) then becomes

$$E^2 = \Big(1 - s_1 \frac{E}{E_{LV,1}}\Big)p^2c^2. \tag{13}$$

The propagation velocity will be modified by the relation $\upsilon = \partial E/\partial P$. Comparing to the speed of EM waves in the previous section, the parameter β has the relation

$$\beta = \Big[1 - s_1\Big(\frac{E}{E_{LV,1}}\Big)\Big]^2. \tag{14}$$

From the relation (14), we can find that the propagation velocity of the GRBs $\sqrt{\beta}c$ depends on the energy of photons and LV energy scale $E_{LV,1}$, that is to say, the LV effect will lead to $\beta \neq 1$. The expression of $E_{LV,1}$ turns out to be

$$E_{LV,1} = s_1 \frac{1}{H_0} \frac{E_h - E_1}{\Delta t_{LV}} \int_0^z \frac{(1+z')dz'}{h(z')}, \tag{15}$$

where $h(z) = \sqrt{\Omega_\Lambda + \Omega_K(1+z)^2 + \Omega_m(1+z)^3 + \Omega_R(1+z)^4}$ and H_0, z, E_h are the Hubble parameter, the redshift and the energy of the high-energy photons, respectively. E_1 is the energy of the low energy photon that the energy is low and we can neglect it.

Removing the intrinsic emission time lag in the source, we can get the value of $E_{LV,1}$ from the time delay or spectral lag of GRB 170817A under ideal conditions. However, due to the lack of the data of high-energy photons (the GRB 170817A

was only observed by Fermi-GBM), the explicit time delay or spectral lag of the GRB 170817A was not detected.[5] Our strategy is to assume that the possible LV observed from other GRBs[6] is generic, that is to say, the GRB 170817A would have the similar LV behavior. We therefore take the value of $E_{LV,1}$ obtained from these GRB data. It turns out that $E_{LV,1}$ has the following characteristics: Firstly, using different GRB data will get different constraints on $E_{LV,1}$. Secondly, different analysis methods, energy sections or cosmological models will effect the result even if the same event such as GRB 090510. The full list of the restrictions on $E_{LV,1}$ can be found in our previous work,[7] which indicates that $E_{LV,1}$ ranges from 10^{17} GeV to 10^{20} GeV from the time lag of the GRBs (the newest GRB events,[8] where $E_{LV,1} \sim 10^{17}$ GeV, is also in this range).

As for the highest energy of the photon of the GRB 170817A, we estimate it by gamma-gamma absorption with the bulk Lorentz factors Γ in the early phase. The specific method is presented in Ref.[9]

$$E_{high} = \frac{\Gamma^2 (m_e c^2)^2}{E_{high,an}(1+z)^2}, \tag{16}$$

where z is the redshift of the GRBs, m_e is the mass of electron, $E_{high,an}$ is the spectral break/cutoff energy and E_{high} is the corresponding highest energy of photons. Generally speaking, one can assume $E_{high,an} = E_{peak}$ (the peak energy of the Band fit of the GBM data), which implies those photons have the maximum probabilities to undergo the absorption with the highest-energy photons (E_{high}). As to the value of the Lorentz factor, we apply the estimated values $(100 - 10^{2.5})$ as suggested in the literatures,[10,11] combining the observations data of the GRB 170817A ($E_{peak} = (185 \pm 62)$ keV and $z \simeq 0.01$ in[2]), we can have an estimation $E_{high} \sim (10 - 200)$ GeV.

Based on these two estimations, we can find that the speed of the GRB 170817A has a tiny deviation with the light speed c due to the possible LV effect, and the deviation depends on the highest energy photons E_{high} and LV energy scale $E_{LV,1}$. In the most stringent constraint $E_{LV,1} \sim 10^{20}$ GeV,[12] the deviation can be restricted in the range

$$|\triangle v/c| < (10^{-19} - 10^{-18}). \tag{17}$$

4. Result

With the constraint (17), now we can turn to discuss the constraint on the HL gravity. Recalling that the speed of electromagnetic and gravitational waves are the same as discussed in the previous sections. Therefore the speed of GW respects the same constraint as Eq. (17). This, in turn, puts a constraints on the parameter β of the model

$$|1 - \sqrt{\beta}| < (10^{-19} - 10^{-18}). \tag{18}$$

This is the main result of the paper. Some points should be addressed in what follows. Firstly, due to the lack of direct observation on the time delay of the GRB 170817A, we do not have direct value of $E_{LV,1}$ of this event. Instead, we estimate it by using values obtained from other GRB events. Therefore, the above result (18) depends on which GRB events we adopt. Secondly, up to date, the lack of more GW event companying EM counterpart makes it difficult to implement a statistic analysis. Hence, the system error of our result expect to be obvious. Moreover, this result has the limitation that it is only valid for the present HL gravity model which has the feature that the speed of EM waves and GWs are the same. In spite of these, our result is meaningful since it provide a new way to constraint the model parameter from the properties of matter (the LV effect of GRBs for example as what we did in this work). Meanwhile, with the development of detectors, the first two flaws will be wiped since we can expect with more events it is possible to directly observe the time lag of the EM counterpart.

5. Conclusion

In this talk we present a (3+1)-dimensional HL gravity couple to an anisotropic EM field, which can be obtained by a KK reduction from a (4+1)-dimensional HL gravity. The most remarkable feature of this model is that the electromagnetic and gravitational waves have the same speed, both in the Minkowski background and the FRW spacetime. Then we can use this feature to restrict the speed of gravitational wave and the parameter of model by analyzing the LV effect of the companying EM event, the GRB 170817A. We find, up to some estimations, the parameter β of the model can be received a more stringent constraint than the one obtained from GW analysis itself.

Summary of the parallel session AT6

Anzhong Wang
GCAP-CASPER, Physics Department, Baylor University, Waco, Texas, 76798-7316, USA
E-mail: Anzhong_Wang@baylor.edu

In this brief report, as the session convener of Hořava-Lifshitz (HL) Gravity (AT6), I summarize the main results of the 15 talks presented in the 16th Marcel Grossmann Meeting, July 5–10, 2021. This session mainly focused on classical and quantum aspects of HL gravity and some related theories, such as Einstein-aether theory and khronometric gravity, as well as their applications to cosmology and astrophysics.

Keywords: Anisotropic scaling; breaking Lorentz symmetry; quantizations; black holes; cosmology

1. A Brief Introduction to Hořava-Lifshitz gravity

Hořava-Lifshitz (HL) gravity is a theory proposed by Hořava in 2009.[1] To avoid Ostrogradsky's ghosts,[2,3] a problem that has been plaguing quantization of general relativity (GR) since the middle of 1970's,[4] Hořava chose to break the Lorentz invariance (LI) by a Lifshitz-type of anisotropic scaling between space and time at the ultra-high energy,[5,6] $t \to b^{-z}t,\ x^i \to b^{-1}x'^i,\ (i = 1, 2, ..., d)$, where z denotes the dynamical critical exponent, and d the spatial dimension of the spacetime. LI requires $z = 1$, while power-counting renomalizibility requires $z \geq d$. With the above scalings, the time and space have, respectively, the dimensions, $[t] = -z$, $\left[x^i\right] = -1$. Clearly, such a scaling breaks explicitly the LI and hence the diffeomorphism invariance. Hořava assumed that it is broken only down to the level

$$t \to \xi_0(t), \quad x^i \to \xi^i\left(t, x^k\right), \tag{1}$$

so the spatial diffeomorphism still remains. The above symmetry is often referred as to *the foliation-preserving diffeomorphism*, denoted by Diff(M, $\mathcal{F}$). Introducing the Arnowitt-Deser-Misner (ADM) variables $\left(N, N^i, g_{ij}\right)$,[7] where $N,\ N^i$ and g_{ij}, denote, respectively, the lapse function, shift vector, and d-dimensional metric of the leaves t = constant, it is found that they are scaling, respectively, as,[1] $N \to N,\ N^i \to b^{z-1}N^i,\ g_{ij} \to g_{ij}$, so that their dimensions are $N = 0,\ \left[N^i\right] = z - 1,\ [g_{ij}] = 0$. With the above symmetry, one can construct the basic operators of the fundamental ADM variables and their derivatives, which turn out to be,

$$R_{ij}, \quad K_{ij}, \quad a_i, \quad \nabla_i, \tag{2}$$

where $a_i \equiv N_{,i}/N$, and ∇_i denotes the covariant derivative with respect to g_{ij}, while R_{ij} and K_{ij} are the d-dimensional Ricci tensor, and the extrinsic curvature tensor of the leaves t= constant, respectively, constructed from the g_{ij} and g^{ij} where

$g_{ij}g^{ik} = \delta^k_j$, and $K_{ij} \equiv \left(-\dot{g}_{ij} + \nabla_i N_j + \nabla_j N_i\right)/(2N)$, with $\dot{g}_{ij} \equiv \partial g_{ij}/\partial t$. These basic quantities are vectors/tensors under the coordinate transformations (1), and have the dimensions, $[K_{ij}] = z,\ [R_{ij}] = 2,\ [a_i] = 1,\ [\nabla_i] = 1$. With the basic blocks of Eq.(2), we can build scalar operators order by order, so the total Lagrangian will take the form,[1]

$$\mathcal{L}_g = \sum_{n=0}^{2z} \mathcal{L}_g^{(n)}\left(N, N^i, g_{ij}\right), \tag{3}$$

where $\mathcal{L}_g^{(n)}$ denotes the part of the Lagrangian that contains operators of the nth-order only. Including all the terms that are allowed by the symmetry, it was found that there are about 100 terms appearing in the above action in the case $d = z = 3$.

To reduce the number of independent coupling terms, Hořava introduced *the projectability condition*,[1] which requires that the lapse function be a function of t only, $N = N(t)$, so that all the terms proportional to a_i and its derivatives will be dropped out. This will reduce the total number of the independent terms in Eq.(3) to 14 (including the cosmological constant and parity-violated terms).[8] However, despite of various desired features, this condition leads to several problems, including that the Newtonian limit does not exist, and the six-order derivative operators are eliminated, so the theory is still not power-counting renormalizable. In addition, it is not clear if this symmetry is still respected by radiative corrections. Even more fundamentally, the foliation-preserving diffeomorphism (1) allows one more degree of freedom in the gravitational sector, in comparing with that of general diffeomorphism. As a result, a spin-0 mode of gravitons appears generically. This mode is potentially dangerous and may cause ghosts and instability problems, which lead the constraint algebra dynamically inconsistent.

To solve these problems, various modifications have been proposed.[8] In some of these models the Einstein-aether theory[9] and khronometric gravity[10] are particular cases. For a recent review on these models, we refer readers to Ref. 8.

2. Summary of the 15 Talks

In this section, I summarize the main results of the 15 talks in a chronological order.

• Sato presented a joint work with Ambjorn, Hiraga and Ito. In particular, they quantized the 2D projectable HL gravity with a bi-local as well as spacelike wormhole interaction, and found that the resulting quantum Hamiltonian coincides with the one obtained through summing over all genus in the string field theory for 2D causal dynamical triangulations. This implies that the wormhole interaction can be interpreted as a splitting or joining interaction of 1D strings.

• Bellorín presented a joint work with Droguett, and showed that the Batalin-Fradkin-Vilkovisky (BFV) quantization scheme can be implemented in the nonprojectable 3D HL theory. The BFV quantization is based on the canonical formalism and suitable to incorporate the measure associated to the second-class constraints

that the theory has. They presented the Becchi-Rouet-Stora-Tyutin symmetry transformations in the canonical variables, and found that the theory is of rank one in the classification introduced by Fradkin and Fradkina. In particular, they found that the nonlocal gauge condition introduced in the projectable theory can be included among these gauges.

• Satheeshkumar presented a talk on how the nature of singularities and horizons in vector-tensor theories differ significantly from GR. In particular, by considering Einstien-aether theory, based on a joint work with Chan and da Silva, he showed that, due to the presence of the aether field, vacuum black holes in GR are replaced by naked singularities, while new singularities appear in some cosmological models of GR.

• Lappicy presented a joint work with Hell and Uggla on bifurcations and chaos in HL cosmology. In particular, they considered the initial singularity in spatially homogeneous Bianchi type VIII and IX vacuum models, where relativistic first principles are replaced with anisotropic scalings of Lifshitz type. Within this class of models, GR is shown to be a bifurcation where chaos becomes generic. To describe the chaotic features of generic singularities in HL cosmology, they introduced symbolic dynamics within Cantor sets and iterated function systems, and obtained the general properties of various cases.

• Shu presented his joint work with Zhang, Tang and Du on constraining HL gravity from GRB 170817A observations. In particular, they considered the HL gravity coupling with an anisotropic electromagnetic field, generated through a Kaluza-Klein reduction of a $(4+1)$-dimensional HL gravity, and found that the model has the same velocity for both gravitational and electromagnetic waves. By analyzing the possible Lorentz invariance violation effect of the GRB 170817A, they found a stringent constraint on a parameter β of the theory with $\left|1-\sqrt{\beta}\right| < (10^{-19}-10^{-18})$.

• Saridakis presented his joint work with Khodadi on Einstein-aether gravity in the light of Event Horizon Telescope (EHT) observations of M87, and calculated the photon effective potential, the unstable photon sphere radius, and the induced angular size of two analytical black hole solutions in the theory. Since d_{M87*} is observationally known from the EHT Probe, they extracted the corresponding parameter regions in order to obtain consistency, and found that the Einstien-aether black hole solutions agree with the shadow size of EHT $M87*$, if the involved aether parameters are restricted within specific ranges, along with an upper bound on the dimensionless spin parameter a, which is verified by a full scan of the parameter space within 1σ-error.

• Ajith presented a joint work with Yagi and Yunes on testing HL gravity with I-Love-Q. The authors studied how the I-Love-Q relations depend on the parameters of the theory, and found that the only un-constrained parameter disappears from the field equations in HL gravity. Therefore, the I-Love-Q relations are universal against not only the nuclear physics uncertainty but also the gravitational physics uncertainty within HL gravity.

• Ghosh presented a joint work with Kumar on the Einstein-Gauss-Bonnet (EGB) gravity under the limit $D \to 4$, and studied rotating black holes in regularized 4D EGB gravity and their horizon properties and shadows. In particular, they found that the $4D$ non-relativistic Horava-Lifshitz theory of gravity also admits the identical black hole solution. The effects of the GB coupling parameter on the shape and size of shadows were investigated and analyzed in recent M87 observations from EHT. They estimated the parameters associated with the 4D EGB gravity Kerr black holes using the shadow observables, and found that the inferred circularity deviation $\Delta C \leq 0.1$ for the M87 black hole, whereas shadow angular diameter $\theta_d = 42 \pm 3\mu as$ within the 1σ region on the GB parameter. Interestingly, the shadow axial ratio obeying undefined control sequence is in agreement with the EHT results and thus eventuates in the 4D EGB gravity black holes being suitable candidates for astrophysical black holes.

• Bamba presented a joint work with Chakraborty and Saa on dynamical system analysis of the homogeneous and anisotropic Bianchi-I spacetimes in $f(R)$ gravity coupled with an anisotropic matter. It was demonstrated that with a suitable choice of the evolution parameter, Einstein's equations are reduced to an autonomous 5D system of ordinary differential equations. Furthermore, for a large class of functions $f(R)$, which includes several cases commonly considered in the literature, all the fixed points are polynomial roots, and thus they can be determined with a good accuracy and classified for stability. In addition, any fixed point corresponding to isotropic solutions in the presence of anisotropic matter will be unstable. The assumption of a perfect fluid as source and or the vacuum cases imply some dimensional reductions and even more simplifications. In particular, it was found that the vacuum solutions of $f(R) = R^{\delta+1}$ (with δ = constant) are governed by an effective 2D phase space which can be constructed analytically, leading to an exactly solvable dynamics.

• Jawad presented various solutions of Einstein-aether gravity through a reconstruction approach. In order to discuss the current cosmic acceleration corresponding to his reconstructed models, he evaluated different cosmological parameters, and discussed the consistency of his results of cosmological parameters with current observational data.

• de Souza Campos presented her joint work with Dappiaggi and Sina on boundary conditions for the Klein-Gordon field in Lifshitz spacetimes. In particular, she considered a free, scalar, massive quantum field theory on a 4D Lifshitz spacetime with a critical exponent $z = 2$ and showed that there are two-point functions for ground and thermal states of the local Hadamard form and satisfying the canonical commutation relations, compatible with Robin's boundary conditions and with mode-dependent boundary conditions, depending on the value of the effective mass. Each of these generalized boundary conditions determine an inequivalent dynamics, but they are all equivalently physically sensible.

• Panotopoulos presented his recent work on non-rotating and isotropic strange quark stars in HL gravity and Einstein-æther theory. For quark matter he adopted

both linear and non-linear equations of state (EoS), corresponding to the MIT bag model and color flavor locked state, respectively. The new structure equations describe the generalization of the hydrostatic equilibrium of the usual Tolman-Oppenheimer-Volkoff (TOV) equations of GR, parameterized by a dimensionless deviation parameter v. He computed the mass, radius and compactness of the stars, and showed graphically the impact of v on the mass-to-radius profiles for different EoS describing quark matter. The energy conditions and stability criteria were also considered, and found that they are all fulfilled.

• Lin presented a joint work with Wang, Zhang, Zhao and Zhu on testing Einstein-aether theory by gravitational wave (GW) observations. In particular, he presented their recent studies of GWs produced by massive and compact objects, including the GW waveforms, polarizations, response function, Fourier transform, and energy loss rate through three different channels of radiation - the scalar, vector and tensor modes, and showed that combination of such theoretical predictions with future observations of GWs can bring severe constraints on the theory.

• Kwapisz presented a joint work with Chojnacki on finite action principle and black holes in HL gravity, and showed that the finite action selection principle works well for HL gravity in the context of black holes. In addition, wormholes possess a finite action and hence contribute to the path-integral of quantum gravity.

• Chojnacki presented a joint work with Kwapisz on their studies of the finite action principle and the beginning of the universe in HL gravity, and showed that field configurations with finite classical action describe a flat universe with a homogeneous and isotropic beginning without the ghost particles.

The emergence of R^2 (Starobinsky) inflation from the semi-classical modification of gravity due to matter quantum fields (trace anomaly) clearly points out the importance of fundamental physics and the first principles in the construction of successful cosmological models. Along with the observational success, R^2 gravity is also an important step beyond general relativity (GR) towards quantum gravity. Furthermore, several approaches of quantum gravity to date are strongly indicating the presence of non-locality at small time and length scales. In this regard, ultraviolet (UV) completion of R^2 inflation has been recently studied in a string theory-inspired ghost-free analytic non-local gravity. We discuss the promising theoretical predictions of non-local R^2-like inflation with respect to the key observables such as tensor-to-scalar ratio, tensor tilt which tell us about the spectrum of primordial gravitational waves, and scalar Non-Gaussianities which tell us about the three-point correlations in the CMB fluctuations. Any signature of non-local physics in the early Universe will significantly improve our understanding of fundamental physics at UV energy scales and quantum gravity.

Keywords: Quantum gravity, Inflation, CMB, Gravitational Waves

1. Status of inflation and the quests for UV-completion

Inflationary cosmology has become the most important field of study in theoretical higher energy physics (THEP) in the recent years not only because of its success with respect to the data of Cosmic Microwave Background (CMB)[1–3] but also it gives a best chance to test our approaches to build physics at the fundamental scales such as Planck energy or length scales. Recent detection of Gravitational Waves from binary black hole merger events further corroborated to build new hopes and strategies to probe the physics of early Universe.[4,5]

Inflationary cosmology is so far developed in two equivalent ways. One is by geometrical modification i.e., by extension of General Relativity (GR) by higher curvature terms (for example "$R + R^2$ gravity which is also known as Starobinsky theory[6–9]). Second way is by the addition of hypothetical (scalar) matter fields which result in modification of right hand side of Einstein equations.[10,11] This second way motivated in the view of particle physics beyond the standard model and several ultraviolet (UV) complete approaches such as string theory and supergravity (SUGRA).[12] In this regard, inflationary cosmology is so far studied from the point of view of beyond the standard model of particle physics and as a low-energy limit of UV-complete approaches such as string theory/M-theory (see left panel of Fig. 1).

In the last decades plethora of inflationary models have been constructed with different scalar fields emerging from simplest set ups to all the way up to the most general scalar tensor theories[13,14] (see left panel of Fig. 1). However the latest data from Planck satellite[1] has found out Starobinsky and Higgs inflation be the most compatible models with the following predictions of spectral index and the tensor to scalar ratio

$$n_s = 1 - \frac{2}{N}\,, \qquad r = \frac{12}{N^2}\,, \tag{1}$$

where $N = 50 - 60$ number of e-folds before the end of inflation. The recent Planck data[1,2] has constrained $n_s = 0.9649 \pm 0.0042$ at 68%CL, $r < 0.036$ at 95% CL. The success of Starobinsky and Higgs inflation has lead to the emergence of equivalent frameworks of inflation in string theory and SUGRA.[12]

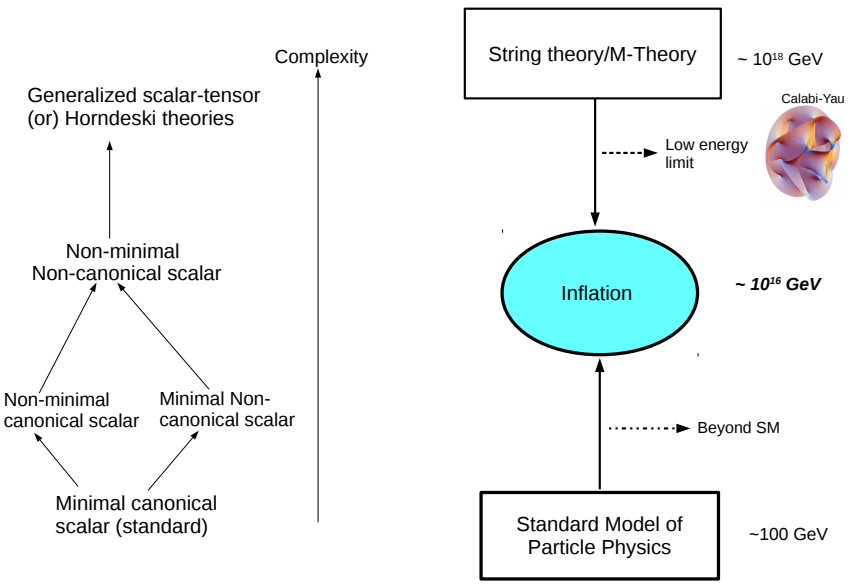

Fig. 1. In the right panel, arrow of complexity shows how one can start with a simplest scalar field Lagrangian and generalized all the way up to most general scalar-tensor theories whose equations of motion are second order in field derivative. In the right panel we can see that inflationary cosmology can be understood well either from beyond the standard model of particle physics or from low-energy limit of a UV-complete approaches such as string theory (This Figure taken from[13]).

The challenging problem of the current status of inflationary cosmology is to break several degeneracies in the frameworks of inflation and find definitive clues towards achieving quantum gravity and UV-completion. For this purpose, from observational point of view, one must go beyond the two observables (n_s, r). In this regard there are two more important observational parameters known as tensor tilt

(n_t) which is the tilt of the tensor power-spectrum and non-Gaussianity parameter (f_{NL}) which is related to the 3-point scalar correlations. If inflation is driven by single (canonical) scalar field with standard slow-roll then the tensor consistency relation[13] and the Maldacena consistency relation[15] given by

$$r = -8n_t \quad f_{NL}^{\rm sq} = \frac{5}{12}(1 - n_s) \tag{2}$$

serves as a crucial test. Here $f_{NL}^{\rm sq}$ is so-called squeezed shape of non-Gaussianity. If inflation is driven by multiple fields then the above consistency relations are understood to be violated.[16] If inflation is driven by non-canonical scalar fields and if non-standard quantum initial conditions are assumed we will find a strong signal in the equilateral ($f_{NL}^{\rm eq}$) and orthogonal ($f_{NL}^{\rm ortho}$) shapes of non-Gaussianities. These shapes are constrained by the latest Planck data as

$$f_{\rm NL}^{\rm loc} = 0.8 \pm 5.0\,, \quad f_{\rm NL}^{\rm equi} = -4 \pm 43\,, \quad f_{\rm NL}^{\rm ortho} = -26 \pm 21\,, \quad \text{at } 68\%\text{CL}. \tag{3}$$

Violation of consistency relations (2) and any detection of $f_{NL} \sim O(1)$ is definitely a new physics in the context of early Universe cosmology which will be crucial for further advancements in THEP. Moreover, in a quest to find signatures of new physics, recently a new program of research has gained significant attention known as "cosmological collider physics"[17] whose aim is to find signatures of higher energy particles interacting with primordial fields during inflation.

Despite numerous phenomenological approaches in understanding inflation and find new observables to probe physics of inflation, it is very vital to focus on consistency of our theoretical endeavors. The success of Starobinsky and Higgs inflationaris (which are almost identical during inflation) covey us a very crucial property that at the scale of inflation approximate "scale invariance" symmetry of the Lagrangian is important. The fact that various setups of SUGRA leading to Starobinsky-like or R^2-like inflation[12] indicate that $R + R^2$ is an important modification of GR. In the next section, we will discuss in detail about the foundations of Starobinsky inflation and how a very straightforward procedure from geoemertric modification of gravity lead us a UV-complete framework.[18–21]

2. From Starobinsky inflation to Stelle gravity and the emergence of ghost-free UV-non-local gravity

$R + R^2$ gravity should not be viewed as a toy model in the class of f(R) gravity. The theory naturally emerges from generic considerations and important questions about UV-completion which dates back the discovery of trace anomaly.[22] The trace anomaly comes from 1-loop quantum corrections to the graviton propagator due to matter conformal fields leading to an anomalous non-zero trace of energy momentum tensor which is proportional to curvature square term.

$$M_p^2 R = g^{\mu\nu}\langle T_{\mu\nu}\rangle = aF + bG + c\Box R\,, \tag{4}$$

where $F = W_{\mu\nu\rho\sigma}W^{\mu\nu\rho\sigma}$ is the the Weyl tensor square and $G = R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} - 4R_{\mu\nu}R^{\mu\nu} + R^2$ is the so-called Gauss-Bonnet term and $R_{\mu\nu\rho\sigma}$, $R_{\mu\nu}$, R Riemann tensor, Ricci tensor and Ricci scalar respectively. Here a, b, c are dimensionless coefficients quantified by the number of conformal fields. Trace anomaly has been widely studied and applied in various fundamental theories including anticipated UV complete theories such as string theory and supergravity (SUGRA).[22] Neglecting the coefficients a, b the trace anomaly equation reduces to the trace equation of the $R + R^2$ given by the action[6,23]

$$S_{R^2} = \int d^4x\sqrt{-g}\left[\frac{M_p^2}{2}R + \frac{M_p^2}{12M^2}R^2\right], \tag{5}$$

where $M \ll M_p$ becomes the mass of a propagating scalar in this model, named scalaron. Independent of what is the right framework of UV-completion R^2 term is very natural term that appears as a classical addition to the GR and it naturally leads to a quasi-de Sitter evolution (which is "cosmic inflation") in the high curvature regime $R \gg M^2$. Therefore it is a matter of fact that $R + R^2$ gravity indeed an unavoidable and very important extension of GR. Further more if we add Weyl square term to the action of $R+R^2$ gravity (5) the resultant gravity theory becomes renormalizable (which is an important property to achieve quantum gravity) as it was proven by K. S. Stelle long ago[24]

$$S_{\text{Stelle}} = S_{R^2} = \int d^4x\sqrt{-g}\left[\frac{M_p^2}{2}R + \frac{M_p^2}{12M^2}R^2 + \frac{M_p^2}{M_g^2}W_{\mu\nu\rho\sigma}W^{\mu\nu\rho\sigma}\right]. \tag{6}$$

However, Stelle gravity unfortunately falls short in becoming a consistent theory of quantum gravity because of the presence of a massive tensor ghost in the spectrum which spoils Unitarity. A natural question one can ask is that whether this ghost can be removed by any higher derivative extension of Stelle gravity. Due to Ostrogradsky theorem any finite derivative extension of Stelle gravity results in further introduction of ghosts in the spectrum and it becomes not a viable option. However, Krasnikov has shown that analytic infinite derivative extension of Stelle gravity (i.e., analytic non-local gravity) can give a ghost-free theory.[25]

$$S = \int d^4x\sqrt{-g}\left(\frac{M_p^2}{2}R + \frac{1}{2}\left[R\mathcal{F}_R\left(\Box_s\right)R + W_{\mu\nu\rho\sigma}\mathcal{F}_W\left(\Box_s\right)W^{\mu\nu\rho\sigma}\right]\right), \tag{7}$$

where $\Box_s = \frac{\Box}{\mathcal{M}_s^2}$ with $\Box$ is being the d'Alembertian and $\mathcal{F}_R, \mathcal{F}_W$ analytic infinite derivative operators or non-local form factors. This theory (7) has been studied over the years and understood to have good properties of UV-completion with respect to renormalizability and Unitarity (See[21] and the references therein). In a nutshell, the action (7) is a very logical extension of Stelle gravity and we very much straightforwardly end up with introducing non-locality in the gravity sector. Note that "Non-locality" is a very important common concept that appears in several approaches to quantum gravity such as string theory, loop quantum gravity,

causal sets and non-commutative gravity. Therefore, (7) is a culmination of various approaches which allow us to give a consistent UV-completion for Starobinsky inflation[a]. Further note that (7) should not be understood as an effective theory but rather a consistent part of a UV-complete theory. We do not have any cut off scales in the theory and the scale $\mathcal{M}_s$ represents the scale at which non-local nature of gravity is prominent. In the next section, we will discuss the cosmological application of (7) and identify the specific features of non-local gravity which can be probed in the future observations.

3. Non-local R^2-like inflation and future targets for CMB and gravitational wave observations

In this section, we apply UV non-local quadratic curvature gravity in the context of inflationary cosmology. The first and foremost difficulty is associated with solving equations of motion of an infinite derivative theory which perhaps appears to be an impossible task. However, this was consistency achieved[18] and it was also quite rigorously shown in[19] that the theory contains an inflationary attractor solution exactly same as the local $R + R^2$ or Starobinsky theory. To see this explicitly let us write down the background equations of motion for (7) Friendmann-Lemaître-Robertson-Walker background for which the Weyl tensor is zero

$$\bar{E}^{\mu}_{\nu} \equiv -\left[M_p^2 + 2\lambda\mathcal{F}\left(\frac{\Box}{\mathcal{M}_s^2}\right)\bar{R}\right]\bar{G}^{\mu}_{\nu}\delta^{\mu}_{\nu} - \frac{1}{2}\bar{R}\mathcal{F}\left(\frac{\Box}{\mathcal{M}_s^2}\right)\bar{R}\delta^{\mu}_{\nu} + 2\left(\nabla^{\mu}\partial_{\nu} - \delta^{\mu}_{\nu}\Box\right)\mathcal{F}\left(\frac{\Box}{\mathcal{M}_s^2}\right)R + \bar{\mathcal{K}}^{\mu}_{\nu} - \frac{\lambda}{2}\delta^{\mu}_{\nu}\left(\bar{\mathcal{K}}^{\sigma}_{\sigma} + \bar{\mathcal{K}}\right) = 0\,,$$

where

$$\bar{\mathcal{K}}^{\mu}_{\nu} = \frac{1}{\mathcal{M}_s^2}\sum_{n=1}^{\infty} f_n \sum_{l=0}^{n-1}\partial^{\mu}\frac{\Box^l}{\mathcal{M}_s^{2l}}\bar{R}\partial_{\nu}\left(\frac{\Box}{\mathcal{M}_s^2}\right)^{n-l-1}\bar{R}\,,$$

$$\bar{\mathcal{K}} = \sum_{n=1}^{\infty} f_n \sum_{l=0}^{n-1}\frac{\Box^l}{\mathcal{M}_s^{2l}}\bar{R}\left(\frac{\Box}{\mathcal{M}_s^2}\right)^{n-l}\bar{R}\,.$$

The trace equation is

$$\bar{E} = M_p^2\bar{R} - 6\bar{\Box}\mathcal{F}\left(\frac{\bar{\Box}}{\mathcal{M}_s^2}\right)\bar{R} - \bar{\mathcal{K}}^{\mu}_{\mu} - 2\bar{\mathcal{K}} = 0\,. \tag{8}$$

It was showed in[19] that the only solution of the above equations is $\bar{\Box}\bar{R} = M^2\bar{R}$ given the following Unique conditions on the form factor are satisfied.

$$\mathcal{F}'_R\left(\frac{M^2}{M_s^2}\right) = 0,\ \frac{M_P^2}{2\lambda} = 3M^2\mathcal{F}_1,\ \text{ where } \mathcal{F}_1 \equiv \mathcal{F}_R\left(\frac{M^2}{\mathcal{M}_s^2}\right) \tag{9}$$

[a]Worth to metion that Starobinsky inflation has also been embedded in SUGRA which gives an interesting route for UV-completion.[26] Here we focus on non-supersymmetric aspects of UV-completion.

Fig. 2. We depict here the hierarchy of mass scales in non-local R^2-like inflation.

where $'$ denotes derivative with respect to argument. Note that $\bar{\Box}\bar{R} = M^2\bar{R}$ is the trace equation of local $R + R^2$ which gives Starobinsky inflationary solutions. Here given the conditions (9) are met we can solve exactly the full non-local gravity equations of motion and also we have good inflationary solution. Now it is important to see how non-local effects of gravity appear through inflationary perturbations. Before we go this step we can draw a heuristic bound on the scale of non-locality shown in Fig. 2 based on the fact that we require near scale invariance at the scale of inflation. This can be seen heuristically by expanding the quadratic Ricci scalar part of the action as

$$S = \int d^4x\sqrt{-g}\left[\frac{M_p^2}{2}R + \frac{M_p^2}{12M^2}R^2 + \mathcal{O}\left(\frac{M_p^2 R\Box R}{M^2\mathcal{M}_s^2}\right)\right].$$

In the high curvature regime $R \gg M^2$ local quadratic curvature term is naturally dominant and it is known to be scale invariance.

3.1. *Scalar and tensor power spectrum*

To study perturbations around quasi-de Sitter we take the perturbed metric of the form

$$ds^2 = a^2(\eta)\left[-(1+2\Phi)\,d\eta^2 + ((1-2\Psi)\,\delta_{ij} + 2h_{ij})\,dx^i dx^j\right], \tag{10}$$

where Φ, Ψ are Bardeen potentials and h_{ij} is tensor fluctuation. The study of non-local perturbed equations of motion[19] has revealed that $\Phi + \Psi \approx 0$ during inflation. Since $\delta W_{\mu\nu\rho\sigma} \propto (\Phi + \Psi)$ the Weyl tensor part in (7) does not contribute to the scalar perturbations during inflation. Following the computations in[19,20] the second order action of scalar degree of freedom in de Sitter approximation becomes

$$\delta^2 S_{(s)} = \frac{1}{2\mathcal{F}_1\bar{R}}\int d\tau d^3x\sqrt{-\bar{g}}\Upsilon\frac{\mathcal{W}\left(\frac{\bar{\Box}}{\mathcal{M}^2}\right)}{\mathcal{F}_R\left(\frac{\bar{\Box}}{\mathcal{M}^2}\right)}(\bar{\Box} - M^2)\Upsilon\,, \tag{11}$$

where $\Upsilon \approx 2\bar{R}\Psi$. In order not to have any more ghost degrees of freedom we choose the structure of form factor as

$$\mathcal{F}_R(\Box_s) = \mathcal{F}_1\frac{3e^{\gamma_S(\Box_s)}\left(\Box_s - \frac{M^2}{\mathcal{M}_s^2}\right) + \left(\frac{\bar{R}}{\mathcal{M}_s^2} + 3\frac{M^2}{\mathcal{M}_s^2}\right)}{3\Box_s + \frac{\bar{R}}{\mathcal{M}_s^2}}, \tag{12}$$

where $\bar{R} \approx$ constant and γ_S is an entire function. Therefore, the theory now has only one scalar(on) degree of freedom similar to local $R + R^2$ theory but however, the the scalar field here is non-local in nature.

Computation of the power spectrum and the scalar spectral index of curvature perturbation $\mathcal{R} = \Psi + H\frac{\delta R}{\dot{R}} = \Psi + \frac{24H^3}{24H\dot{H}}\Phi \approx -\frac{1}{\epsilon}\Psi$ we get

$$\mathcal{P}_{\mathcal{R}} = \frac{H^2}{16\pi^2\epsilon^2}\frac{1}{3\lambda\mathcal{F}_1\bar{R}}\bigg|_{k=aH}, \quad n_s \equiv \frac{d\ln\mathcal{P}_{\mathcal{R}}}{d\ln k}\bigg|_{k=aH} \approx 1 - \frac{2}{N}. \tag{13}$$

Similarly the computation of the second order action of tensor perturbations gives (with addition of the non-trivial contributions from the Weyl tensor part in (7))

$$\delta^2 S_{(T)} = \frac{1}{2}\int d^4x\sqrt{-\bar{g}}h^{\perp}_{ij}e^{2\gamma_T\left(\Box_s - \frac{2\bar{R}}{3\mathcal{M}_s^2}\right)}\left(\bar{\Box} - \frac{\bar{R}}{6}\right)h^{\perp ij}, \tag{14}$$

where

$$\mathcal{F}_W(\Box_s) = \frac{\mathcal{F}_1\bar{R}}{\mathcal{M}_s^2}\frac{e^{\gamma_T\left(\Box_s - \frac{2}{3}\frac{\bar{R}}{\mathcal{M}_s^2}\right)} - 1}{\Box_s - \frac{2\bar{R}}{3\mathcal{M}_s^2}}. \tag{15}$$

which fixes the tensor degree of freedom to be just massless graviton.

Computing the tensor power spectrum in the leading order in slow-roll we obtain

$$\mathcal{P}_{\mathcal{T}}|_{k=aH} = \frac{H^2}{\pi^2\mathcal{F}_1\bar{R}}e^{-2\gamma_T\left(\frac{\bar{R}}{6\mathcal{M}_s^2}\right)}. \tag{16}$$

As a result the key inflationary parameter called tensor-to-scalar ratio becomes

$$r = \frac{12}{N^2}e^{-2\gamma_T\left(\frac{-\bar{R}}{2\mathcal{M}_s^2}\right)}\bigg|_{k=aH}. \tag{17}$$

The tilt of the tensor power spectrum can be obtained as

$$\begin{aligned} n_t \equiv \frac{d\ln\mathcal{P}_{\mathcal{T}}}{d\ln k}\bigg|_{k=aH} &\approx -\frac{d\ln\mathcal{P}_{\mathcal{T}}}{dN}\left(1 + \frac{1}{2N}\right)\bigg|_{k=aH} \\ &\approx -\frac{3}{2N^2} - \left(\frac{2}{N} + \frac{3}{2N^2}\right)\frac{\bar{R}}{2\mathcal{M}_s^2}\gamma_T^{(\prime)}\left(-\frac{\bar{R}}{2\mathcal{M}_s^2}\right)\bigg|_{k=aH}, \end{aligned} \tag{18}$$

where $'$ denotes derivative with respect to the argument.

4. Primordial (scalar) non-Gaussianities

Beyond two point correlations it is interesting to see if there will be non-Gaussianities in non-local R^2-like inflation. As we discussed before the scalar(on) in the non-local R^2-like inflation is non-local in nature. Therefore, we generally expect the non-local interactions to play a role in predicting inflationary 3-point correlations different from the local theories. The primordial (scalar) non-Gaussianities in

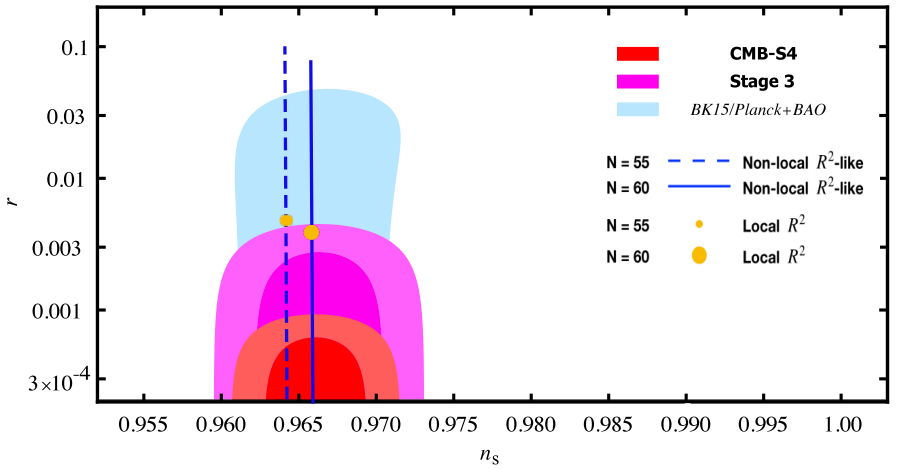

Fig. 3. We depict the predictions of non-local R^2-like inflation in the (n_s, r) plane of the latest CMB S-4 science paper about future forecast of detecting B-modes.[19, 21, 27]

the non-local R^2-like inflation are computed in[20] and here we briefly review the main results. The 3-point correlations and the parameter f_{NL} are defined by

$$\langle \mathcal{R}(\mathbf{k_1})\,\mathcal{R}(\mathbf{k_2})\,\mathcal{R}(\mathbf{k_3})\rangle = (2\pi)^3\,\delta^3(\mathbf{k_1}+\mathbf{k_2}+\mathbf{k_3})\,\mathcal{B}_{\mathcal{R}}(k_1,k_2,k_3)\ ,$$

and

$$B_{\mathcal{R}}(k_1,k_2,k_3) = (2\pi)^4\frac{1}{\prod_i k_i^3}\mathcal{P}_{\mathcal{R}}^{*2} f_{NL}(k_1,\,k_2,\,k_3)\ ,$$

where

$$f_{NL} = -\frac{5}{6}\frac{A_{\mathcal{R}}(k_1,\,k_2,\,k_3)}{\sum_i k_i^3}\,. \tag{19}$$

The interactions of the curvature perturbations in the non-local R^2-like inflation can be schematically explained as in Fig. 5.

To calculate bi-spectrum, first we expand our action to cubic order to the leading order in slow-roll parameter. Then we compute the correlations using the following definition

$$\langle \mathcal{R}(\mathbf{k_1})\,\mathcal{R}(\mathbf{k_2})\,\mathcal{R}(\mathbf{k_3})\rangle = -i\int_{-\infty}^{\tau_e} a d\tau \langle 0|[\mathcal{R}(\tau_e,\,\mathbf{k_1})\mathcal{R}(\tau_e,\,\mathbf{k_2})\mathcal{R}(\tau_e,\,\mathbf{k_3}),\,H_{int}]|0\rangle\ , \tag{20}$$

where $\boldsymbol{k}_i$ are wave vectors and H_{int} is the interaction Hamiltonian. It is related to a perturbation of the Lagrangian (7) expanded up to the 3rd order in curvature perturbations ($\mathcal{L}_3$) as $H_{int} \approx -\mathcal{L}_3$. We consider the mode functions as

$$\mathcal{R} \approx -\Psi/\epsilon, \quad \bar{\Box}\mathcal{R} = M^2\mathcal{R}\,. \tag{21}$$

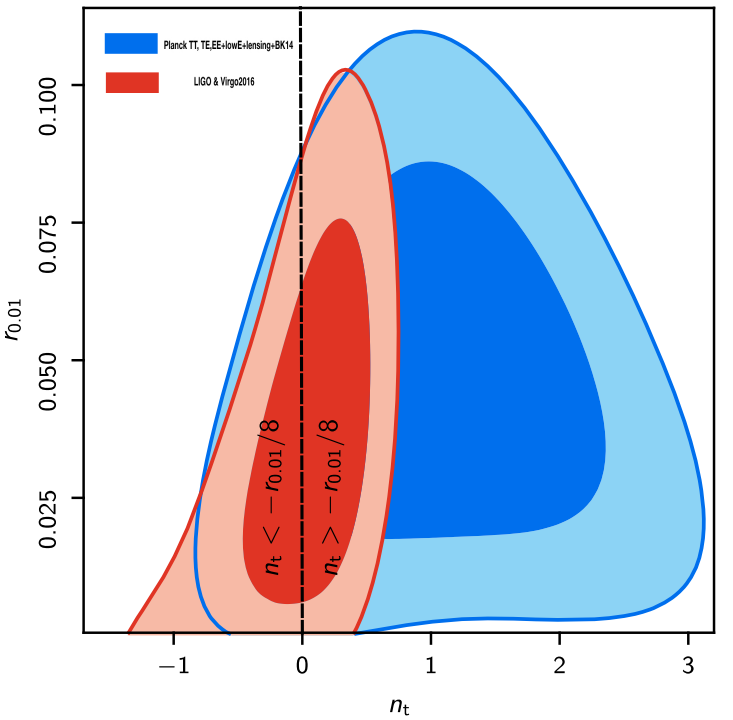

Fig. 4. We note that the predictions of non-local R^2-like inflation can be anywhere within the likelihood projected (n_t, r) plane of latest Planck 2018.[19, 21, 28]

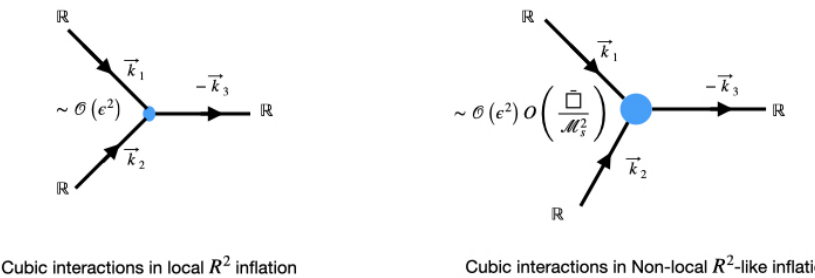

Fig. 5. In the above plot $\mathbb{R} = \{\mathcal{R}, \partial\mathcal{R}, \mathcal{D}^\mu\partial\mathcal{R}\}$ imply various tree level interactions of different modes of the curvature perturbation in the local R^2 and the non-local R^2-like inflation. $O\left(\frac{\bar{\Box}}{\mathcal{M}_s^2}\right)$ is some analytic non-local operator.

New Interactions arise via the commutation relation in de Sitter approximation

$$\Box\nabla_\mu\mathcal{R} = \nabla_\mu\Box\mathcal{R} + \frac{\bar{R}}{4}\nabla_\mu\mathcal{R}. \tag{22}$$

After numerous steps of computation the cubic order action in $\mathcal{R}$ of (7) in the leading order slow-roll approximation is obtained as[20]

$$\begin{aligned}\delta^{(3)}S_{(S)} =&4\epsilon M_p^2\int d\tau d^3x\Big\{T_1^*\mathcal{R}\nabla\mathcal{R}\cdot\nabla\mathcal{R}+T_2^*\mathcal{R}\mathcal{R}'^2+T_3^*\mathcal{H}^2\mathcal{R}^3\\&+T_4^*\mathcal{H}\mathcal{R}\mathcal{R}\mathcal{R}'+T_5^*\mathcal{H}^{-1}\nabla\mathcal{R}\cdot\nabla\mathcal{R}\mathcal{R}'+T_6^*\mathcal{H}^{-1}\mathcal{R}'^3\\&+T_7^*\mathcal{H}^{-2}\mathcal{R}'\nabla\mathcal{R}\cdot\nabla\mathcal{R}'\Big\},\end{aligned}$$

where T_i's are dimensionless constants whose can be found in[20]

Computing different shapes of f_{NL} parameter when $k=aH$ we get[20]

$$\begin{aligned}f_{NL}^{sq}\Big|_{k=aH}&\approx\frac{5}{12}(1-n_s)-23\epsilon^2\left[e^{\gamma_S\left(\frac{\bar{R}}{4\mathcal{M}_s^2}\right)}-1\right]-\frac{4\bar{R}}{\mathcal{M}_s^2}\epsilon^3e^{\gamma_S\left(\frac{\bar{R}}{4\mathcal{M}_s^2}\right)}\gamma_S'\left(\frac{\bar{R}}{4\mathcal{M}_s^2}\right)\\f_{NL}^{eq}\Big|_{k=aH}&\approx\frac{5}{12}(1-n_s)-49\epsilon^2\left[e^{\gamma_S\left(\frac{\bar{R}}{4\mathcal{M}_S^2}\right)}-1\right]-\frac{9\bar{R}}{\mathcal{M}_s^2}\epsilon^3e^{\gamma_S\left(\frac{\bar{R}}{4\mathcal{M}_s^2}\right)}\gamma_S'\left(\frac{\bar{R}}{4\mathcal{M}_s^2}\right)\\f_{NL}^{ortho}\Big|_{k=aH}&\approx\frac{5}{12}(1-n_s)-43\epsilon^2\left[e^{\gamma_S\left(\frac{\bar{R}}{4\mathcal{M}_s^2}\right)}-1\right]-\frac{22\bar{R}_*}{3\mathcal{M}_s^2}\epsilon^3e^{\gamma_S\left(\frac{\bar{R}}{4\mathcal{M}_s^2}\right)}\gamma_S'\left(\frac{\bar{R}}{4\mathcal{M}_s^2}\right).\end{aligned}\tag{23}$$

These characterize the non-local interactions of curvature perturbation. Clearly from the above expressions single field Maldacena consistency relation is violated in non-local theories and one can obtain detectable level of non-Gaussianities due to non-local nature of interactions (See Fig. 6). This is totally non-trivial effect in comparison with all the known mechanisms of producing large non-Gaussianities in the local theories.

5. Concluding remarks

We conclude here with highlighting the notable results of early Universe cosmology in the context of UV-non-local ghost-free theories of gravity. First of all we note that the UV non-local gravity action (7) is a consistent and necessary extension of Stelle gravity in order to achieve UV-completion based on the first principles. Another point to note here is "non-locality" is an important concept that is needed for building a consistent theory of quantum gravity. We have discussed how one can have a successful realization of inflation with the action action (7) and how non-local nature of gravity can be seen through inflationary observables. These are the important conclusions we can draw here to probe non-local nature of gravity in the scope of future CMB and gravitational wave observations.[5,16,27–29]

- In the non-local R^2-like inflation the primordial scalar power spectrum remains same as in the case of local $R+R^2$ inflation. However the tensor power spectrum is modified and one can have any value of tensor-to-scalar

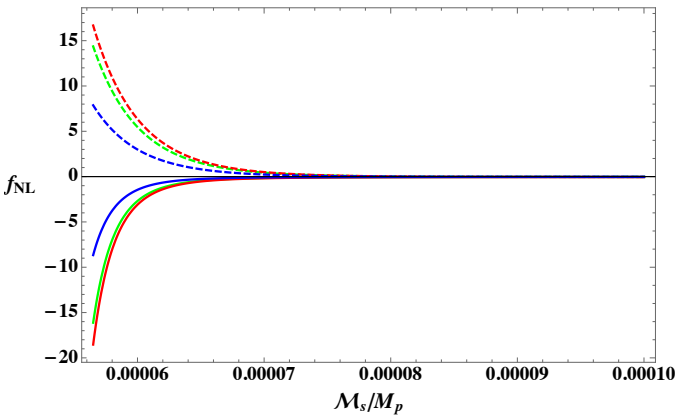

Fig. 6. In the above plots, f_{NL} versus the scale of non-locality $\mathcal{M}_s$ (in the units of M_p) is depicted for squeezed (blue), equilateral (red), and orthogonal (green) configurations for the polynomial entire functions γ_T given by eqs. (4.19) and (4.20) of arXiv:2003.00629 and represented by solid and dashed lines respectively. Here $N = 55$ of e-foldings is assumed. In the limit $\mathcal{M}_s \to M_p$ the predictions of the local R^2 model are recovered.

ratio[2, 20, 21] $r < 0.036$. As a result of modification of tensor power spectrum the tensor tilt in this theory is modified and ultimately tensor consistency relation $r = -8n_t$ is violated. Note that the violation of consistency relation is purely a non-local effect, the sound speed of primordial fluctuations are unity in this theory.

- The blue tensor tilt $n_t > 0$ is possible with non-local R^2-like inflation. Since not many frameworks of inflation can predict blue tilt any detection of it automatically favours non-local theory. Also $n_t < 0$ can also equally possible too.
- Non-local nature of gravity leads to detectable range of non-Gaussianities especial one can have squeezed limit of $f_{NL}^{\rm eq} \sim O(1)$ despite there is only one scalar degree of freedom and nature of inflation is standard-slow-roll. Further more, other shapes of f_{NL} can also be large despite the sound speed of primordial scalar field is unity.

In summary, non-local nature of gravity brings very unique predictions which are indeed very interesting in the view of future observations as well as further theoretical investigations.

Palatini kinetic scalar-tensor theory: Analytical and numerical solutions

D. V. Gal'tsov* and D. S. Bushuev†

Faculty of Physics, Moscow State University, 119899, Moscow, Russia
**E-mail: galtsov@phys.msu.ru*
†E-mail:bushuev.ds16@physics.msu.ru

We investigate static spherically symmetric solutions in the Palatini kinetically coupled scalar-tensor theory, which reduces to gravity minimally coupled to a scalar field in Einstein frame. Using the fact that the Jordan and Einstein frame are related by a reversible disformal transformation, which can be solved in closed form, we derive the general solution in the Jordan frame and show that it does not contain black holes. There is a wormhole branch and a naked singularity branch between which lies a non-singular asymptotically flat solution with kernel $M_{1,1} \times S^2$. This theory strongly violates the null energy condition.

Keywords: Black holes, wormholes, Palatini scalar-tensor theories

1. Introduction

Recently[1] was discovered a particularly simple, albeit nontrivial, example of scalar-tensor theory with kinetic coupling, which strongly violates the null energy condition. This theory is a Palatini version of the well-known model with a scalar field coupled to Ricci tensor and Ricci scalar through derivatives.[2] With a certain ratio of the two coupling constants, the metric version of this theory belongs to Horndeski class,[3–5] and has an attractive feature to generate inflationary cosmological solutions without scalar potentials.[6–9]

The situation is different in the Palatini version of this theory, what is typical for scalar-tensor theories in general.[10–14] In this case, another ratio of the two coupling constants gives a theory admitting an Einstein frame in which the scalar coupling is minimally coupled. Moreover, the Einstein metric turns out to be the metric, the Levi-Civita connection of which is the Palatini connection of the original theory. The two metrics are related by an invertible disformal transformation.[15–17] The reversibilty of the disformal transformations ensures classical equivalence of the theories in two frames,[18–20] which probably extends to the quantum level.[21] It also opens a way to use disformal transformations as a generating tool to construct exact solutions of new theories.[1,22] Some examples of solutions of Palatini kinetic theory were presented in[1] demonstrating desingularization of solutions which are singular in the Einstein frame. For deeper discussion of singularities of general relativity in the context of modified gravity theories see.[23,24]

Further investigation of[25] showed a connection between this theory and the metric conformally coupled theory, both of which demonstrate a strong violation

of the null energy condition. The natural question is whether our theory allows for wormhole solutions.[26,27] Here we show that this is indeed the case.

2. The setup

We consider the action with two independent couplings of the derivatives of the scalar field $\phi_\mu \equiv \phi_{,\mu}$ to the Ricci tensor and the Ricci scalar[2,6–8]

$$S = \int d^4x\sqrt{-g}\left[R - \left(g_{\mu\nu} + \kappa_1 g_{\mu\nu}R + \kappa_2 R_{\mu\nu}\right)\phi^\mu\phi^\nu\right], \tag{1}$$

where $\phi^\mu = \phi_\nu g^{\mu\nu}$. In the metric formalism, an interesting case is $\kappa_1 = -\kappa_2/2$ when the Ricci tensor and Ricci scalar are combined into the Einstein tensor, which has zero covariant divergence. This case belongs to the Horndeski ghost-free class.

In the Palatini version, the action will read

$$S = \int d^4x\sqrt{-g}\big[(\hat{R}_{\mu\nu} - \phi_\mu\phi_\nu)g^{\mu\nu} - \hat{R}_{\alpha\beta}\phi_\mu\phi_\nu(\kappa_1 g^{\alpha\beta}g^{\mu\nu} + \kappa_2 g^{\alpha\mu}g^{\beta\nu})\big], \tag{2}$$

where $\hat{R}_{\alpha\beta}$ is the Ricci-tensor constructed with the Palatini connection $\hat{\Gamma}$. The corresponding Einstein equations are

$$\lambda\hat{R}_{\mu\nu} - \phi_\mu\phi_\nu(1 + \kappa_1\hat{R}) - 2\kappa_2\hat{R}_{\alpha(\mu}\phi_{\nu)}\phi^\alpha - g_{\mu\nu}L/2 = 0, \tag{3}$$

where the Lagrangian and the factor λ are

$$L = \hat{R}_{\mu\nu}Z^{\mu\nu} - \phi_\mu\phi_\nu g^{\mu\nu}, \;\; Z^{\mu\nu} = \lambda g^{\mu\nu} - \kappa_2\phi^\mu\phi^\nu, \;\; \lambda = (1 - \kappa_1 X), \tag{4}$$

and $X = \phi_\alpha\phi_\beta g^{\alpha\beta}$. Variation over ϕ gives rise to a scalar equation

$$\partial_\mu\left[\sqrt{-g}\left(\phi^\mu + \kappa_1\hat{R}\phi^\mu + \kappa_2\hat{R}_{\alpha\beta}g^{\beta\mu}\phi^\alpha\right)\right] = 0, \tag{5}$$

and variation over an independent connection gives:

$$\hat{\nabla}_\lambda\left(\sqrt{-g}Z^{\mu\nu}\right) = 0, \tag{6}$$

where the covariant derivative refers to the $\hat{\Gamma}$-connection.

Direct solution of the Einstein-scalar equations (3,5) does not seem possible. But as was shown in,[1] the Palatini equation (6) can be solved giving the Levi-Civita connection

$$\hat{\Gamma}^\lambda_{\mu\nu} = \hat{g}^{\lambda\tau}\left(\partial_\mu\hat{g}_{\lambda\nu} + \partial_\mu\hat{g}_{\mu\lambda} - \partial_\lambda\hat{g}_{\mu\nu}\right)/2 \tag{7}$$

of the second metric

$$\hat{g}_{\mu\nu} = \sqrt{\Lambda\lambda}\left(g_{\mu\nu} + \kappa_2\Lambda^{-1}\phi_\mu\phi_\nu\right), \quad \Lambda = 1 - (\kappa_1 + \kappa_2)X. \tag{8}$$

This is a disformal transformation, which can be inverted (for details see[1]). It is clear that setting $\kappa_1 + \kappa_2 = 0$, will greatly simplify the above relation, and we assume that from now on. Then, remarkably, when expressed in the second metric, the action (2) is transformed into an Einstein-Hilbert action plus a minimally coupled scalar:

$$S_E = \int\sqrt{-\hat{g}}\left[R_{\mu\nu}(\hat{g}) - \phi_\mu\phi_\nu\right]\hat{g}^{\mu\nu}d^4x. \tag{9}$$

This action gives (setting torsion to zero) the same equations in the Palatini version and in the metric version:

$$R_{\mu\nu} = \phi_\mu \phi_\nu, \qquad \hat{\Box}\phi = 0. \tag{10}$$

So our strategy will be first to integrate the system (10) and then to use an inverse of the disformal transformation (8) to obtain the desired metric $g_{\mu\nu}$. To be sure that we get the general solutions in the Jordan frame we need a general solution in the Einstein frame.

3. Einstein frame: Complete integration

Static solutions of the minimally coupled scalar-tensor gravity were investigated in the past in various contexts.[28–31] The most popular solution belongs to Fisher.[28] To make sure that it is unique in the class of static spherically symmetric solutions, we repeat the derivation here.

It is convenient to present the metric ansatz as

$$ds^2 = Adt^2 + \frac{dr^2}{A} + R(d\theta^2 + \sin^2\theta d\phi^2), \tag{11}$$

where A and R are functions of r only, and it is assumed that $R > 0$ (note that we are using R and not R^2 in the angular part). The non-zero components of the Ricci tensor are

$$R_{tt} = \frac{A}{2R}(A'R)', \tag{12}$$

$$R_{rr} = -\frac{1}{2AR^2}(2ARR'' + A'RR' - AR'^2 + A''R^2), \tag{13}$$

$$R_{\theta\theta} = \frac{1}{\sin^2\theta}R_{\phi\phi} = -\frac{1}{2}(AR')' + 1, \tag{14}$$

where the prime denotes the radial derivative. The scalar field satisfies the simple divergence equation

$$(AR\phi')' = 0. \tag{15}$$

With our choice of the action, the Einstein equations read $R_{\mu\nu} = \phi_\mu\phi_\nu$, so the equations for (tt) and $(\theta\theta)$ components of the Ricci tensor are sourceless and can be integrated once, giving

$$A'R = C = \text{const}; \quad AR' = 2(r + a), \quad a = \text{const}.$$

Similarly, integrating the scalar equation we get

$$\phi' = \frac{q}{AR},$$

where the integration constant q represents the scalar charge.

From the (rr) component of the Einstein equation we obtain a constraint

$$(2R - CR')A - 2(r + a)^2 + q^2 = 0,$$

Finally, we derive a separate equation for R:

$$\frac{2}{R'} - \frac{2(r+a)R''}{R'^2} = \frac{C}{R}.$$

To solve it, we put $R = e^u$, obtaining a non-linear equation for u:

$$u'' + u'^2 - \frac{u'}{x} + \frac{Cu'^2}{2x} = 0,$$

where $x = r + a$. This equation can be integrated once, giving

$$u' = \frac{2x}{x^2 + Cx + 2C_1}$$

with some new integration constant C_1. This constant, using the constraint equation, is reduced to $C_1 = -q^2/4$. Further integration gives

$$u = \ln\left(2x^2 + 2Cx - q^2\right) + \frac{2C}{\sqrt{C^2 + 2q^2}} \tanh^{-1} \frac{2x + C}{\sqrt{C^2 + 2q^2}} + u_0,$$

where u_0 is a trivial integration constant which can be changed by angular coordinates rescaling, so we put $u_0 = -\ln 2$. Rewriting the quadratic function under logarithm as

$$x^2 + Cx - \frac{q^2}{2} = (x - x_+)(x - x_-), \quad x_\pm = -\frac{1}{2}\left(C \pm \sqrt{C^2 + 2q^2}\right).$$

To get the metric function R, one has to take the power that leads to:

$$R = e^u = (x - x_-)(x - x_+)\left(\frac{x - x_-}{x - x_+}\right)^\gamma = r^2\left(1 - \frac{b}{r}\right)^{1-\gamma}, \tag{16}$$

where we have introduced two new parameters instead of C, q^2:

$$\gamma = \frac{C}{\sqrt{C^2 + 2q^2}} \quad b = \sqrt{C^2 + 2q^2}, \tag{17}$$

and a new radial coordinate $r = x - x_-$. The metric function A in the new variables reads

$$A = \frac{2(r + x_-)}{R'}.$$

Differentiating (16), we find

$$A = \left(1 - \frac{b}{r}\right)^\gamma. \tag{18}$$

Summarizing, we obtained the famous Fisher-Janis-Newman-Winicour (FJNW) solution, proving its uniqueness within the static spherically symmetric class:

$$ds^2 = -\left(1 - \frac{b}{r}\right)^\gamma dt^2 + \left(1 - \frac{b}{r}\right)^{-\gamma} dr^2 + r^2\left(1 - \frac{b}{r}\right)^{1-\gamma} d\Omega. \tag{19}$$

The derivative of the scalar field in terms of b, γ reads:

$$\phi' = \frac{b\sqrt{1-\gamma^2}}{\sqrt{2}\, r(r-b)}. \tag{20}$$

Note that the range of the radial variable is chosen $r \in (b, \infty)$ to ensure positivity of the function R. The region $r < b$ corresponds to cosmological solution.[32]

4. Disformal transformation

To pass to the Jordan frame, it is necessary to carry out the inverse disformal transformation

$$g_{\mu\nu} = \hat{g}_{\mu\nu}\lambda^{-1/2} - \kappa\phi_\mu\phi_\nu, \tag{21}$$

where

$$\lambda = (g_{rr}/w)^{-2/3}, \quad w = A = \left(1 - \frac{b}{r}\right)^{-\gamma}, \tag{22}$$

and g_{rr} obeys the following equation:

$$\left(g_{rr} - \frac{2x}{3\sqrt{3}}\right)^3 = w g_{rr}, \quad x = \frac{3\sqrt{3}\kappa q^2}{2r^2(r-b)^2}. \tag{23}$$

A real solution of this equation reads

$$g_{rr} = \frac{2x}{3\sqrt{3}} + \frac{1}{\sqrt{3}} \begin{cases} 2w\cos\left(\frac{1}{3}\arccos x/w\right), & x < w, \\ w^{2/3}B + w^{1/3}B^{-1}, & x > w, \end{cases} \tag{24}$$

where

$$B = \left(x + \sqrt{x^2 - w^2}\right)^{1/3}.$$

Two other Jordan frame metric components are

$$g_{tt} = \hat{g}_{tt}\lambda^{-1/2} \qquad g_{\theta\theta} \equiv Q = \hat{g}_{\theta\theta}\lambda^{-1/2} = R\lambda^{-1/2}. \tag{25}$$

It is easy to see that the above transformation to the Jordan frame preserves asymptotic flatness. Indeed, when $r \to \infty$, the variables $x \to 0$, $w \to 1$, so that

$$g_{rr} \sim 1 + x/\sqrt{3} \Rightarrow \lambda = 1 + O(1/r^4),$$

and we get as $r \to \infty$:

$$g_{tt} \simeq -1 + \frac{\gamma b}{r} \quad g_{rr} \simeq 1 - \frac{\gamma b}{r} \quad g_{\theta\theta} \sim r^2. \tag{26}$$

5. Wormholes

Consider first an asymptotic behavior of the Jordan metric as $r \to b$. Without loss of generality, let the dimensionless parameter $\kappa q^2/b^4$ be equal to one. Then a careful analysis of the behavior of various terms for $x \to \infty$, $w \to 0$ assuming arbitrary values $0 < \gamma < 1$ gives the following leading approximation for small $u = (r/b - 1)$:

$$ds^2 = -u^{2(2\gamma-1)/3}dt^2 + \frac{b^2du^2}{u^2} + b^2u^{(1-2\gamma)/3}d\Omega. \tag{27}$$

As $r \to b$, the metric component $g_{\theta\theta} = Q(r)$ explodes if $\gamma > 1/2$, while it goes to zero for $\gamma < 1/2$. One can suspect that in the first case the intrinsic volume of a region close to $r = b$, namely $r \in [b + \delta, r_0]$, such that $\delta \ll r_0 - b \ll b$, will be infinite as $\delta \to 0$. Indeed,

$$V_\delta = 4\pi \int_{b+\delta}^{r_0} \sqrt{h}dr = \frac{12\pi}{2\gamma - 1} b^3 \left(\frac{\delta}{b}\right)^{(1-2\gamma)/3}.$$

Thus, for $\gamma > 1/2$ one has the second infinite region of three-space. This region is not flat, and not Ricci flat. It is not asymptotically flat as $r \to b$ either, moreover the scalar field diverges there. But one can suspect the existence of an asymmetric wormhole, connecting our AF-region with the second sheet to the left of the local minimum of $Q(r)$ (a turning point) at some point $r_t > b$, if exists:

$$\left.\frac{dQ}{dr}\right|_{r=r_t} = 0, \quad \left.\frac{d^2Q}{dr^2}\right|_{r=r_t} > 0, \tag{28}$$

which could correspond to a wormhole throat.

Numerical analysis shows that for $\gamma < 1/2$, $g_{\theta\theta}$ does not have a local minimum for all positive values of the coupling constant κ. For $\gamma > 1/2$ a local minimum arises, with r_t depending on γ and κ.

5.1. *Numerical solutions*

Though we obtained solutions in the Jordan frame analytically, the algebraic functions involved are difficult for understanding the nature of the metric, so we undertake numerical plotting. On Fig. 1, 2 we plot the metric functions for various values of $1/2 < \gamma < 1$. In this case a local minimum of $Q(r)$ arises at $r = r_t$, whose position depends on γ and κ. This corresponds to the throat radius of an asymmetric wormhole. The values r_t can be found numerically with any desired accuracy. For $\kappa = 2$, the radii of the throat for some selected γ are

γ	3/5	3/4	0,95	0,99
r_t/b	1.041	1.078	1.072	1.041

With growing κ, the throat radius increases, as can be seen from the left panel of Fig. 1. Left to the minimum, the radial function Q increases again and tends to

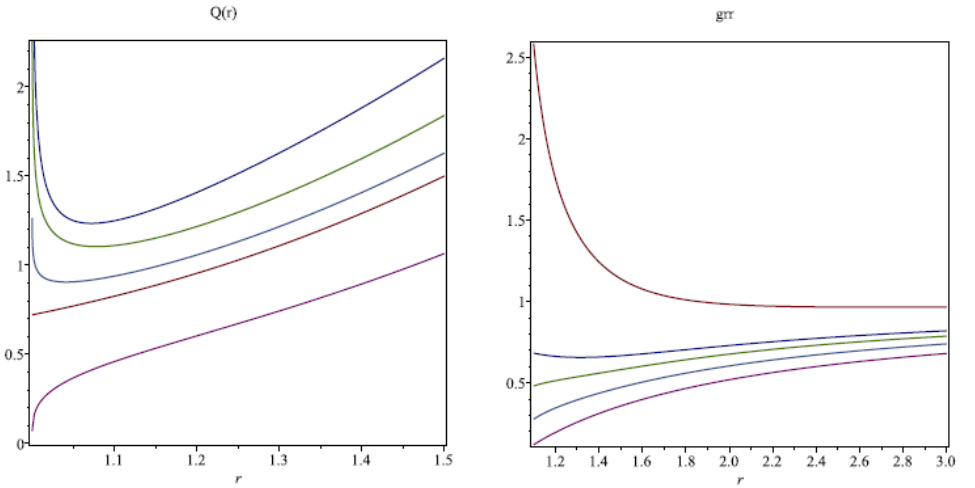

Fig. 1. Metric functions $g_{\theta\theta}$ and g_{tt} for various values of γ: $\gamma = 0.1$ (purple), $\gamma = 0.5$ (red), $\gamma = 0.6$ (light blue), $\gamma = 0.75$ (green), $\gamma = 0.95$ (blue).

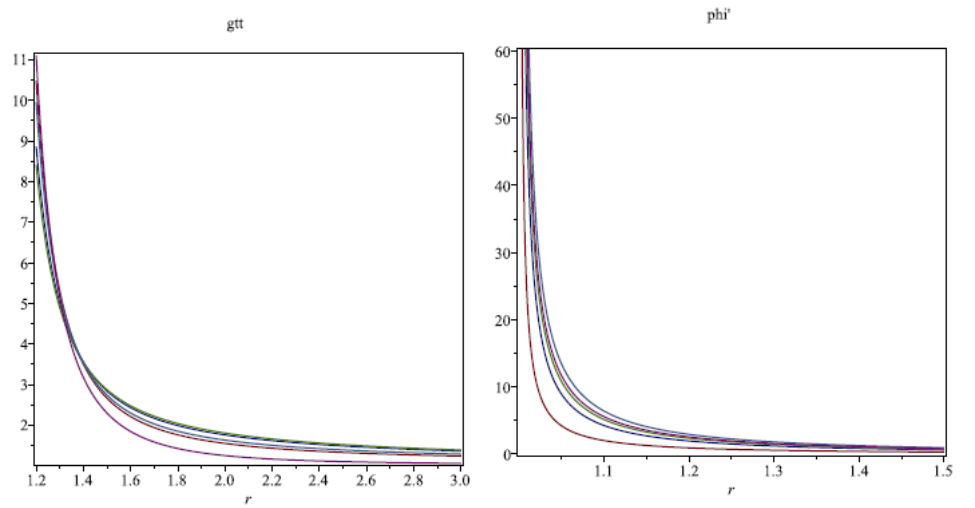

Fig. 2. Metric function g_{rr} and the derivative of the scalar field (ϕ') for various values of γ : $\gamma = 0.1$ (purple), $\gamma = 0.5$ (red), $\gamma = 0.6$ (light blue), $\gamma = 0.75$ (green), $\gamma = 0.95$ (blue).

infinity as $r \to b$ for $\gamma > 1/2$. From Fig. 2 (left panel) one can also see that $g_{tt} > 0$ for all $r > b$, so the solutions do not have horizons.

It can be shown that our wormhole is traversable: radial time-like and null geodesics freely pass through the throat. The tidal forces remain finite.

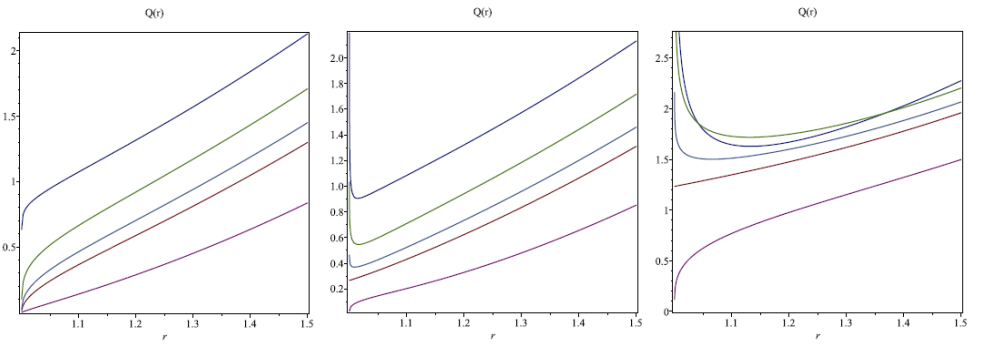

Fig. 3. Metric function ($g_{\theta\theta}$) for various values of κ: $\kappa = 0$ (left figure), $\kappa = 0.01$ (center), $\kappa = 10$ (right); and γ: $\gamma = 0.1$ (purple), $\gamma = 0.5$ (red), $\gamma = 0.6$ (light blue), $\gamma = 0.75$ (green), $\gamma = 0.95$ (blue).

5.2. *Geometry of the second sheet*

To investigate the geometry of the second leaf of the wormhole $r < r_t$, we first calculate the asymptotic behavior of the Ricci tensor and the Ricci scalar constructed from the Jordan metric (which is not the Palatini Ricci tensor):

$$R_{\mu\nu}(g)dx^\mu dx^\nu = -\frac{(1-2\gamma)^2}{6u^2}du^2 + d\Omega, \tag{29}$$

$$R(g) = \frac{2u^{(2\gamma-1)/3}}{b^2} - \frac{(1-2\gamma)^2}{6\mu^2}. \tag{30}$$

The rr-component of the Ricci tensor diverges as $u \to 0$, but the square of the Ricci tensor is finite for $\gamma > 1/2$:

$$R_{\mu\nu}R^{\mu\nu} = \frac{2u^{2(2\gamma-1)/3}}{b^4} + \frac{(2\gamma-1)^2}{36\,b^4}. \tag{31}$$

We then calculate the effective energy density and pressure by defining them in terms of the mixed components of the (diagonal) Einstein tensor, again constructed using the Jordan metric:

$$G^\nu_\mu(g) = (-\epsilon,\ p_r,\ p_\theta,\ p_\varphi). \tag{32}$$

This is not the physical energy density and pressure in Palatini's theory (see below), but only the effective ones used to illustrate geometry in terms of the notions of the Riemann geometry. The calculation gives for the energy density and radial pressure:

$$\epsilon = \frac{u^{(2\gamma-1)/3}}{b^2} - \frac{(2\gamma-1)^2}{12b^2}, \qquad p_r = -\frac{u^{(2\gamma-1)/3}}{b^2} - \frac{(2\gamma-1)^2}{12b^2}. \tag{33}$$

Their sum is negative, demonstrating violation of NEC in our theory. The tangential pressure is positive and finite

$$p_\theta = p_\varphi = (2\gamma-1)^2/12b^2. \tag{34}$$

In the sense of the Palatini theory, the Ricci scalar must be computed by contracting the Ricci tensor built from the Palatini connection, which is the Levi-Civita connection of Einstein's frame (i.e. $R_{\mu\nu}(\hat{g})$), with the Jordan contravariant metric tensor. Near the boundary $r = b$ the leading behavior of this quantity will be:

$$R_P = R_{\mu\nu}(\hat{g})\, g^{\mu\nu} = \frac{(1-2\gamma)^2}{6\,b^2}\frac{1}{u^{2-\gamma}}, \tag{35}$$

which diverges as $u \to 0$ for any $0 < \gamma < 1$. The question arises whether an observer will see the second sheet as a regular or a singular space. In fact, with independent connection, the curves of minimum length do not coincide with the curves along which the tangent vector is parallel transported. More generally, the matter action can depend only on the metric, or on the metric and the connection. The point particle action belongs to the first type, so the particle will move along the curves of minimal length. Such an observer will not see singularities on the internal sheet of the wormhole. If the notion of geodesic completeness is attributed to curves of minimal length, then this spacetime should be regarded as nonsingular indeed.

5.3. *Isotropic coordinates*

The asymptotic metric of the second sheet can be presented in isotropic coordinates t, ρ, θ, ϕ changing the radial variable as

$$\rho = b \exp\left(\nu^{-1} u^{\nu}\right), \quad \nu = (2\gamma - 1)/6.$$

The resulting metric reads

$$ds^2 = -\left(\nu \ln \frac{\rho}{b}\right)^4 dt^2 + f^2 dl_3^2, \quad dl_3^2 = d\rho^2 + \rho^2 d\Omega. \tag{36}$$

The conformal factor $f = \frac{b}{\rho\nu}\left(\ln \rho/b\right)^{-1}$, shown in Fig. 4 as a function of ρ, clearly demonstrates two asymptotic behavior of a wormhole:

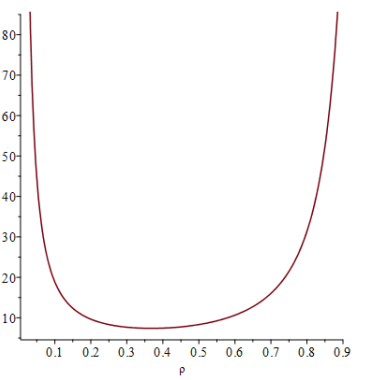

Fig. 4. The radial scale factor in isotropic coordinates.

5.4. *The soliton $\gamma = 1/2$*

In the Einstein frame the FJNW solution for $\gamma = 1/2$ satisfies the condition $g_{rr} = 1/|g_{tt}|$:

$$ds^2 = -\sqrt{1 - \frac{b}{r}}dt^2 + \frac{dr^2}{\sqrt{1 - \frac{b}{r}}} + r^2\sqrt{1 - \frac{b}{r}}d\Omega. \tag{37}$$

It has curvature invariants divergent as $r \to b$. But its Jordan frame counterpart turns out to be non-singular, namely

$$ds^2 = -dt^2 + \xi^{-2}dr^2 + b^2(d\theta^2 + \sin^2\theta d\varphi^2). \tag{38}$$

Passing to a new radial coordinate $z = b\ln\xi$, we transform the domain $r \in (b, \infty)$ into the complete real line $-\infty < z < \infty$

$$ds^2 = -dt^2 + dz^2 + b^2(d\theta^2 + \sin^2\theta d\varphi^2). \tag{39}$$

Therefore the manifold is isomorphic to the product of the two-dimensional Minkowski space and a sphere of radius b: $M_{1,1} \times S^2$. This manifold is geodesically complete in the Riemannian geometry sense. Thus, our solution can be regarded as a regular scalar-tensor soliton. Its striking feature is that, within the framework of our theory, it is supported by a singular scalar. The singularity now is transfered to the Palatini connection.

5.5. *Naked singularities*

The range of the power index $0 < \gamma < 1/2$ corresponds to Jordan metrics singular in the Riemannian sense. This can be seen already from inspection of the Ricci scalar constructed with the Jordan metric:

$$R(g) = \frac{2u^{(2\gamma-1)/3}}{b^2} - \frac{(1-2\gamma)^2}{6b^2}. \tag{40}$$

The constant term is due to the two-sphere sector of the metris, while the first term originates from radial component of the Ricci tensor and it tends to infinity for $\gamma < 1/2$.

Also, one can see that the three-volume of the region between $r = b - \delta$ and $r = b$ for $\gamma < 1/2$ tends to zero when $\delta \to 0$:

$$V_\delta = 12\pi b^3\,(\delta/b)^{(1-2\gamma)/3}. \tag{41}$$

The metric function $g_{\theta\theta}$ for various κ and γ is plotted in Fig. 3. From these plots one can see that in all three cases the metric has no horizons. More general numerical tests show that the static spherical sector of our theory does not contain black holes indeed.

5.6. *Classification of solutions*

Since our solution in the Einstein frame is generic in its class, we conclude that the above three types of static spherically symmetric solutions in the Jordan frame exhaust all possibilities, namely:

a) $\gamma > 1/2$ — asymmetric wormholes,
b) $\gamma = 1/2$ — regular soliton with the $M_{1,1} \times S_2$ core,
c) $\gamma < 1/2$ — asymptotically flat spacetime with a naked sigularity.

No solutions contain horizons.

Finally, we have two options for introducing the Kretschman scalar to investigate non-Ricci singularities. The Riemannian type scalar is simply $K_R = R_{\mu\nu\lambda\tau}(g)R^{\mu\nu\lambda\tau}(g)$. The Palatini-type Kretschmann scalar reads

$$K_P = R^{\mu}{}_{\nu\lambda\tau}(\hat{g})R^{\alpha}{}_{\beta\gamma\delta}(\hat{g})\, g_{\mu\alpha}\, g^{\nu\beta}\, g^{\lambda\gamma}\, g^{\tau\delta}.$$

In the asymptotic region of the second sheet (small u) the first one is:

$$K_R = \frac{1}{9\, b^4}\left(36u^{2(2\gamma-1)/3} - 2(2\gamma-1)^2 u^{(2\gamma-1)/3} + 12\gamma^2(\gamma-1)^2 + 6\gamma(\gamma-1) + 3/4\right). \tag{42}$$

It is finite in the cases a, b and singular in the case c as expected. The Palatini Kretschmann scalar always diverges as $u \to 0$:

$$K_P = \frac{(\gamma-1)^2(5\gamma^2 - 2\gamma + 2)}{4b^4\, u^{4(2-\gamma)/3}}, \tag{43}$$

reflecting singular nature of the Palatini connection.

6. Conclusion

To summarize: we have found that Palatini scalar-tensor theory with a scalar field kinetically coupled to the Ricci tensor and the Ricci scalar is an example of theory that does not admit solutions with an event horizon at least in the static case.

The theory has Palatini connection which is the Levi-Civita connection of the Einstein frame metic. The general static spherically symmetric solution in the Einstein frame is given by the Fisher family of metrics, specified by the power index $0 < \gamma < 1$. We have shown that for $1/2 < \gamma < 1$ the Jordan metric describes wormholes, interpolating between an asymptotically flat space and a Ricci non-flat second space of an infinite volume.The second sheet of the wormholes is not asymptotically flat. Its spacetime metric is regular, and the Riemannian Einstein tensor corresponds to an effective matter violating the null energy condition.

For $\gamma < 1/2$ the Jordan solutions are one-sheeted and represent naked singularities in asymptotically flat space. In the intermediate case $\gamma = 1/2$ the Jordan metric is non-singular, and have a core of cylindrical topology.

THE MARCEL GROSSMANN MEETINGS

Series Editor: REMO RUFFINI

Publications in the Series of Proceedings

Proceedings of the Sixteenth Marcel Grossmann Meeting on General Relativity
(Virtual Meeting, 2021)
Edited by G. Vereshchagin, R. Ruffini
World Scientific, 2022

Proceedings of the Fifteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2018)
Edited by E.S. Battistelli, R.T. Jantzen, R. Ruffini
World Scientific, 2022

Proceedings of the Fourteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2015)
Edited by M. Bianchi, R.T. Jantzen, R. Ruffini
World Scientific, 2017

Proceedings of the Thirteenth Marcel Grossmann Meeting on General Relativity
(Stockholm, Sweden, 2012)
Edited by K. Rosquist, R.T. Jantzen, R. Ruffini
World Scientific, 2015

Proceedings of the Twelfth Marcel Grossmann Meeting on General Relativity
(Paris, France, 2009)
Edited by T. Damour, R.T. Jantzen, R. Ruffini
World Scientific, 2012

Proceedings of the Eleventh Marcel Grossmann Meeting on General Relativity
(Berlin, Germany, 2006)
Edited by H. Kleinert, R.T. Jantzen, R. Ruffini
World Scientific, 2007

Proceedings of the Tenth Marcel Grossmann Meeting on General Relativity
(Rio de Janiero, Brazil, 2003)
Edited by M. Novello, S. Perez-Bergliaffa, R. Ruffini
World Scientific, 2005

Proceedings of the Ninth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2000)
Edited by V.G. Gurzadyan, R.T. Jantzen, R. Ruffini
World Scientific, 2002

Proceedings of the Eighth Marcel Grossmann Meeting on General Relativity
(Jerusalem, Israel, 1997)
Edited by T. Piran
World Scientific, 1998

Proceedings of the Seventh Marcel Grossmann Meeting on General Relativity
(Stanford, USA, 1994)
Edited by R.T. Jantzen and G.M. Keiser
World Scientific, 1996

Proceedings of the Sixth Marcel Grossmann Meeting on General Relativity
(Kyoto, Japan, 1991)
Edited by H. Sato and T. Nakamura
World Scientific, 1992

Proceedings of the Fifth Marcel Grossmann Meeting on General Relativity
(Perth, Australia, 1988)
Edited by D.G. Blair and M.J. Buckingham
World Scientific, 1989

Proceedings of the Fourth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 1985)
Edited by R. Ruffini
World Scientific, 1986

Proceedings of the Third Marcel Grossmann Meeting on General Relativity
(Shanghai, People's Republic of China, 1982)
Edited by Hu Ning
Science Press – Beijing and North-Holland Publishing Company, 1983

Proceedings of the Second Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1979)
Edited by R. Ruffini
North-Holland Publishing Company, 1982

Proceedings of the First Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1975)
Edited by R. Ruffini
North-Holland Publishing Company, 1977

International Center for Relativistic Astrophysics (ICRA)

FREEDOM OF MOVEMENT FOR SCIENTISTS

The Marcel Grossmann Meetings were founded with the premise that scientists of all nations have a right to meet to exchange knowledge independent of national borders.

ACKNOWLEDGEMENTS

We acknowledge the outstanding job done before, during and after the meeting by the ICRANet/ICRA administrative and secretarial staff: Cristina Adamo, Silvia Latorre, Elisabetta Natale, and Cinzia di Niccolo. Finally this meeting and its proceedings could not have functioned without the dedicated IT support of the ICRANet system manager Gabriele Brandolini, with some temporary assistance from Domenico La Selva and Damiano Verzulli. We would like to thank Linda Kwan from World Scientific for valuable assistance during preparation of these proceedings.

ORGANIZING BODIES OF THE SIXTEENTH MARCEL GROSSMANN MEETING

INTERNATIONAL ORGANIZING COMMITTEE

Blair David, Choquet Bruhat Yvonne, Damour Thibault, De Bernardis Paolo, Everitt C. W. Francis, Fryer Chris, Haensch Theodor, Henneaux Marc, Jones Christine, Kerr Roy, Kleinert Hagen, Kunz Jutta, Laemmerzahl Claus, Longair Malcolm, Mirabel Felix, Mirzoyan Razmik, Piran Tsvi, Rueda Jorge, Ruffini Remo (chair), Sasaki Misao, Sato Humitaka, Sunyaev Rashid, 't Hooft Gerard, Weinberg Steven, Yau Shing-Tung, Zhang Bing

LOCAL ORGANIZING COMMITTEE

Adamo Cristina, Bianco Carlo Luciano, Brandolini Gabriele A., di Niccolo Cinzia, Latorre Silvia, La Selva Domenico, Li Liang, Loppini Alessandro, Natale Elisabetta, Verzulli Damiano, Vereshchagin Gregory (chair), Wang Yu

INTERNATIONAL COORDINATING COMMITTEE

ALBANIA: Hafizi M. - ARGENTINA: Arguelles C., Scoccola C., Reula O., Romero G.E. - ARMENIA: Sahakyan N. - AUSTRALIA: Blair D., Ju L., Lun A., Manchester D., Melatos A., Quinn P., Scott S.M., Steele J.D. - AUSTRIA: Aichelburg P.C., Schindler S. - BELARUS: Kilin S., Prakapenia M., Siutsou I. - BELGIUM: Henneaux M. - BOLIVIA: Aguirre C.B. - BOSNIA: Pasic V. - BRAZIL: Barres de Almeida U., Coelho Goulart J., Dalmolin F.T., de Lima Rafael C.R., Guzzo M., Maia C., Malheiro M., Romero Filho C.A., Shellard R.C., Zen Vasconcellos C. - BULGARIA: Yazadjiev S. - CANADA: Singh D., Smolin L., Turok N. - CHILE: Bauer F., Bunster W.C., Giacomini A. - CHINA (MAINLAND): Cai R., Cai Y., Cao Z., Chang J., Chen J., Chen X., Dai Z., Feng L.-L., Han W., Jing Y., Li T.-P., Lin W., Lou Y.-Q., Luo J., Mei J., Tam T., Wang A., Wang Y., Wu X.-P., Wu Y.-L., Yuan Y.-F., Zhang B.-B., Zhang S.-N., Zhao G. - CHINA (TAIWAN): Chen Chiang-Mei, Chen Pisin, Lee Da-Shin, Lee Wo-Lung, Ni Wei-Tou - COLOMBIA: Bargueño de Retes P., Gonzalez G., Higuera Garzon M.A., Núñez L., Romano A.E., Valenzuela Toledo C.A., Zuluaga J.I. - CROATIA: Dominis Prester D., Karlica M., Milekovic M., Smolcic V., Smolic I., Suric T. - CUBA: Perez Martinez A., Pérez Rojas H. - CZECH REPUBLIC: Bicak J., Stuchlik Z. - DENMARK: Naselsky P. - ECUADOR: Contreras E. - EGYPT: Tawfik A.N., Wanas M.I. - ESTONIA: Einasto J., Saar E. - FINLAND: Poutanen J., Volovik G. - FRANCE: Brillet A., Buchert T., Chardonnet P., Coullet P., de Freitas Pacheco J.A., Deruelle N., Iliopoulos J., Lamanna G., Mignard F. - GEORGIA: Lavrelashvili George, Machabeli Giorgi - GERMANY: Biermann P., Blumlein J., Di Piazza A., Fritzsch H., Genzel R., Gilmozzi R., Hasinger G., Hehl F., Keitel C., Kiefer C., Mirzoyan R.,

Neugebauer G., Nicolai H., Renn J., Ringwald A., Ruediger A. - GREECE: Batakis N.A., Cotsakis S., Vagenas E.C. - HUNGARY: Fodor G., Levai P. - ICELAND: Bjornsson G., Jakobsson P. - INDIA: Chakrabarti S.K., Iyer B., Padmanabhan T., Souradeep T. - IRAN: Baghram S., Bavarsad E., Eslam Panah B., Firouzjahi H., Haghighat M., Mansouri R., Mashhoon B., Shakeri S., Sobouti Y., Taghi Mirtorabi M. - IRELAND: O'Murchada N. - ISRAEL: Milgrom M., Nakar E., Pe'er A., Piran T. - ITALY: Belinski V., Bianchi M., Bianco C.L., Cherubini C., Della Valle M., Falciano S., Filippi S., Haardt F., Menotti P., Merafina M., Pani P., Ricci F., Treves A., Vereshchagin G.V., Vitale S., Xue S.- S. - JAPAN: Fujimoto M.-K., Makishima K., Nakamura T., Sato K., Shibata M. - KAZAKHSTAN: Abishev M., Aimuratov Y., Boshkayev K., Mychelkin E.G., Spitaleri C. - KOREA (PYEONGYANG): Kim J.S. - KOREA (SEOUL): Kim S.P., Kim S.-W., Lee H.K., Lee H.-W., van Putten M. - KYRGYZSTAN: Gurovich V.Ts. - LIBYA: Gadri M. - MEXICO: Breton N., Cervantes-Cota J.L., Fraija Cabrera N.I., García-Diaz A.A., Macías Alvarez A., Mielke Eckehard W., Quevedo H., Rodriguez L.F. - NETHERLANDS: Slagter R. - NEW ZEALAND: Visser M., Wiltshire D. - NORWAY: Elgaroy O., Fonseca Mota D., Knutsen H. - PAKISTAN: Qadir A., Qamar S. - PERU: Vargas T. - POLAND: Belczynski K., Demianski M., Lewandowski Jerzy, Nurowski P., Sokolowski L. - PORTUGAL: Costa M., Da Silva A., Lemos J.P.S., Lobo F., Moniz P., Silva L.O. - ROMANIA: Visinescu M. - RUSSIA: Aksenov A., Arkhangelskaja I., Bisnovatyi-Kogan G., Blinnikov S., Chechetikin V.M., Cherepaschuk A.M., Khriplovich I., Lipunov V.M., Lukash V.N., Novikov I., Rudenko V.N., Starobinsky A.A. - SERBIA: Djordjevic G., Jovanovic P., Knezevic Z., Pankov-Hzvojevic M., Popovic L., Prodanovic T., Sijacki D., Simic S. - SLOVAKIA: Balek V. - SLOVENIA: Cadez A., Gomboc A., Zavrtanik D. - SOUTH AFRICA: Larena J., Maharaj S. - SPAIN: Elizalde E., Ibanez J., Perez M.J., Verdaguer E. - SWEDEN: Abramowicz M.A., Marklund M., Ryde F. - SWITZERLAND: Durrer R., Jetzer P. - TURKEY: Aliev A., Gurses M. - UKRAINE: Novosyadlyj B., Zaslavskii O., Zhuk A. - UNITED ARAB EMIRATES: Fernini I. - UNITED KINGDOM: Cruise A.M., Frenk Carlos S., Green M., Mavromatos N., Perry M., Willingale R. - USA: Abel T., Ashtekar A., Bardeen J., Carlstrom J., Cornish N., Dermer C., Fan X., Flanagan E., Fraschetti F., Fryer C., Incera V., Jantzen R.T. (chairperson), Kolb R., Laguna P., Lousto C., Madau Piero, Mathews Grant, Matzner Richard, Melia Fulvio, Mester John, Michelson Peter, Nordtvedt Kenneth, Parker Leonard, Pretorius F., Pullin J., Shapiro I., Shapiro S., Shoemaker D., Smoot G., Stiavelli M., Teukolsky S., van Nieuwenhuizen P., Zhang B. - UZBEKISTAN: Ahmedov B., Zalaletdinov R.M. - VATICAN CITY: Gionti G. - VENEZUELA: Fuenmayor E. - VIETNAM: Long H.N.

MARCEL GROSSMANN AWARDS

Sixteenth Marcel Grossmann Meeting

Institutional Awards

"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance".

S.A. LAVOCHKIN ASSOCIATION
- presented to its Designer General **Alexander Shirshakov**

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
- presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
- presented to Professor **Rashid Sunyaev,** Principal Investigator of SRG Observatory in Russia

Individual Awards

DEMETRIOS CHRISTODOULOU
"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."

GERARD 't HOOFT
"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon".

TSVI PIRAN
"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory".

STEVEN WEINBERG
"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory".

Each recipient is presented with a silver casting of the TEST sculpture by the artist A. Pierelli. The original casting was presented to His Holiness Pope John Paul II on the first occasion of the Marcel Grossmann Awards.

15th Marcel Grossmann Meeting
July 2018, Rome, Italy

Institutional Awards

PLANCK SCIENTIFIC COLLABORATION (ESA)
"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding B-polarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy"

- presented to Jean-Loup Puget, the Principal Investigator of the High Frequency Instrument (HFI)

HANSEN EXPERIMENTAL PHYSICS LABORATORY AT STANFORD UNIVERSITY
"to HEPL for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology"

- presented to Research Professor Leo Hollberg, HEPL Assistant Director

Individual Awards

LYMAN PAGE
"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and as founding director of the Atacama Cosmology Telescope"

RASHID ALIEVICH SUNYAEV
"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe"

SHING-TUNG YAU
"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics"

14th Marcel Grossmann Meeting
July 2015, Rome, Italy

Institutional Award

EUROPEAN SPACE AGENCY (ESA)
"for the tremendous success of its scientific space missions in astronomy, astrophysics, cosmology and fundamental physics which have revolutionized our knowledge of the Universe and hugely benefited science and mankind"

- presented to its Director General Johann-Dietrich Woerner

Individual Awards

KEN'ICHI NOMOTO
"for heralding the role of binary systems in the evolution of massive stars"

MARTIN REES
"for fostering Research in black holes, gravitational waves and cosmology"

YAKOV G. SINAI
"for applying the mathematics of chaotic systems to physics and cosmology"

SACHIKO TSURUTA
"for pioneering the physics of hot neutron stars and their cooling"

FRANK C.N. YANG
"for deepening Einstein's geometrical approach to physics in the best tradition of Paul Dirac and Hermann Weyl"

T.D. LEE (award received by Yu-Qing Lou on behalf of Prof. T.D. Lee)
"for his work on white dwarfs motivating Enrico Fermi's return to astrophysics and guiding the basic understanding of neutron star matter and fields"

13th Marcel Grossmann Meeting
July 2012, Stockholm, Sweden

Institutional Award

ALBANOVA
for its innovative status as a joint institute established by Stockholm University and the Royal Institute of Technology and for fostering contributions to cosmology and astrophysics in the profound scientific tradition established by Oskar Klein.

- presented to the Rector of Stockholm University, Prof. Kåre Bremer.

Individual Awards

DAVID ARNETT
for exploring the nuclear physics and yet unsolved problems of the endpoint of thermonuclear evolution of stars, leading to new avenues of research in physics and astrophysics.

VLADIMIR BELINSKI and I.M. KHALATNIKOV
for the discovery of a general solution of the Einstein equations with a cosmological singularity of an oscillatory chaotic character known as the BKL singularity.

FILIPPO FRONTERA
for guiding the Gamma-ray Burst Monitor Project on board the BeppoSAX satellite, which led to the discovery of GRB X-ray afterglows, and to their optical identification.

12th Marcel Grossmann Meeting
July 2009, Paris, France

Institutional Award

INSTITUT DES HAUTES ÉSTUDES SCIENTIFIQUE (IHÉS)
for its outstanding contributions to mathematics and theoretical physics, and notably for having renewed basic geometrical concepts, and having developed new mathematical and physical aspects of spacetime.

- presented to Prof. Jean-Pierre Bourguignon

Individual Awards

JAAN EINASTO
for pioneering contributions in the discovery of dark matter and cosmic web and fostering research in the historical Tartu Observatory.

CHRISTINE JONES
for her fundamental contributions to the X-ray studies of galaxies and clusters tracing their formation and evolution and for her role in collaborations using clusters to study dark matter and in analyzing the effects of outbursts from supermassive black holes on the intracluster gas.

MICHAEL KRAMER
for his fundamental contributions to pulsar astrophysics, and notably for having first confirmed the existence of spin-orbit precession in binary pulsars.

11th Marcel Grossmann Meeting
July 2006, Berlin, Germany

Institutional Award

FREIE UNIVERSITÄT BERLIN
for the successful endeavor of re-establishing — in the spirit of the Humboldt tradition — freedom of thinking and teaching within a democratic society in a rapidly evolving cosmos

- presented to Dr. Dieter Lenzen, President of FUB

Individual Awards

ROY KERR
for his fundamental contribution to Einstein's theory of general relativity: "The gravitational field of a spinning mass as an example of algebraically special metrics."

GEORGE COYNE
for his committed support for the international development of relativistic astrophysics and for his dedication to fostering an enlightened relationship between science and religion.

JOACHIM TRUMPER
for his outstanding scientific contributions to the physics of compact astrophysical objects and for leading the highly successful ROSAT mission which discovered more than 200,000 galactic and extragalactic X-ray sources: a major step in the observational capabilities of X-ray astronomy and in the knowledge of our universe.

10th Marcel Grossmann Meeting
July 2003, Rio de Janeiro, Brazil

Institutional Award

CBPF (Brazilian Center for Research in Physics)
for its role as a teaching and research institution and as a place originating fundamental physics ideas in the exploration of the universe.

- presented to its founders Cesar Lattes, Josè Leite Lopez and Jayme Tiomno

Individual Awards

YVONNE CHOQUET-BRUHAT AND JAMES W. YORK, JR.
for separate as well as joint work in establishing the mathematical framework for proving the existence and uniqueness of solutions to Einstein's gravitational field equations.

YUVAL NE'EMAN
for his contributions to science, epistimology, mathematics and physics from subnuclear to space sciences.

9th Marcel Grossmann Meeting
July 2000, Rome, Italy

Institutional Award

SOLVAY INSTITUTES
for identifying and recording in discussions by the protagonists the crucial developments of physics and astrophysics in the twentieth century.

- presented to Jacques Solvay

Individual Awards

CECILLE AND BRYCE DEWITT
for promoting General Relativity and Mathematics research and inventing the "summer school" concept.

RICCARDO GIACCONI
for opening, five successive times, new highways for exploring the Universe.

ROGER PENROSE
for extending the mathematical and geometrical foundations of General Relativity.

8th Marcel Grossmann Meeting
June 1997, Jerusalem

Institutional Award

HEBREW UNIVERSITY
for its role as a cradle of Science and Humanities and for hosting the manuscripts of Albert Einstein.

- presented to M. Magidor, President of the Hebrew University of Jerusalem

Individual Awards

TULLIO REGGE
for his contributions to the interface between mathematics and physics leading to new fields of research of paramount importance in relativistic astrophysics and particle physics.

FRANCIS EVERITT
for leading the development of extremely precise space experiments utilizing superconducting technology to test General Relativity and the Equivalence Principle.

7th Marcel Grossmann Meeting
June 1994, Stanford, USA

Institutional Award

SPACE TELESCOPE SCIENCE INSTITUTE
for its critical role in the direction and operation of the Hubble Space Telescope, a truly unique international laboratory for the investigation and testing of general relativity in the context of modern astrophysics and cosmology.

- presented to Peter Stockman

Individual Awards

SUBRAHMANYAN CHANDRASEKHAR
for his contributions to the analysis of gravitational phenomena from Newton to Einstein and especially for leading the way to relativistic astrophysics with the concept of critical mass for gravitational collapse.

JIM WILSON
for having built on his experience in nuclear physics, thermonuclear reactions, and extensive numerical simulation to create a new testing ground for the novel concepts of relativistic astrophysics.

6th Marcel Grossmann Meeting
June 1991, Kyoto, Japan

Institutional Award

RITP
for keeping alive first in Hiroshima and them in Kyoto research in relativity, cosmology, and relativistic field theory and the development of a school of international acclaim.

- presented to Professor K. Tomita

Individual Awards

MINORU ODA
for participating in the pioneering work of the early sixties in X-ray astronomy and for his subsequent molding of an agile and diversified Japanese scientific space program investigating the deepest aspects of relativistic astrophysics.

STEPHEN HAWKING
for his contributions to the understanding of spacetime singularities and of the large scale structure of the Universe and of its quantum origins.

5th Marcel Grossmann Meeting
August 1988, Perth, Australia

Institutional Award

THE UNIVERSITY OF WESTERN AUSTRALIA
for its contributions to relativistic astrophysics.

- presented to the Vice Chancellor, Professor Robert Smith

Individual Awards

SATIO HAYAKAWA
for his contributions to research in gamma, X-ray and infrared radiation as well as cosmic rays.

JOHN ARCHIBALD WHEELER
for his contributions to geometrodynamics and Einstein's visions.

4th Marcel Grossmann Meeting
July 1985, Rome, Italy

Institutional Award

THE VATICAN OBSERVATORY
for its contributions to the origin and development of astrophysics.

- presented to His Holiness Pope John Paul II

Individual Awards

WILLIAM FAIRBANK
for his work in gravitation and low temperature physics.

ABDUS SALAM
for his work in unifying fundamental interactions.

Institutional Awards for the Spektrum-Roentgen-Gamma (SRG) mission

"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance".

S.A. LAVOCHKIN ASSOCIATION
- presented to its Designer General **Alexander Shirshakov**

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
- presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
- presented to Professor **Rashid Sunyaev,** Principal Investigator of SRG Observatory in Russia

S.A. LAVOCHKIN ASSOCIATION
presented to its Designer General **Alexander Shirshakov**

Dr Alexander Shirshakov

S.A. Lavochkin Association created the Navigator space platform carrying German eRosita and Russian ART-XC X-Ray Telescopes, organized the launch of SRG Orbital X-Ray Observatory to the second Lagrangian point of the Sun-Earth system at a distance of 1.5 million km from the Earth and managed the observatory flight and the daily reception of its scientific data on Earth for 23.5 months.

Dr Alexander Shirshakov, Designer General of the S.A. Lavochkin Association, is specialized in design, manufacture, testing, launch and control of S/C for scientific purposes. Among those S/C launched, there are the «Radiostron» Astrophysical Observatory (2011) and the «Spektr-RG» space observatory (2019), while the planned S/C launches are «Luna-25» and «Exomars».

Dr Shirshakov started his career in 1973, working as an engineer of the State Unitary Enterprise «NPO named by S.A. Lavochkin» in Khimki (Russian Federation). Starting from 1989 he has played multiple roles within the Lavochkin Association, been appointed head of the group, head of the sector, head of department, deputy head of the complex, head of the branch, director of the center, deputy head of the Design Bureau, deputy General Designer and deputy General Director.

Dr Shirshakov is an editorial board Member of the reviewed edition of «Vestnik of Lavochkin Association». Since 2017, he is also member of the General Designer council. He has been awarded Honored Mechanical engineer of the Russian Federation as well as Agency-level award of the Russian Federal Space Agency.

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

Professor Peter Predehl

eROSITA is the soft X-ray telescope on-board the Russian-German Spektr-RG mission which was successfully launched from Baikonur on July 13, 2019 and placed in a halo orbit around the L2 point. 30 years after ROSAT, eROSITA performs an all-sky survey with an unprecedented sensitivity, spectral and angular resolution. Clusters of galaxies are the largest collapsed objects in the Universe. Their formation and evolution is dominated by gravity, i.e. Dark Matter, while their large scale distribution and number density depends on the geometry of the Universe, i.e. Dark Energy. X-ray observations of clusters of galaxies provide information on the rate of expansion of the Universe, the fraction of mass in visible matter, and the amplitude of primordial fluctuations which are the origin of clusters of galaxies and the whole structure of the universe. eROSITA has been designed to detect at least 100.000 clusters of galaxies and to detect systematically more than 3 million obscured accreting Black Holes. eROSITA will also allow to study the physics of galactic X-ray source

populations, like pre-main sequence stars, supernova remnants and X-ray binaries. The eROSITA telescope consists of seven identical Wolter-1 mirror modules. A novel detector system has been developed by MPE on the basis of the successful XMM-Newton pn-CCD technology. MPE is the scientific lead institute of eROSITA, responsible for the development of the instrument, the operation, the analysis software and data archive. Peter Predehl led this development as Principal Investigator of eROSITA and German lead scientist of the SRG mission for more than 15 years until the completion of the first of eight surveys in 2020. At this time eROSITA has already discovered more than 1 million X-ray sources, more than all X-ray observatories of the last 50 years together. This demonstrates that the design goals of the mission will easily be fulfilled.

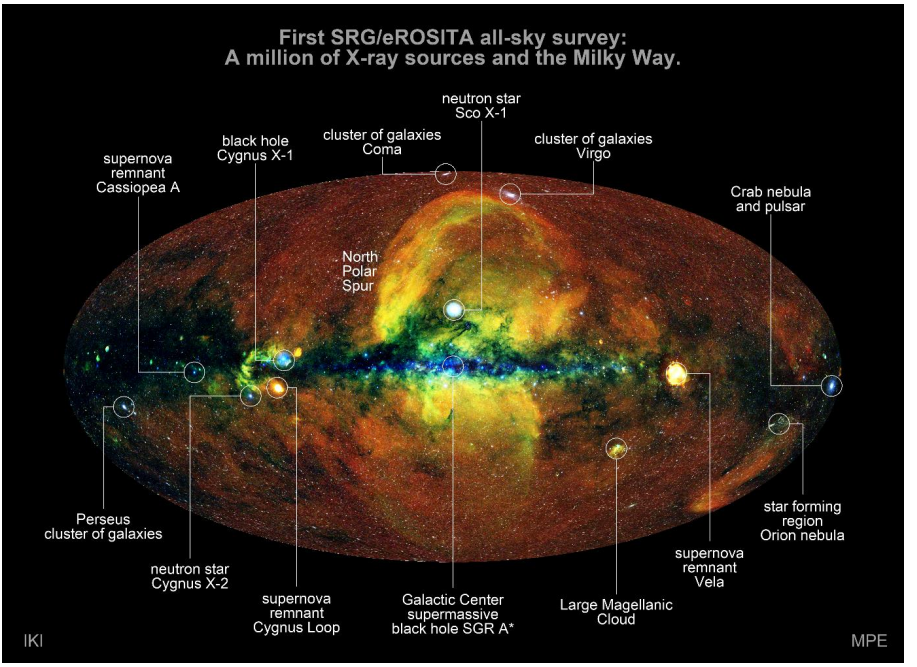
SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
presented to Professor **Rashid Sunyaev**

Professor Rashid Sunyaev

Space Research Institute (IKI) of the Russian Academy of Sciences was responsible for developing the overall concept and scientific program of the SRG Orbital observatory and played a leading role in developing the ART-XC telescope and the entire SRG observatory as part of the Russian space science program carried out by Roskosmos Corporation in the interests of the Russian Academy of Sciences.

During the flight to the L2 point of the Sun-Earth system, SRG with German (eRosita) and Russian (ART-XC named after Mikhail Pavlinsky) X-ray Telescopes aboard performed calibrations and long duration Performance Verification observations of a dozen of targets and deep fields. Starting in the middle of December 2019, the SRG scanned the whole sky three times. During these scans, SRG discovered two million point X-ray sources: mainly quasars, stars with hot and bright coronae, and more than 30 thousand clusters of galaxies. There is a competition and synergy in the search for clusters of galaxies between SRG and the ground-based Atacama Cosmology and South Pole Telescopes, which are searching for clusters of galaxies in microwave spectral band using Sunyaev-Zeldovich effect. SRG provided the X-Ray map of the whole sky in hard and soft bands, the last is now the best among existing. The huge samples of the X-ray selected quasars at the redshifts up to z = 6.2 and clusters of galaxies will be used for well-known cosmological tests and detailed study of the growth of the large scale structure of the Universe during and after reionization. SRG/eRosita is discovering every day several extragalactic objects which increased or decreased their brightness more than 10 times during half of the year after the previous scan of the same one-degree wide strip on the sky. A significant part of these objects has observational properties similar to the Events of Tidal Disruption of a star orbiting in the vicinity of the supermassive black hole. ART-XC discovered a lot of bright galactic and extragalactic transients.

Rashid Sunyaev is the Principal Investigator of SRG mission in Russia, director-emeritus of the Max-Planck Institute for Astrophysics and Maureen and John Hendricks distinguished visiting professor of the Institute for Advanced Study, Princeton.



Individual Awards

Professor **DEMETRIOS CHRISTODOULOU**

"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."

Professor Demetrios Christodoulou

It was back in 1967 that Achille Papapetrou mentioned the case of the 16-year-old Demetrios Christodoulou to John Archibad Wheeler. Wheeler interviewed Demetrios in Paris and brought him immediately to Princeton where he was registered as an undergraduate at the university. After one year he entered the graduate school and started collaborating with me. At the time I was working with Wheeler on the effective potential approach to geodesics co-rotating and counter-rotating (see e.g. reference in The Classical Theory of Fields (Landau and Lifshitz, 1980) in the Kerr metric (later renamed as ISCO; see e.g. (Gravitation Misner, Thorne, Wheeler. 1973). In parallel, Frank Zerilli was working on the gravitational radiation emitted by the fall of a test particle in a Schwarzschild black hole (Zerilli 1970). From these limited conceptual arena Charles Misner and later Kip Thorne launched a program for the detection of gravitational waves on the Earth; see e.g. Misner 1974, Abbott et al. 2016, Abbott et al. 2017. See however Davis et al. 1972, Rodriguez et al. 2018 and J.A. Rueda et al. 2018.

A new approach started with the arrival of Demetrios: he was just creating mathematics following his needs. We identified the reversible and irreversible transformations of a Kerr black hole. Wheeler advanced a thermodynamic analogy. I addressed the need of identifying the concept of irreducible mass (from the Italian "irriducibile"), and was Demetrios's contribution to integrate, overnight, the differential equation for infinitesimal reversible transformations which led to the finite mass-energy formula of a Kerr black hole. That evening, while walking back home through IAS woods, I expressed to Wheeler the great relevance of the newly found formula by Demetrios and proposed to let Demetrios be the single author of this article, admiring his great mathematical talent. Wheeler agreed. The Editor of PRL objected since in that two pages article the Fig. 2 by Wheeler and myself was still unpublished. Actually that Fig. 2 followed a discussion I previously had with Penrose in Florence (Penrose 1961) which allowed us to present there, for the first time, a "Penrose Process". Some difficulties in achieving this process were obvious from the example in Fig. 2, which Roger later recognized himself (Penrose & Floyd 1971). The Editor finally agreed on our written request and the paper appeared on September 17, 1970 (Christodoulou, 1970). On January 1971 appeared my article with Johnny introducing the Black Hole (Ruffini & Wheeler, 1971), with the new physics we were developing in Princeton, including the concept of the "ergosphere". On march 1 1971 we submitted the mass formula of the Kerr Newmann metric, including the relation between the surface area of the horizon and the irreducible (Christodoulou & Ruffini, 1971). On March 11, 1971 the same results were independently confirmed by Steven Hawking, extending further the applicability of our equation (Hawking 1971).

The thesis was successfully discussed by a committee including Eugene Wigner (see Fig. 1), one of the closest collaborators of Albert Einstein and David Wilkinson (see Fig. 2), the head of the NASA WMAP mission, and Johnny and myself as supervisors. The new message was clear: Black Holes, far from being a sink of energy, were energy sources emitting "in principle" 50% of their mass energy, being extractable (Christodoulou & Ruffini, 1971).

Fig. 1 and Fig. 2: Demetrios during his thesis presentation with Eugene Wigner (Fig. 1) and David Wilkinson (Fig.2). Johnny and I were supervisors, ready to intervene in case of need, but no need of intervention was necessary! Wigner elaborated the aphorism of Niels Bohr "Interesting = wrong" in the most definite "very interesting if true = totally wrong".

Demetrios turned soon to the study of partial differential equations and mathematical physics, to which he dedicated for the rest of his career and results were published in four monographs: (Christodoulou and Klainerman 1994, Christodoulou 2007, Christodoulou 2009, Christodoulou 2019). In 1968, Johnny proposed to Demetrios the collapse of a "geon" composed of massless scalar field as a second topic for his thesis. It took almost forty years for him to solve this problem, extended by Demetrios to the focusing of gravitational waves leading to black hole formation (Christodoulou 2009).

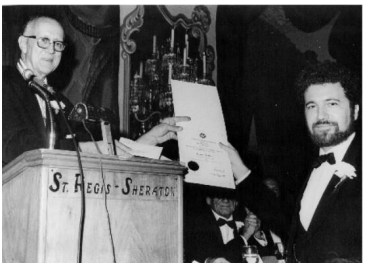


Fig. 3: Prof. Remo Ruffini receiving the Cressy Morrison Award of the New York Academy of Sciences, 1972 for the discovery of the first Black Hole in our galaxy Cygnus X1.

A "long march" started on 12 December 1970 with the launch of the Uhuru satellite by Riccardo Giacconi. Early in 1971 an almost daily conversation with him and Herb Gursky at the Smithsonian Astrophysical Observatory, leading to the discovery of binary X-ray sources. This was soon followedby the announcement of Cygnus X1 identified as the first black hole in our galaxy (Ruffini 1973); see e.g. Gursky & Ruffini 1975, which contained as well the first publicannouncement of the Discovery of Gamma Ray burst, as well as Giacconi & Ruffini 1980, 2009; see Figs. 3 and 4).

Fig. 4: In the second row, from left to right, there are, among others: E. T. Newman, S. Chandrasekhar (Nobel 1983), R. Giacconi (Nobel 2002), R. Ruffini, A. Treves, A. Hewish (Nobel 1974), D. Arnett, J.H. Taylor (Nobel 1993), J. Wilson, R. Penrose (Nobel 2020), as well as J. Bahcall, T. Damour, T. Piran et al.

Today, after fifty years, this "long march" has reached a definite result: through the grandest observational multi-wavelength effort in the history of mankind, from space, ground and underground observatories, we are finally finding evidence that black holes are "alive" and their "extractable energy" in our mass formula (Christodoulou & Ruffini, 1971), is the energy source of the most energetic cosmological sources: gamma ray bursts (GRBs),the active galactic nuclei (AGNs) as well as the ultra-high energy cosmic rays (UHECRs) (Ruffini et al. 2021 and references therein). Their "inner engine", has three independent components: 1) a Kerr black hole which is neither in a stationary state nor in vacuum, 2) a background magnetic field aligned with the black hole rotation axis, and 3) an extremely diluted fully ionized plasma (Moradi et al. 2021).There is no role in this inner engine for ISCO. Indeed a new electro dynamical field equations describe the synchrotron radiation emitted close to the black hole horizon, they point to a discrete and repetitive emission of "blackholic quanta" in the MeV and in the GeV. The magnitudes and the emission time scales of these quanta, for M87 and GRB 130427A, are expressed as a function of the above three parameters (Rueda & Ruffini, 2021). A long lasting GeV emission with a luminosity decreasing as a temporal power law, allows for the first time in GRBs, the determination of the black hole mass and spin as well as their time evolution perfectly fulfilling our mass energy formula (Christodoulou & Ruffini, 1971): a long lasting emission process profoundly different from the traditional process of continued gravitational contraction.

Remo Ruffini

Professor **GERARD 't HOOFT**

"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon".

Professor Gerard 't Hooft

Prof. Gerard 't Hooft has been a full Professor at the Utrecht University (the Netherlands), since 1977. Nowadays, he is an Emeritus Professor at that University. During his career, he has paid extended scientific visits to CERN (Geneva), Harvard, Stanford, Princeton and Duke University, NC. In 1999, together with M. Veltman, he received the Nobel Prize in Physics, awarded by The Royal Swedish Academy of Sciences, *"For elucidating the quantum structure of electroweak interactions in physics"*.

Prof. 't Hooft's main subjects of research includes:

– Gauge Theories for the sub-atomic particles and forces, various aspects and ingredients of what is now called "The Standard Model of the sub-atomic particles: renormalizability, topological features such as magnetic monopoles and instantons, 1/N expansions.

– Theories for the quantization of the gravitational force and black holes: producing models for the quantum properties of a black hole, as derived from Standard Model and General Relativity alone; its topological features such as antipodal identification.

– Fundamental theories underlying quantum mechanics, in particular returning determinism and reality to the dynamics of the tiniest material entities in his universe.

Prof. 't Hooft has been awarded the Wolf Prize of the State of Israel (1982), the Pius XI Medal (Vatican City, 1983), the Lorentz Medal (KNAW Amsterdam, 1986) as well as the Spinoza Premium (Netherlands Organization for Scientific Research NWO, 1995).

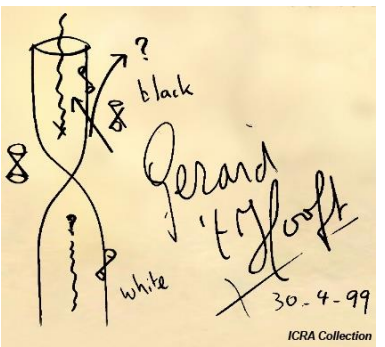

Fig. 2: The signature of Gerard 't Hooft on the wall of ICRA Room 301 (April 4, 1999).

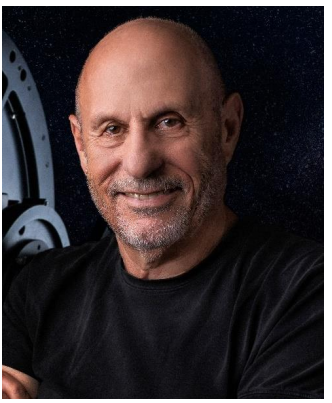
A special event took place at ICRA on April 30, 1999. Prof. Ruffini invited Gerard 't Hooft to Rome to discuss a boundary condition for a quantum field on the black hole horizon, a topic Prof. Ruffini discussed in a previous article "Black-hole evaporation in the Klein-Sauter-Heisenberg-Euler formalism" with Thibault Damour (Phys. Rev. D 14, 332, 1976), but which needed to be examined in more detail. Prof. Ruffini planned to direct Gerard's attention to some specific aspects of this problem. Because we have traditionally been very attentive in spending ICRA travel funds, ICRA offered Gerard to come to Rome on a reduced fare weekend ticket arriving Friday and departing Monday. He had a great relaxing weekend together with Prof. Ruffini following his seminar, which among other things allowed Gerard to sign the wall in our ICRA Room (see Fig. 2), and during this splendid Rome spring weekend he also was able to find a missing factor of 2 in a formula in Prof. Ruffini's 1971 paper with Demetri Christodoulou on the black hole mass formula. The following October, Gerard received the Nobel prize, which meant that we could no longer get away with bringing him to Rome on a cheap ticket! Ever since Gerard has been in our MG IOC helping us with the preparation of the meetings. We are very happy to announce this MG16 Award to Gerard 't Hooft with the motivating phrase *"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon"*.

Remo Ruffini

Professor **TSVI PIRAN**

"for extending relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory".



Professor Tsvi Piran

Tsvi Piran is the emeritus Schwartzmann professor at the Hebrew University of Jerusalem. He obtained his PhD in Physics, in 1976 from the Hebrew University working on the collisional Penrose process. Piran returned to the Hebrew University at 1981after being a post doc at Oxford and Texas and a long-term member at the IAS at Princeton. In 1982 he initiated and directed the first ever summer school on Gravitational Waves that took place at Les Houches. Piran was a visiting professor at Harvard, Columbia and New York and a Moore scholar at Caltech.

Piran's research deals with numerous aspects of relativistic astrophysics, ranging from the foundation of numerical relativity to modeling of observer relativistic phenomena and analytic work on the fate of gravitational collapse. Piran's research work focuses mostly on black holes and in particular on gamma-ray bursts. He was among the first to point out their cosmological origin and their association with merging neutron stars and heavy r-process nucleo synthesis. Piran's achievements were recognized in the 2019 EMET prize for Physics.

Professor **STEVEN WEINBERG**

"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory".

Professor Steven Weinberg. Photo courtesy of Matt Valentine.

Steven Weinberg is a member of the Physics and Astronomy Departments at The University of Texas at Austin. His research has covered a broad range of topics in quantum field theory, elementary particle physics and cosmology. He has been honored with numerous awards, including the Nobel Prize in Physics, the National Medal of Science, the Heinemann Prize in Mathematical Physics and in 2020, the Breakthrough Prize. He is a member of the US National Academy of Sciences, Britain's Royal Society, and other academies in the USA and abroad. The American Philosophical Society awarded him the Benjamin Franklin Medal, with a citation that said he is "considered by many to be the preeminent theoretical physicist alive in the world today." His books for physicists include *Gravitation and Cosmology*, the three-volume work *The Quantum Theory of Fields*, *Cosmology* and published in April of 2021, *Foundations of Modern Physics*. Educated at Cornell, Copenhagen, and Princeton, he also holds honorary degrees from sixteen other universities. He taught at Columbia, Berkeley, M.I.T., and Harvard, where he was Higgins Professor of Physics, before coming to Texas in 1982.

Fig. 1: Chuo Pei Yuan and Cheng Ning Yang at MG2 in Trieste, Italy (1979).

The Sixteenth Marcel Grossmann Meeting (MG16) is a very special one in many respects: it will take place during a pandemic and in spite of the many difficulties, we have decided not to postpone it but to organize it as a virtual meeting. As described on the MG series webpage, these meetings started in 1975 with the first meeting at the International Centre for Theoretical Physics (ICTP) in Trieste (Italy) that I organized with Nobel Prize winner Abdus Salam. A second meeting followed in 1979, with a significantly larger participation including Nobel Laurate Cheng Ning Yang and a Chinese delegation led by Chuo Pei Yuan (see Fig. 1), including Fang Li-Zhi who had accompanied me during my entire first visit to China in 1979. The first truly international MG meeting followed in 1982 in Shanghai (China):this represented an especially important step forward both for the meeting and for China. A multi-millennia *"motto"* in China, which was then proclaimed on banners everywhere, read *"Friends from all over the world are welcomed"*.

We were soon at an impasse over the participation of scientists from Israel, since no diplomatic relations existed between China and Israel at that time and the Israeli scientists were not to be allowed to attend the meeting. A long negotiation began. The boundary conditions were clearly set by Steven Weinberg, a member of the present MG16 IOC: no MG meetings on Einstein's theory of general relativity could occur without the participation of Israeli scientists. The intervention of Yuval Ne'emann, also a member of the MG IOC then as well as the Minister of Science of Israel (see Fig.2), proposed a compromise that would admit at least one Israeli scientist. I went to Beijing alone, meeting every morning for a week with 12 Chinese representatives led by Chuo Pei Yuan going over all possible options. I stayed in an isolated villa not far from Tiananmen Square, accompanied by the 3 volumes of Matteo Ricci (RI MA TO) to keep me company. No solution was in sight the entire week. At the last moment, just before my departure, an agreement was finally reached allowing two Israeli scientists into China. The historic compromise would admit Gerard Tauber and Tsvi Piran into China using a special ICRA travel document I had proposed for them to be able to participate in the meeting, accepted by the Chinese Ambassador in Rome. This modified the thousand-year Chinese *"motto"* to read *"Scientists from all over the world are welcomed"*. The event was extremely beneficial for China and signaled the truly international nature of the MG meetings.

Fig. 2: From right to left: Chaim Weizmann, President of Israel; Yuval Ne'emann, Minister of Science of Israel; R. Ruffini.

I kept on meeting Tauber in the years which followed (see Fig. 3). Soon after, Yuval Ne'emann visited China. The development of bilateral relations, including military cooperation and economical tights, grow exponentially until the establishment of normal diplomatic relations between Israel and China in 1992.

Fig. 3: From right to left: Arrigo Finzi, Remo Ruffini, Gerard Tauber and Konrad Bleuler.

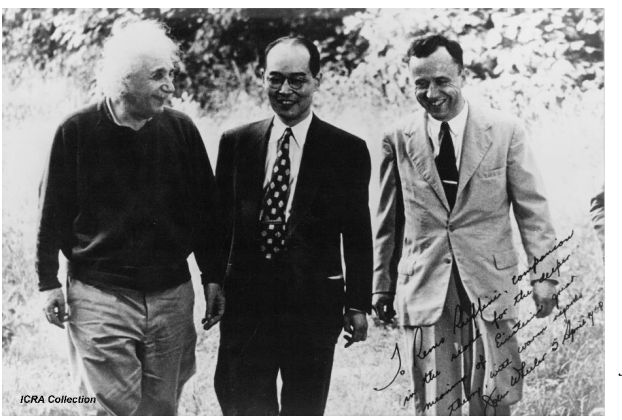


Fig. 4: Albert Einstein, Hideki Yukawa and John. A. Wheeler with a hand-written dedication to Remo Ruffini "To Remo Ruffini, companion in the search for the deeper meaning of Einstein great theory. With warm regards, John Wheeler 5 April 1968".

Given their key role played in the foundations of the MG meetings, I am very happy to propose on behalf of the MG16 IOC, two special Marcel Grossmann Individual Awards: one to Steven Weinberg for *"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory"* and another one to Tsvi Piran, *"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory"*, in the words of John A. Wheeler's photo dedication to me (see Fig. 4).

Remo Ruffini

PREFACE

Since 1975, the Marcel Grossmann Meetings on Recent Developments in Theoretical and Experimental General Relativity, Gravitation, and Relativistic Field Theories have been organized in order to provide opportunities for discussing recent advances in gravitation, general relativity and relativistic field theories, emphasizing mathematical foundations, physical predictions and experimental tests. The objective of these meetings is to elicit exchange among scientists that may deepen our understanding of spacetime structures as well as to review the status of ongoing experiments aimed at testing Einstein's theory of gravitation either from the ground or from space. Previous meetings have been held in Trieste (MG1: 1975) and (MG2: 1979), Shanghai (MG3: 1982), Rome (MG4: 1985, MG9: 2000), Perth (MG5: 1988), Kyoto (MG6: 1991), Stanford (MG7: 1994), Jerusalem (MG8: 1997), Rio (MG10: 2003), Berlin (MG11: 2006), Paris (MG12: 2009), Stockholm (MG13: 2012), MG14 in 2015 and MG15 in 2018 both in Rome.

Due to the COVID-19 pandemic spreading in the last two years the decision was taken to organize the Sixteenth Marcel Grossmann meeting for the first time in history entirely online. Despite numerous challenges, related to the organization of large worldwide event, MG16 showed the strongest ever interest from the scientific community with a record-breaking number of almost 1200 registered participants and of more than 1000 speakers.

The traditional six-day schedule has been modified to account for different time zones of the speakers and each day the program of the meeting was divided in three blocks with the reference to the Central European Summer Time. The first block was starting at 06:30 in the morning, allowing comfortable time for speakers from Asia and Oceania. The second block was held in the daytime in Europe and Africa. The third block was starting in the afternoon and ending at 19:30 allowing accommodation of the speakers from the Americas. Each day the blocks of plenary sessions were interchanging with the blocks of about 30 parallel sessions each, making this one of the most intense MG meetings ever. All this was possible thanks to recent developments in communication technologies. The Indico open-source software was selected as a web platform for this meeting, while Zoom platform was adopted for the video-conferencing. The meeting was streamed on ICRANet YouTube channel.

The meeting started on Monday July 5 with the Award ceremony. The individual awards went to Demetrios Christodoulou, Tsvi Piran, Gerard 't Hooft and Steven Weinberg, while the Institutional Awards went to the S.A. Lavochkin Association, to the Max Planck Institute for Extraterrestrial Physics – MPE and to the Space Research Institute IKI of the Russian Academy of Sciences. Overall there were 54 plenary talks, 4 public lectures and 5 roundtables and about 90 parallel sessions. The plenary session "Events in Relativistics Astrophysics" on Monday have seen the contributions from Rashid Sunyaev, Michael Kramer, James Miller-Jones, Felix Mirabel. The public lectures were delivered by Razmik Mirzoyan, Asghar Qadir

and Mohammad Bagheri. Plenary talks on Tuesday session "Black holes and the Quantum" by Juan Maldacena, Ahmed Almheiri, Gerard 't Hooft, Mihalis Dafermos, Sergiu Klainerman, Abhay Ashtekar and Frank Wilczek were bracketed by two roundtables on "New results from SRG/eRosita" with the participation of Andrea Merloni, Prof. Rashid Sunyaev, Alexander Lutovinov, Chandreyee Maitra, Esra Bulbul and "Solar neutrinos and Borexino" with the participation of Gianpaolo Bellini and Wick Haxton. Plenary talks on Wednesday in the session "Lambda CDM tensions" by George Efstathiou, Scolnic Daniel, Marc Kamionkowski, Wendy Freedman, Priya Natarajan and Licia Verde were followed by the roundtable "Precision cosmology" with the participation of Licia Verde, Marc Kamionkowski, Piero Rosati, and the public lecture by Francis Halzen. Two blocks of Thursday plenary sessions "Black holes in GRBs" and "Precision tests" included the talks by Roy Kerr, Yuan Ha, Lorenzo Amati, Elena Pian, Carlos Raúl Argüelles, Di Li, Jianglai Liu, Claus Lämmerzahl, Gerhard Heinzel and Ignazio Ciufolini and were followed by the roundtable "GRB 170817A and GRB 190829A" with the participation of Eleonora Troja, Liang Li, Rahim Moradi, Jorge Armando Rueda Hernandez. Two plenary blocks on Friday "Massive stars" and "Physics behind stellar collapse" included the talks by Selma de Mink, Norbert Langer, Jiri Bicak and Tomáš Ledvinka, Ivan De Mitri, Rahim Moradi and Giancarlo Cella. Finally, two plenary blocks on Saturday "Current and future missions" have seen the talks by Shuang-Nan Zhang, Weimin Yuan, Makoto Tashiro, Ruoyu Liu, Jean-Luc Atteia, Jim Hinton and Nicholas White and were followed by the roundtable "What is in our Galactic center" with the participation of Reinhard Genzel, Carlos Raúl Argüelles, Andreas Krut, Jorge Armando Rueda Hernandez, Eduar Becerra Vergara. The program of the meeting can be found at the official website http://www.icra.it/mg/mg16 and at ICRANet Indico website https://indico.icranet.org/event/1/.

These proceedings include about 400 papers containing the results presented at the Sixteenth Marcel Grossmann meeting. The plenary papers from the meeting have been published in International Journal of Modern Physics D as they were submitted. The table of contents includes also the links to YouTube videos with talks given at the meeting and cover plenary talks, public lectures, roundtables and all parallel sessions. The general link to the videos from MG16 is: https://www.youtube.com/watch?v=QFe1lsSid-o&list=PLr5RLbSWSonsaOnZukBDs0qsNIWM8AvRF.

As the editors we would like to express our gratitude to all the chairpersons of the parallel sessions at MG16, who peer-reviewed the papers submitted for these proceedings, as well as to the ICRANet secretariat office and in particular to Cinzia di Niccolo, Elisabetta Natale and Yasmina Di Domizio, as well as to ICRANet system manager Gabriele Brandolini for their help in preparation of this publication.

Preface xxxvi

PART A
PLENARY SESSIONS

New results from testing relativistic gravity with radio pulsars
Michael Kramer 3

Dragging of inertial frames by matter and waves
Jiří Bičák and Tomáš Ledvinka 22

Probes of the progenitors, engines and physics behind stellar collapse
Chris L. Fryer 39

The observation of high-energy neutrinos from the cosmos: Lessons learned for multimessenger astronomy
Francis Halzen 59

The first results of PandaX-4T
Jianglai Liu on behalf of the PandaX Collaboration 85

XRISM: X-ray imaging and spectroscopy mission
Makoto S. Tashiro and the XRISM team 95

The SVOM mission
J.-L. Atteia, B. Cordier and J. Wei on behalf of the SVOM Collaboration 104

Quantum field theory with boundary conditions at the horizons
Gerard 't Hooft 133

The development of general relativity and the cosmological constant
Asghar Qadir 143

The irreducible mass of Christodoulou-Ruffini-Hawking mass formula
Yuan K. Ha 154

Reshaping our understanding on structure formation with the quantum nature of the dark matter
C. R. Argüelles, E. A. Becerra-Vergara, A. Krut et al. 164

First results of LHAASO
Ruo-Yu Liu for the LHAASO Collaboration 180

On the MG16 awards 2021
Remo Ruffini 196

The white dwarf binary merger model of GRB 170817A
J. A. Rueda, R. Ruffini, Liang Li et al. 217

PARALLEL SESSIONS

Accretion

• MHD Processes Near Compact Objects
Chairperson: Sergey Moiseenko
YouTube link: https://youtu.be/2WMTg06ZmV8

A semi-implicit multidimensional unstructured gas dynamical solver for astrophysical applications
Ilya A. Kondratyev and Sergey G. Moiseenko 242

Magnetized neutron stars propagating through a non-uniform ISM
O. D. Toropina, M. M. Romanova and R. V. E. Lovelace 255

Calculation of the kinetic coefficients of arbitrary degenerate electrons in magnetized dense matter
M. V. Glushikhina and G. S. Bisnovatyi-Kogan 264

Modeling of magnetic fields of accretion discs, using no-z- and RZ-approximations
M. V. Pashentseva and E. A. Mikhailov 272

• Accretion Discs and Jets
Chairpersons: Audrey Trova and Shokoufe Faraji
YouTube link: https://youtu.be/29Wj9RCVEKw

Limiting effects in tori clusters
D. Pugliese and Z. Stuchlik 280

Hydrodynamical transport of angular momentum in accretion disks in the presence of nonlinear perturbations due to noise
Subham Ghosh and Banibrata Mukhopadhyay 295

Properties of accretion disc models in the background quadrupole
Shokoufe Faraji 307

Magnetized tori around a uniformly accelerating black hole
Shokoufe Faraji and Audrey Trova 317

Multifrequency behaviour of high mass X-ray binaries (Time lag between optical and X-ray outbursts)
Franco Giovannelli 321

Active Galactic Nuclei

• The Black Hole in M87
Chairpersons: Brian Punsly and Jorge Rueda
YouTube link: https://youtu.be/l1lTgksyJag

Rotation of the crescent image of M87* and polarization of its ESE hotspot
Krzysztof Nalewajko 339

Magnetic reconnection in jet-accretion disk systems
Chandra B. Singh, Elisabete M. de Gouveia Dal Pino, Luis H. S. Kadowaki et al. 344

• Machine Learning in Astronomy: AGN, Transient Events, Cosmology and Others
Chairpersons: Rahim Moradi and Yu Wang
YouTube link: https://youtu.be/ErqrmMZQsBk

Exact fractal model of the universe and possible machine learning methods for the verification of the fractality
A. A. Kirillov, E. P. Savelova and P. O. Vladykina 352

Estimating the photometric redshifts of galaxies and QSOs using regression techniques in machine learning
A. Momtaz, M. H. Salimi and S. Shakeri 368

Deep learning in quasar physics
F. Rastegar Nia, M. T. Mirtorabi, R. Moradi, Y. Wang and A. Vafaei Sadr 382

Cosmological density field emulation and gravitational wave inference based on dimensionality reduction and supervised machine learning
Miguel Conceição, António da Silva and Alberto Krone-Martins 391

Unsupervised photometric detection of galaxy cluster candidates in large surveys
Ana Carvalho, Alberto Krone-Martins and Antonio da Silva 409

• Multiwavelength and Multi-Messenger Observations of Active Galactic Nuclei
Chairpersons: Paolo Giommi and Narek Sahakyan

Teaching relativity: A paradigm change
F. Herrmann and M. Pohlig 2371

Teaching relativity: Computer-aided modeling
F. Herrmann and M. Pohlig 2381

Solstices and Equinoxes in 1703 at the meridian line of St. Maria degli Angeli in Rome, and the stellar aberration of Sirius
Costantino Sigismondi and Silvia Pietroni 2388

Positional astrometry at arcsecond accuracy using historical instruments, with light equipment
Costantino Sigismondi and Lorenzo Ricciardi 2398

Daily, seasonal, and equinoctial solar paths on a school soccer field
Costantino Sigismondi 2411

Teaching relativity at the AstroCamp
C. J. A. P. Martins 2415

Sungrazing comets as General Relativistic gravitational probes
Silvia Pietroni and Costantino Sigismondi 2424

The three Summer solstice's markers of 1721 unveiled in the Basilica of Santa Maria degli Angeli in Rome
Costantino Sigismondi 2428

Einstein-First: Bringing children our best understanding of reality
A. Popkova, K. Adams, S. Boublil et al. 2438

Exact Solutions

• **Exact Solutions in Four and Higher Dimensions**
Chairpersons: David Blair and Matteo Luca Ruggiero

YouTube link: https://youtu.be/GHZUS5-4gVQ

Kundt spacetimes in the Einstein–Gauss–Bonnet theory
R. Švarc, J. Podolský and O. Hruška 2453

Exact decoupled solutions in curvature-matter coupled gravity
M. Sharif and Fizza Furqan 2464

Tolman-Oppenheimer-Volkov conditions beyond spherical symmetry
José P. Mimoso, Alan Maciel and Morgan Le Delliou 2479

A spherically symmetric stiff fluid spacetime in light of cosmic structure formation
Daniele Gregoris 2497

• **Exact Solutions (Including Higher Dimensions)**
Chairperson: Susan Scott

YouTube link: https://youtu.be/-hJjJvmmOew

Three-parameter solution for the null-surface formulation in 2+1 dimensions
Tina A. Harriott and J. G. Williams 2510

New exact stationary cylindrical anisotropic fluid solution of GR
M.-N. Célérier 2522

Early Universe

• **Quantum Fields**
Chairperson: Andrei Lebed

YouTube links: https://youtu.be/BLaTp0r0TkQ
https://youtu.be/ZifgaSDy5Vc

Hydrodynamic representation and energy balance for the Dirac and Weyl fermions in curved space-times
Tonatiuh Matos, Omar Gallegos and Pierre-Henri Chavanis 2533

Breakdown of the Equivalence Principle for a composite quantum body
A. G. Lebed 2551

Extended DeWitt-Schwinger subtraction scheme, heavy fields and decoupling
Antonio Ferreiro and Jose Navarro-Salas 2557

Renormalization and decoupling for the Yukawa model in curved spacetime
Sergi Nadal-Gisbert, Antonio Ferreiro and José Navarro-Salas 2562

Trace anomaly and evaporation of spherical black holes
P. Meda 2573

On decay of the false Unruh vacuum
A. Shkerin 2587

Behaviour of noise kernel in de Sitter and FRW space-times
Ankit Dhanuka and Kinjalk Lochan 2600

Breaking Buchdahl: Ultracompact stars in semiclassical gravity
Julio Arrechea, Carlos Barceló, Raúl Carballo-Rubio and Luis J. Garay 2608

Einstein anomaly with tensors of odd order in six dimensional curved space
Kohei Yamamoto and Satoshi Yajima 2619

Quantum memory and BMS symmetries
Sanved Kolekar and Jorma Louko 2623

• Topological Methods, Global Existence Problems, and Spacetime Singularities
Chairperson: Spiros Cotsakis

YouTube link: https://youtu.be/H8Itnc_C10c

Gravitational singularities, scattering maps for bouncing, and structure-preserving algorithms
Philippe G. LeFloch 2630

Brane-world asymptotics in a nonlinear fluid bulk
I. Antoniadis, S. Cotsakis and Ifigeneia Klaoudatou 2645

Primordial synchronization of Mixmaster spatial points
Spiros Cotsakis 2657

Reconstruction of a star motion in the vicinity of black hole from the redshift of the electromagnetic spectrum

S. O. Komarov* and A. K. Gorbatsievich
Theoretical Physics and Astrophysics Department, Belarusian State University, Minsk, Belarus
**E-mail: StasKomarov@tut.by*
www.KomarovSO.bsu.by

The problem of calculating the redshift of electromagnetic spectrum of the star, moving in the vicinity of Schwarzschild black hole is solved within the framework of the General Theory of Relativity. The inverse problem — determination the parameters of the motion of a star from observational data of redshift is considered. The approach that gives possibilities to solve the inverse problem is proposed. The approach is tested on the numerical model that gives possibilities to calculate redshift as function of time of observation for a star moving in the vicinity of Schwarzschild black hole. The parameters of the star in numerical model are close to parameters of the S-stars, moving in the vicinity of the Sgr A*.

Keywords: Black hole; gravitational redshift.

1. Introduction

It is well-known from astrophysical observations that supermassive black hole with mass $m_{SBH} \approx 4 \cdot 10^6 m_\odot$,[1,2] where $m_\odot$ is the mass of the Sun, exists in the Galactic Center.[1,3–5] Apart from this, large amount of stars exists in this region. For example, S-cluster includes stars closest to supermassive black hole.[2,6–8]

Astrophysical observations of such stars give possibility to study the structure of the Galactic Center and to test theories of gravity. The main source of information about the motion of these stars is their electromagnetic radiation. In the present work, we have performed theoretical investigation of the redshift of electromagnetic radiation of a star moving in the vicinity of a black hole. This problem includes two parts: the direct problem — calculation the redshift of the electromagnetic radiation of a star moving in external gravitational field and the inverse problem: — determination the motion of the star in external gravitational field if redshift as function of time of observation is known.

The direct problem within the framework of the General Relativity is considered in many papers see, e.g.,[6–12]. The mentioned studies consider different general relativistic effects such as Shapiro delay, gravitational redshift, and Doppler shift. To solve the direct problem, one needs to solve the boundary value problem for the isotropic geodesic that connects the source and the observer. In the cited studies, if the corresponding general relativistic effects are taken into account, this problem is solved using tables of impact parameters that make the accuracy of the solution limited by the step of the data in the tables. In our previous papers,[13–15] we developed a covariant approach that allows one to obtain compact expressions

for redshift as a function of observation time. We have solved the boundary value problem by numerically solving a non-linear equation, which allows for much more accurate solutions than table-based methods.

For the solution of inverse problem it is necessary to use statistical methods such us MCMC method.[6,8–10,12] But mentioned studies do not contain any approach for constructing initial guess for the solution of the problem. The method that is presented in this paper gives possibility to obtain such guesses from graphics.

As an example of solving the inverse problem, we consider a mathematical model of a star moving close to a supermassive black hole. For the demonstration purpose, we chose the parameters of motion corresponding to a star on a slightly closer orbit around the black hole than the orbits of known S-stars (see, e.g.,[2,5]). Such orbits allow us to test the approach in the strong-field regime apply to the cases when the sources are on very tight orbits near the Galactic Center. Sources with such orbits may be found with future observations.

In this paper, we use a system of units where the speed of light in the vacuum is equal to unity ($c = 1$), and the metric has signature $-\,+\,+\,+$.

2. Theoretical model

In the present paper consider only the case of spherically symmetric non-charged black hole. In General Relativity such a black hole can be described by the Schwarzschild metric (see, e.g.,[16]):

$$\mathrm{d}s^2 = \frac{\mathrm{d}r^2}{1-2M/r} + r^2\mathrm{d}\theta^2 + r^2\sin^2\theta\mathrm{d}\varphi^2 - \left(1-\frac{2M}{r}\right)\mathrm{d}t^2\,. \tag{1}$$

Here, $x^i = \{t,\, r,\, \theta,\, \varphi\}$ are Schwarzschild coordinates. Furthermore, $M = Gm_{SBH}$, where G is the gravitational constant. In our model, the mass of the black hole m_{SBH} is much larger than the mass of the star $m_s \sim m_\odot$. Because of this, we model source stars as test particles moving in the external gravitational field of the supermassive black hole. One can obtain the 4-velocity components of the star from the geodesic equation. They have the following form (see, e.g.,[16]):

$$\begin{aligned}
u^0 &= \frac{\mathrm{d}t}{\mathrm{d}\tau} = \frac{E}{(1-2M/r)}\,;\\
u^1 &= \frac{\mathrm{d}r}{\mathrm{d}\tau} = e_s\sqrt{E^2-(1-2M/r)(1+L^2/r^2)}\,;\\
u^2 &= \frac{\mathrm{d}\theta}{\mathrm{d}\tau} = 0\,;\\
u^3 &= \frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = \frac{L}{r^2}\,,
\end{aligned} \tag{2}$$

where we chose the orientation of the spatial part of the coordinate system in such a way that the trajectory of the star lies in the plane $\theta = \pi/2$. Here L is the specific angular momentum of the star (in mass), E is its specific energy (in mass), and τ is its proper time. Factor e_s describes whether the considered part of the trajectory is receding or approaching.

From the system of equations (2), one can find the trajectory of the star in analytic form. In the case of finite motion, it has the following form (see, e.g.,[17]):

$$\frac{1}{r} = \frac{1}{r_s(\varphi,\, \delta,\, p_1,\, p_2)} = \frac{1}{p_1} - \frac{p_2 - p_1}{p_1 p_2}\,\mathrm{sn}^2\left[\frac{(\varphi-\delta)}{2}\sqrt{1 - \frac{4M}{p_2} - \frac{2M}{p_1}},\, k_s\right], \qquad (3)$$

where

$$k_s = \sqrt{\frac{p_2 - p_1}{p_1 p_2/(2M) - p_2 - 2p_1}},$$

where $\mathrm{sn}[\varphi,\, k]$ is the Jacobi sine of the first kind (see[18] for definition), δ is the longitude of pericenter, and p_1 and p_2 are pericenter and apocenter distances respectively. They are uniquely related to E and L as follows:

$$L = \frac{p_1 p_2}{\sqrt{\left(1 + \frac{p_1 + p_2}{2M}\right) p_1 p_2 - (p_1 + p_2)^2}}\,; E = \sqrt{\frac{(p_1 + p_2)\left(2M + \frac{p_1 p_2}{2M} - p_1 - p_2\right)}{\left(1 + \frac{p_1 + p_2}{2M}\right) p_1 p_2 - (p_1 + p_2)^2}}\,. \qquad (4)$$

The proper time of the star τ can be expressed as a function of its angular coordinate φ by using the well-known analytic formula (see, e.g.,[17]):

$$\tau = \tau_s(\varphi,\, p_1,\, p_2) + \tau_0\,. \qquad (5)$$

Here, $\tau_s(\delta,\, p_1,\, p_2) = 0$. We will not write down this expression explicitly due to cumbersomeness.

Astrophysical observations of stars in the vicinity of the Galactic Center use electromagnetic radiation in the wavelength range of $1\mu\mathrm{m} - 10\mathrm{m}$ (including observations of pulsars, see, e.g.,[3]). Such wavelengths are small compared to the typical orbit sizes of S-stars, which allows us to use the geometric optics approximation (see, e.g.,[19]). In this approximation, electromagnetic radiation propagates along a null geodesic with tangent vector k_i that satisfies the following relations: $k_j k^j = 0$ and $k_{i;j} k^j = 0$. Here we chose the following coordinate frame $\tilde{K} : \{t,\, r,\, \tilde{\theta},\, \tilde{\varphi}\}$. Therefore, the observer resides on the axis $\tilde{\theta} = 0$, $\tilde{\varphi} = 0$, we find that the trajectory of the light ray lies in the plane $\tilde{\varphi} = const$ and obtain (see, e.g.,[16]):

$$\begin{aligned}
k^0 &= \frac{\mathrm{d}t}{\mathrm{d}\nu} = \frac{1}{(1 - 2M/r)}\,;\\
k^1 &= \frac{\mathrm{d}r}{\mathrm{d}\nu} = e_r\sqrt{1 - (1 - 2M/r)D^2/r^2}\,;\\
k^2 &= \frac{\mathrm{d}\tilde{\theta}}{\mathrm{d}\nu} = -\frac{D}{r^2}\,;\\
k^3 &= \frac{\mathrm{d}\tilde{\varphi}}{\mathrm{d}\nu} = 0\,,
\end{aligned} \qquad (6)$$

where ν is an affine parameter along the ray and D is the impact parameter. Factor e_s describes whether the considered light trajectory is receding or approaching.

The sign in the expression for $\tilde{\theta}$ in equation (6) is chosen so that $D > 0$. We only consider zeroth-order trajectories, i.e. trajectories for which the increment of $\tilde{\theta}$ from the source to observer is less then π (see, e.g.,[20,21]).

From equations (6) and by using the boundary condition $r \to \infty$ for $\tilde{\theta} = 0$, we obtain the following analytic expression for the trajectory of the ray:

$$\frac{1}{r} = \frac{1}{r_r(\tilde{\theta},\, D)} = \frac{1}{P} - \frac{Qk^2}{2PM}\,\mathrm{cn}^2\left[\frac{\tilde{\theta}}{2}\sqrt{\frac{Q}{P}} + \mathrm{F}\left[\arccos\left(\sqrt{\frac{2M}{Qk^2}}\right), k\right], k\right],$$

where $r_r = r$ is satisfied for the points on the world line of the ray,

$$Q = \sqrt{P^2 + 4PM - 12M}\,; \qquad k = \sqrt{\frac{Q - P + 6M}{2Q}}\,, \tag{7}$$

$\mathrm{cn}\,[\varphi,\, k]$ and $\mathrm{F}\,[\varphi,\, k]$ are the Jacobi cosine and the elliptic integral of the first kind, respectively (see[18] for definition). If real, P has a physical meaning of the closest approach distance (see, e.g.,[17]). However, whether P is real or complex, it can be expressed through the impact parameter D as follows:

$$P = -\frac{2}{\sqrt{3}} D \sin\left[\frac{1}{3}\arcsin\left(\frac{3\sqrt{3}M}{D}\right) - \frac{\pi}{3}\right].$$

The angular coordinates in both coordinate systems are connected by the following relation (see Fig. 1):

$$\tilde{\theta} = \arccos[\cos(\varphi)\sin(i_0)]\,, \tag{8}$$

where angle i_0 is the inclination of the orbit of the star.

Redshift of the spectrum of electromagnetic radiation can be calculated from the formula (see, e.g.,[10]):

$$z = \frac{\delta\lambda}{\lambda} = \frac{(u_i)_s (k^i)_s}{(u_j)_o (k^j)_o} - 1\,. \tag{9}$$

Here, λ is the wavelength of emitted light, $\delta\lambda$ is the wavelength difference between received and emitted light. $(k_i)_o$ and $(k_i)_s$ denote the wave vector at the location of the observer and source, respectively. Likewise, $(u_i)_o$ and $(u_i)_s$ denote the 4-velocity vector of the observer and the star, respectively.

Consider the case of a stationary observer located at spatial infinity. Therefore, the spacetime around the observer is described to good accuracy by the Minkowsky metric. Therefore, for the observer we have $(u^i)_o = \{1,\, 0,\, 0,\, 0\}$. To calculate the components of the wave vector $(k_i)_s$, it is necessary to solve the boundary value problem for the system of differential equations (6) (see Fig. 2). The zeroth-order trajectory corresponds to the maximal intensity, and one may find it almost in all cases for S-stars (see, e.g.,[20,21]). Because of this, we will consider only light rays of zeroth order. Therefore, the solution is unique. For the chosen assumptions, solving the mentioned boundary value problem reduces to solving the following non-linear ordinary equation for the impact parameter D:

$$r_s(\varphi,\, p_1,\, p_2) = r_r(\tilde{\theta},\, D)\,. \tag{10}$$

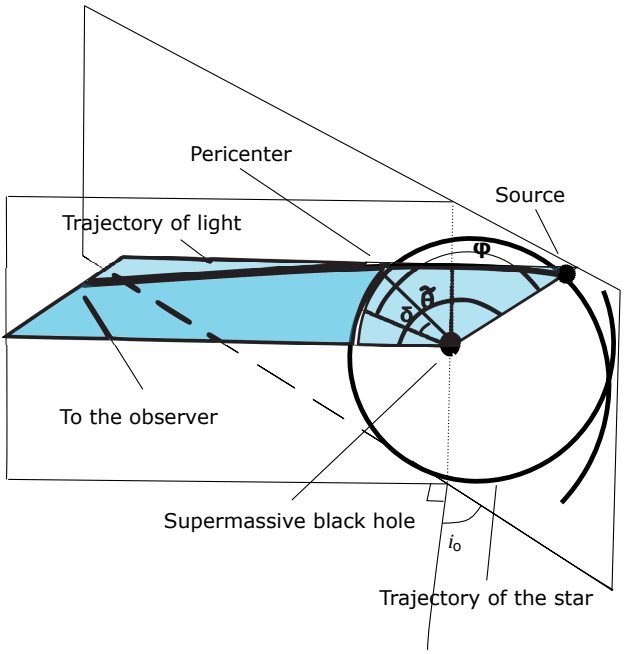

Fig. 1. For the derivation of formula (8)

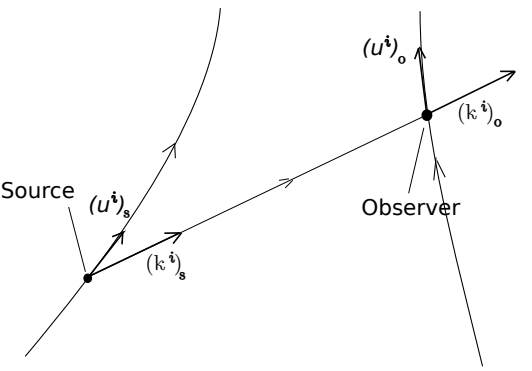

Fig. 2. $(k^i)_o$ and $(k^i)_s$ are tangent vectors to null geodesic that intersect both the worldline of the source and the worldline of the observer

Taking into account the stationarity of the observer, the relation between the angles (8), and substituting expressions (2), (6) into (9), we obtain the redshift in the following form:

$$z = -1 + \frac{E}{q} + \frac{DL}{r^2}\beta - e_s e_r \frac{1}{q}\sqrt{\left(E^2 - q\left(1 + \frac{L^2}{r^2}\right)\right)\left(1 - q\frac{D^2}{r^2}\right)}. \qquad (11)$$

Here, we denote $1 - 2M/r = q$ and $\beta = \sin(i_0)\sin(\varphi)/\sin(\tilde{\theta})$. The presented equations allow one to solve the direct problem: calculating the redshift of a star moving

in an external gravitational field of a supermassive black hole as a function of observation time. We illustrate the method by using a numerical model as shown in Fig. 3.

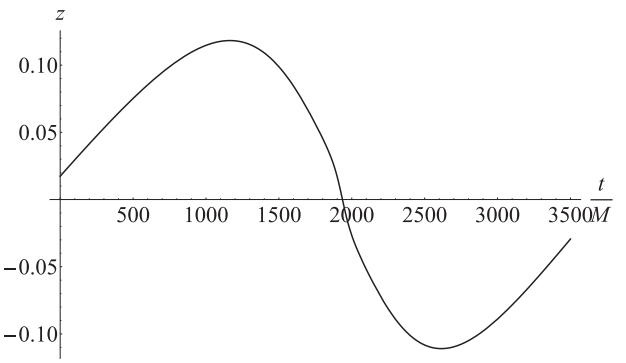

Fig. 3. Redshift of electromagnetic spectrum of a star in an external Schwarzschild gravitational field as a function observation time t. The pericenter distance of the stellar orbit is $p_1 = 60M$, its apocenter distance is $p_2 = 90M$, its inclination is $i_0 = 1.4\,\mathrm{rad}$, the longitude of pericenter is $\delta = 1\,\mathrm{rad}$ and the initial time of pericenter passage is $\tau_0 = 0M$

However, it is more interesting for astrophysical purposes to solve the inverse problem: determining the parameters of motion of a star in the external gravitational field of a supermassive black hole based on its redshift data. In the literature, the inverse problem is solved by minimizing the χ^2 function (see, e.g.,[9,10]):

$$\chi^2 = \sum_{j=1}^{N} \left[\frac{(z_j - z_{\mathrm{obs},j})^2}{\sigma_Z^2} \right] , \tag{12}$$

where z_j and $z_{\mathrm{obs},j}$ are the theoretical and observed values of the redshift, respectively, for the times of observation t_j ($j \in [1,\, N]$). σ_Z^2 is the dispersion of the redshift observation data. Since function $z_{\mathrm{obs},j}(t)$ has no explicit expression (at least, because D is the solution of non-linear equation 10), minimizing χ^2 can only be performed numerically (for example, using the Metropolis-Hastings algorithm[22]).

In this work, we present another approach based on deriving a system of equations expressed explicitly using elementary or special functions of the parameters of motion of the star. To obtain such equations for the inverse problem, one has to find expressions not only for z but also for $\mathrm{d}z/\mathrm{d}\tau$. We describe this calculation in the following section.

3. Derivative of the redshift function

3.1. *Newman-Penrose null tetrad and optical scalars*

In this section we will use the Newman-Penrose null tetrad (see, e.g.,[23,24]), determined along the world line of the ray emitted by the star:

$$k^i,\, n^i,\, m^i\, \bar{m}^i\,. \tag{13}$$

Here k^i is the wave vector of the ray. Symbol $^-$ denotes the complex conjugation. All vectors in (13) are null. All scalar products between vectors in (13) are equal to 0 apart from

$$k_i n^i = -1;\, m_i \bar{m}^i = 1\,. \tag{14}$$

Consider a congruence of isotropic geodesics that have tangent vectors k^i and intersect the world line of the observer at time t_o. Also, consider the Newman-Penrose tetrad (13) at all points of this congruence. Then the components of the vectors of the tetrad in the coordinate basis of $\tilde{K}$ have the form (we chose the affine parameter ν such that k_0=-1):

$$\begin{aligned}
&k_j = \left\{-1,\, e_r \frac{\sqrt{1-(1-2M/r)D^2/r^2}}{1-2M/r},\, -D,\, 0\right\};\\
&n_j = \left\{-\frac{1}{2}(1-2M/r),\, -\frac{e_r}{2}\sqrt{1-(1-2M/r)D^2/r^2},\right.\\
&\left.\frac{D}{2}(1-2M/r),\, 0\right\};\\
&m_j =\\
&\frac{1}{\sqrt{2}}\left\{0,\, i\frac{D}{r},\, ie_r r\sqrt{1-(1-2M/r)D^2/r^2},\, r\sin\tilde{\theta}\right\};\\
&\hat{m}_j =\\
&\frac{1}{\sqrt{2}}\left\{0,\, -i\frac{D}{r},\, -ie_r r\sqrt{1-(1-2M/r)D^2/r^2},\, r\sin\tilde{\theta}\right\}.
\end{aligned} \tag{15}$$

For the considered congruence, one can obtain the following equations (see, e.g.,[24–26], $\epsilon = k_{[i;j]} = 0$[14])

$$k_{i;j} m^i \bar{m}^j = -\rho\,, k_{i;j} m^i m^j = -\sigma\,, \qquad k_{i;j} k^j = k_{i;j} k^i = 0\,. \tag{16}$$

Here, ρ and σ are optical scalars. They are can be found numerically from well-known equations (see, e.g.,[23–26]): Only the sum $\rho+\sigma$ admits an analytical expression (see, e.g.,[25]):

$$\begin{aligned}
&\rho+\sigma = -\frac{\dfrac{\mathrm{d}}{\mathrm{d}\nu}\left(r\sin\tilde{\theta}\right)}{r\sin\tilde{\theta}} =\\
&-\frac{e_r}{r}\sqrt{1-\left(1-\frac{2M}{r}\right)\frac{D^2}{r^2}} + \frac{D}{r^2}\cot\tilde{\theta}\,.
\end{aligned} \tag{17}$$

We now write down components of the vector of 4-velocity of the star in the basis of the null tetrad (15):

$$u^j = \frac{1}{\sqrt{2}}\left(\bar{A} m^j + A\bar{m}^j\right) + Bk^j + Cn^j\,. \tag{18}$$

Here A, B, C — are coefficients of decomposition. We obtain $-k_j u^j = (1+z) = C$. Denoting the components of the Killing vector $\frac{\partial}{\partial t}$ as ξ^j, we have

$$\xi^j = \frac{1}{2}\left(1 - \frac{2M}{r}\right) k^j + n^j \,. \tag{19}$$

Furthermore

$$E = -u^i \xi_i = B + \frac{1}{2}\left(1 - \frac{2M}{r}\right)(1+z) \,. \tag{20}$$

From the relation for the norm of u_i, we obtain

$$u_j u^j = |A|^2 - 2(1+z)B = -1 \,. \tag{21}$$

From (20) and (21), it follows that

$$B = \frac{1+|A|^2}{2(1+z)} \,, \qquad |A|^2 = -1 + 2E(1+z) - (1-2M/r)(1+z)^2 \,.$$

Now, we express the time derivative of redshift, using the relation $k_{[j;l]} = 0$ satisfied for the considered congruence in Schwarzschild spacetime (see, e.g.,[14]):

$$\begin{aligned}
&\frac{\mathrm{d}z}{\mathrm{d}\tau} = -k_{j;l} u^j u^l = -|A|^2 k_{j;l} m^j \bar{m}^l - A^2 k_{j;l} m^j m^l - \\
&\bar{A}^2 k_{j;l} \bar{m}^j \bar{m}^l - 2\bar{A}(1+z) k_{j;l} n^j m^l - 2A(1+z) k_{j;l} n^j \bar{m}^l = \\
&|A|^2(\rho + \sigma\cos(2P_A)) - 2\sqrt{2}(1+z)\frac{D}{r^3}|A|\sin(P_A) + \\
&\frac{e_r}{r^2}(1+z)^2\sqrt{1 - \left(1 - \frac{2M}{r}\right)\frac{D^2}{r^2}} \,.
\end{aligned} \tag{22}$$

Here we use $A = |A| e^{iP_A}$, where $|A|$ and P_A are real. Numerical calculations show that optical scalar σ have very small value comparing to other terms in 22. Due to this will neglect the value of σ in calculations.

From equations (22) and (17) for the time derivative of redshift, we obtain

$$\begin{aligned}
&\frac{\mathrm{d}z}{\mathrm{d}\tau} = \left[2E(1+z) - \left(1 - \frac{2M}{r}\right)(1+z)^2 - 1\right] \times \\
&\left[-\frac{e_r}{r}\sqrt{1 - \left(1 - \frac{2M}{r}\right)\frac{D^2}{r^2}} + \frac{D}{r^2}\cot\hat{\theta}\right] - \\
&2\frac{D}{r^3}\sin P_A \sqrt{2E(1+z) - \left(1 - \frac{2M}{r}\right)(1+z)^2 - 1} + \\
&\frac{e_r}{r^2}(1+z)^2\sqrt{1 - \left(1 - \frac{2M}{r}\right)\frac{D^2}{r^2}} \,.
\end{aligned} \tag{23}$$

To obtain an analytical formula, it is convenient to exclude the impact parameter D from equations (11) and (23). We obtain:

$$\frac{D}{r} = \tag{24}$$
$$\frac{\frac{L}{r}\beta\left((1+z)\left(1-\frac{2M}{r}\right)-E\right) \pm \sqrt{\left(E^2-\left(1-\frac{2M}{r}\right)\left(1+\frac{L^2}{r^2}\right)\right)\left(|A|^2+(\beta^2-1)\frac{L^2}{r^2}\right)}}{E^2-1+\frac{2}{r}+\frac{L^2}{r^2}(\beta^2-1)(1-\frac{2}{r})} =$$
$$\mathcal{F}_1(r,\, z,\, p_1,\, p_2,\, i_0,\, \tilde{\theta})\,;$$
$$\text{and } \frac{D}{r} = \mathcal{F}_2(r,\, z,\, \frac{\mathrm{d}z}{\mathrm{d}\tau},\, p_1,\, p_2,\, i_0,\, \tilde{\theta}) =$$
$$\frac{r\frac{\mathrm{d}z}{\mathrm{d}\tau}\left(|A|^2\cot\tilde{\theta}-\frac{2(1+z)}{r}|A|S\right)}{\left(1-\frac{2M}{r}\right)\left(\frac{(1+z)^2}{r}-|A|^2\right)^2+\left(|A|^2\cot\hat{\theta}-\frac{2(1+z)}{r}|A|S\right)^2} \pm$$
$$\frac{\sqrt{\left(1-\frac{2M}{r}\right)\left[\left(\frac{(1+z)^2}{r}-|A|^2\right)^2-r^2\left(\frac{\mathrm{d}z}{\mathrm{d}\tau}\right)^2\right]+\left(|A|^2\cot\tilde{\theta}-\frac{2(1+z)}{r}|A|S\right)^2}}{\left(1-\frac{2M}{r}\right)\left(\frac{(1+z)^2}{r}-|A|^2\right)^2+\left(|A|^2\cot\hat{\theta}-\frac{2(1+z)}{r}|A|S\right)^2} \times$$
$$\left(\frac{(1+z)^2}{r}-|A|^2\right). \tag{25}$$

Here, $S = \sin P_A$. To find an exact expression for $\sin P_A$, one may use the law of angular momentum conservation:

$$u_i\Psi^i = L = const\,, \tag{26}$$

where Ψ^i is the Killing vector field associated with the symmetry of the Schwarzschild metric relative to spatial rotation around an arbitrary axis (we chose it to be orthogonal to the orbit plane). Components of Ψ^i in the coordinate basis of $\hat{K}$ are given by (see, e.g.,[19])

$$\Psi^j = \left\{0,\, 0,\, (\cos i + \sin i\cot\tilde{\theta}\cos\tilde{\varphi}),\, \sin i\sin\tilde{\varphi}\right\}. \tag{27}$$

Equation of the orbital plane has the following form

$$-\sin i\sin\tilde{\theta}\cos\tilde{\varphi}+\cos i\cos\tilde{\theta}=0\,. \tag{28}$$

From equations (26), (27), (28), (18) and (15), it follows

$$e_r\frac{l}{r}\frac{1-\beta^2}{|A|\sqrt{1-\left(1-\frac{2M}{r}\right)\frac{D^2}{r^2}}}+e_P\beta\sqrt{1-\frac{l^2}{r^2}\frac{(1-\beta^2)}{|A|^2}} =$$
$$\beta\sin P_A+e_r\frac{\sqrt{1-\beta^2}}{\sqrt{1-\left(1-\frac{2M}{r}\right)\frac{D^2}{r^2}}}\cos P_A\,, \tag{29}$$

where e_P is defined as

$$e_P = \operatorname{sign}\left[e_r \beta l \sqrt{1 - \left(1 - \frac{2M}{r}\right)\frac{D^2}{r^2}} + e_s D \sqrt{E^2 - \left(1 - \frac{2M}{r}\right)\left(1 + \frac{L^2}{r^2}\right)}\right]. \tag{30}$$

The exact solution of (29) has the form

$$\sin P_A = e_P \sqrt{1 - \frac{L^2}{r^2}\frac{(1-\beta^2)}{|A|^2}}. \tag{31}$$

4. The inverse problem

4.1. *The surface of parameters of motion*

The main purpose of the present subsection is to obtain the relation between the parameters of motion of the star from one hand and the redshift z and the derivative $\mathrm{d}z/\mathrm{d}\tau$ for certain moments of proper time from another. From (25) and (25), we obtain:

$$\mathcal{F}_1(r,\, z(t_o),\, p_1,\, p_2,\, i_0,\, \tilde{\theta}) = \mathcal{F}_2(r,\, z(t_o),\, \frac{\mathrm{d}z}{\mathrm{d}\tau}(t_o),\, p_1,\, p_2,\, i_0,\, \tilde{\theta}). \tag{32}$$

For the known redshift data $z(t_o)$ and $\frac{\mathrm{d}z}{\mathrm{d}\tau}(t_o) = (z(t_o)+1)\frac{\mathrm{d}z}{\mathrm{d}\tau}(t_o)$ (t_o is a certain observation time), equation (32) allows one to implicitly express the constant parameters of motion p_1, p_2 and i_0 in the case, when the radial location of emission r and the angle $\tilde{\theta}$ are known. Therefore, more equations are needed to solve the problem. For this purpose, one can use equations (25) and (10). We express $\tilde{\theta}$ from (10). The impact parameter D in equation (10) can be expressed using (25). This way, we obtain:

$$\tilde{\theta} = f(r,\, \mathcal{F}_1(r,\, z(t_o),\, p_1,\, p_2,\, i_0,\, \tilde{\theta})). \tag{33}$$

Here f is some known explicit function. This equation can be solved for $\tilde{\theta}$ using the iteration method. Because the right-hand side of (33) depends on $\tilde{\theta}$ only through the small optical scalar ρ, it has little influence on the whole expression, and the solution of (33) converges quickly. For our numerical model, we have used only two iterations to obtain the solution in explicit form. Therefore, we obtain the following equation:

$$r = r_s(\varphi(\tilde{\theta}(r,\, z(t_o),\, p_1,\, p_2,\, i),\, i) - \delta,\, p_1,\, p_2). \tag{34}$$

The system (32), (34 obtained for certain observation time t_o contains 2 equations and 5 unknown variables: p_1, p_2, i_0, δ, r. Because of this, the solution is a 3-surface in a corresponding 5-dimensional space. Since we are only interested in the relations that connect the parameters of motion we must numerically calculate a projection of this space into a 4-dimensional space (with four coordinates: p_1, p_2, i_0, δ). The calculation results for our numerical model of the radiation of the star are presented (see Fig. 4–7) for different points of redshift data. To uniquely visualise the solution, we present it graphically on 2-dimensional sections of the mentioned 4-dimensional

space. As seen from Fig. 4–5, the 3-surfaces obtained for each data point do not coincide. Therefore, the intersection point of the surfaces gives an exact value of the parameters of motion of the star. This point can be determined from the obtained figures with high accuracy.

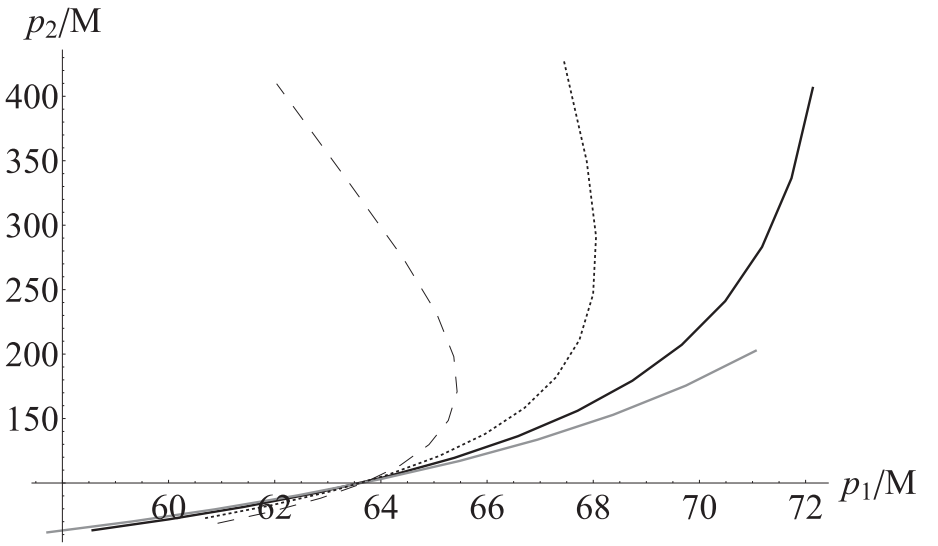

Fig. 4. 2-sections of the solution of (32), (34) for $i_0 = \pi/2$ and $\delta = 1$ by plane p_1, p_2 for different points of data (dashed: $t = 777M$, dotted: $t = 851M$, black: $t = 923M$, gray: $t = 992M$, see also Fig. 3)

Figures 4–7 also illustrate that in the case when the angular parameters are chosen to coincide with the exact solution, sections have a unique point of intersection (Fig. 6) that corresponds to the solution of the inverse problem. At the same time, if the angular parameters are not exact, a unique intersection point does not exist (Fig. 7). This is because the chosen 2-dimensional surface in the last case does not intersect with the solution in the whole 4-dimensional space of motion parameters. By using these figures, one may find if there exists a unique point of intersection in a certain region of the surface. Therefore, an initial approximation to the exact solution of the inverse problem can be found from these figures with a fairly good accuracy.

4.2. *Solution of the inverse problem*

A further improvement of the results can be obtain using the least squares method. For this purpose, we use functions $\tau_s(\varphi,\, p_1,\, p_2)$ and $r_s(\varphi,\, p_1,\, p_2)$. From (32), obtain the following equation:

$$\mathcal{F}_1(r_s(\varphi+\delta,\, E,\, L),\, z(\tau_s+\tau_0),\, p_1,\, p_2,\, i,\, \tilde{\theta}(\varphi,\, i)) = \\ \mathcal{F}_2(r_s(\varphi+\delta,\, E,\, L),\, z(\tau_s+\tau_0),\, \frac{\mathrm{d}}{\mathrm{d}\tau} z(\tau_s+\tau_0),\, p_1,\, p_2,\, i,\, \tilde{\theta}(\varphi,\, i))\,. \qquad (35)$$

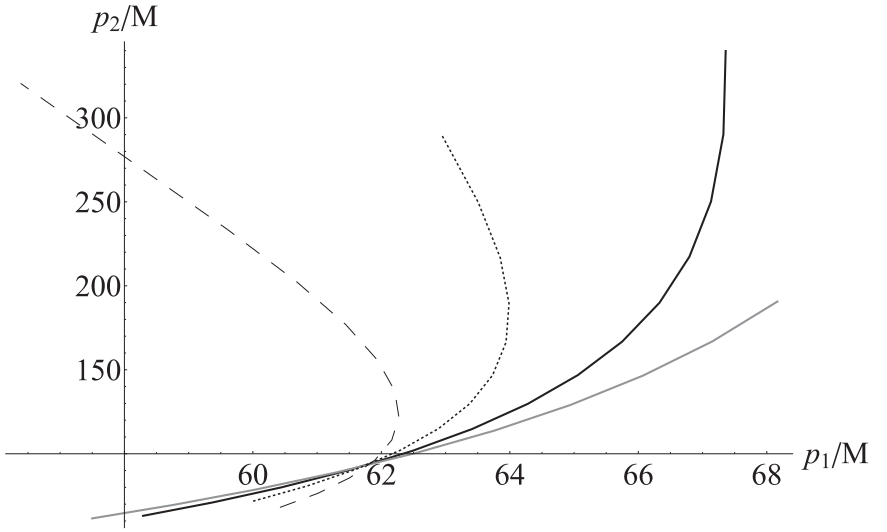

Fig. 5. 2-sections of solution of (32), (34) for $i_0 = \pi/2$ and $\delta = 1, 4$ by plane p_1, p_2 for different points of data (dashed: $t = 777M$, dotted: $t = 851M$, black: $t = 923M$, gray: $t = 992M$, see also Fig. 3)

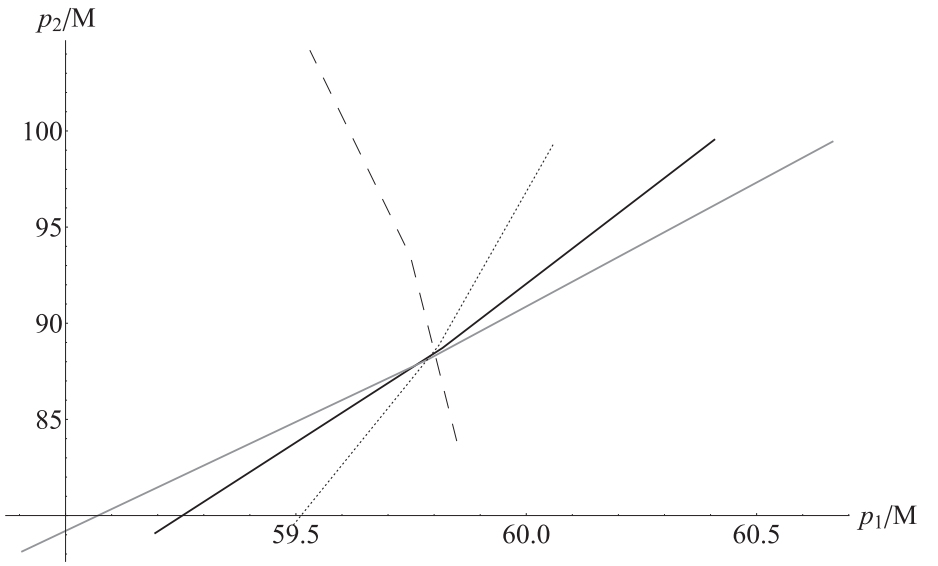

Fig. 6. Magnification of a part of figure (4)

Here, function $z(\tau)$ can be constructed based on the observational data for $z(t)$ and from function $\tau(t)$ given as an implicit function from:

$$\tau(t) = \int_0^t \frac{\mathrm{d}t'}{(1 + z(t'))}\,. \tag{36}$$

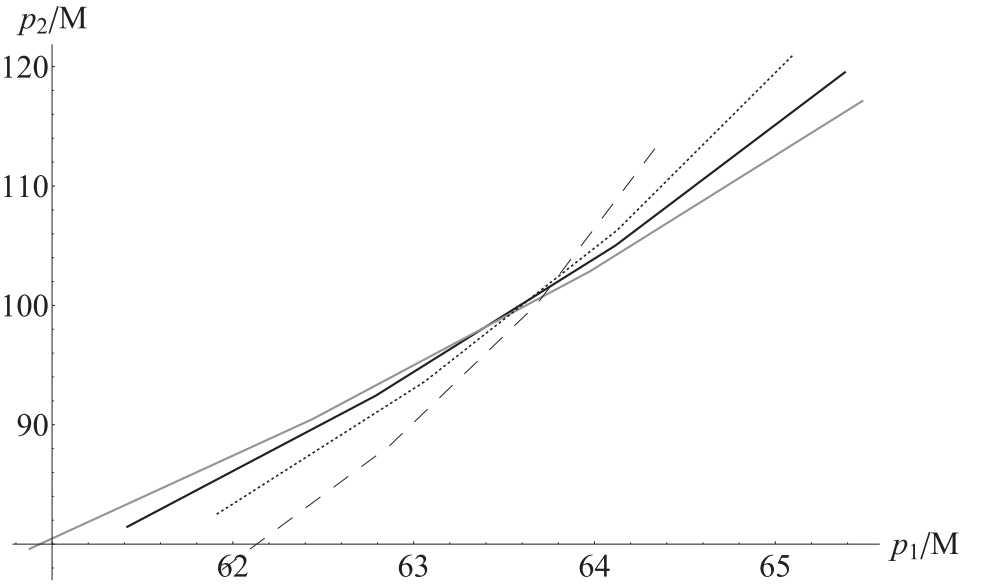

Fig. 7. Magnification of a part of figure (5)

Table 1. Results

Parameter	Initial approximation	Reconstructed value	Exact value
Pericenter distance, p_1/M	62.0	60.1	60.0
Apocenter distance, p_2/M	95.0	89.1	90.0
Orbital inclination, i_0, rad	1.5	1.48	1.4
Initial phase, δ, rad	0.9	1.0	1.0
Initial time of pericenter passage, τ_0/M	–	0.0	0.0

The left-hand side of (35) and the right-hand side of (35) are certain functions of φ. As follows from (35), these functions must be equal for a certain set of unknown parameters E, L, i_0, δ, τ_0. Therefore, one may find these parameters by using the least-squares method. As an example, we choose 10 points for different values of φ in the range [1rad, 1.4rad]. We obtain the initial approximation using the results from the previous subsection. We show the obtained results in Table 1.

5. Conclusion

The presented approach allows one to solve the inverse problem: reconstructing the motion of a star moving in the external gravitational field of a supermassive

black hole based on its redshift. The approach uses the properties of congruences of isotropic geodesics to account for the difference between trajectories of light that come to the observer from the different locations of the star during the observation time.

As the main result of the paper, we have provided a method for obtaining good starting values for the parameters of motion of a star. These starting values allow one to solve the inverse problem more accurately by using statistical methods. For this purpose, we used the graphs of the surfaces in the space of parameters of motion. However, the approach may also be formulated in terms of solving a system of equations. If one writes down equations (32) and (34) for four moments of time of observation (t_{o1}, t_{o2}, t_{o3}, t_{o4}), one may obtain a system of 8 equations for 8 unknown variables (p_1, p_2, δ, i_0 and four values of the radius of radiation: r_1, r_2, r_3, r_4). Therefore, one will obtain a complete system of equations. Even numerically, it is not easy to solve a system of 8 non-linear equations. However, in future work, developed mathematical methods will allow one to efficiently solve this system of equations and analyse the conditions for obtaining non-unique solutions. The problem of non-unique solutions can be solved, for instance, by adding more equations to the considered system. The last parameter of motion τ_0 can be determined from the least-squares method. Therefore, in principle, equations (32) and (34) can be used to obtain a unique solution of the inverse problem, rather than the graphic solution presented in our paper.

The obtained equations are exact equations in General Relativity (we only neglect the optical scalar σ). Therefore, one may use the presented approach for all possible sources moving at arbitrary distances from the black hole (if they can be approximated as test particles in an external gravitational field of the black hole).

Furthermore, the approach can be directly applied to pulsar timing data for a pulsar moving in an external gravitational field. A large number of pulsars will likely be detected in the Galactic Center in the near future (see, e.g.,[12]). Pulsars can move closer to the supermassive black hole than S-stars. This way, they may be even more interesting for testing theories of gravity. The arrival times of the radio pulses can be expressed through the redshift by using:

$$t_{TOA}^{(N)} = t_{TOA}^{(N-1)} + T_p(z+1) = t_{TOA}^{(N-1)} + T_p \frac{(k^i u_i)_s}{(k^i u_i)_o}\,.$$

Here T_p — is the pulsar period in the reference frame of the pulsar, z is the redshift, $t_{TOA}^{(j)}$ — is the time of arrival of the j-th the pulse. In the problem of reconstructing the pulsar motion in the neighbourhood of a supermassive black hole, there exists one more unknown parameter — T_p.

Another interesting application of the results of this paper is reconstructing the motion of a binary star in the vicinity of a black hole. Determining the motion of such objects is a very important problem in astrophysics and stellar mechanics (see, e.g.,[27–31]). An approach for solving the problem of determining only the relative motion of the binary components was presented in our previous paper.[32]

The approach can be applied directly to the redshift data for the stars, moving near the supermassive black hole in the Galactic Center (for example, the S62 star[2]) to test General Relativity. To do this, one may obtain the parameters of motion of a star by using the presented algorithm and calculate the redshift as a function of observation time for future observations. Then, comparing the obtained curve with the observational data will allow one to test the theory.

One may use statistical methods (for example, Metropolis-Hastings algorithm, see[22]) to increase the accuracy of reconstructing the motion of the star. Such methods allow one to calculate the likelihood probability distribution and optimise values of parameters of motion of the star according to the distribution. The approach can be generalised to reconstruct the motion of a star in the vicinity of a rotating black hole. We leave this problem for future work.

In the wake of the *Event Horizon Telescope* (*EHT*) observations of the supermassive black hole M87*, efforts are underway to distinguish the black holes in general relativity (GR) and modified theories of gravity (MoG). We study the rotating hairy Kerr black holes with a deviation α and primary hair l_0, apart from rotation parameter a and mass M. Interestingly, the hairy Kerr black holes possess smaller sizes but more distorted shadows than the Kerr black holes. We find that, within 1σ uncertainty of the *EHT* observations, the inferred circularity deviation $\Delta C \leq 0.1$ for the M87* black hole is satisfied, whereas the shadow angular diameter $\theta_d = 42 \pm 3\mu as$, for a given choice of α, places bounds on the parameters a and l_0. Thusfore, the hairy Kerr black holes are inferred to be suitable candidates for astrophysical black holes.

Keywords: Black hole physics, gravitation, strong gravitational lensing, black hole shadow.

1. Introduction

The term "black hole shadow" has come to represent the interior of an "apparent boundary" as termed by Bardeen,[1] the inside of which is dark when the black hole is illuminated by distant, uniform, isotropic emission surrounding it. Indeed,the photons moving in unstable orbits around a black hole form a shadow silhouette that appears as a sharp boundary between bright and dark regions. The seminal work by Synge in 1966[2] gave the critical escape cone of photons from the surface of strong field stars. After that, Cunningham and Bardeen in 1973,[3] using geometrical optics, calculated the apparent position and energy flux of high-frequency radiation emitted by stars in a circular orbit around extremal Kerr black hole and also presented the first image of visible shapes for inner and outer circumferences of accretion disks (cf. Fig. 8[3]). Luminet in 1979[4] investigated the optical appearance of a thin accretion disk around spherically symmetric black holes and obtained the relative intrinsic intensity as well as the gravitational and Doppler spectral shifts of the relativistic photons. The shape and size of a shadow depend entirely upon the black hole parameters and spacetime geometry.[5–8, 8–24] However, it is expected that its shape and size will get influenced by the gravity governing a black hole and the matter around it.[5–10, 12–18, 20, 21, 25]

The first shadow image of the supermassive black hole M87* has been unveiled by the international *Event Horizon Telescope* (*EHT*) collaboration.[26–28] Using the

very long base interferometry (VLBI) technique, the shadow of the M87* – an asymmetric bright emission ring with a diameter of 42 ± 3 μas has been found to harbour an angular gravitational radius 3.8 ± 0.4 μas while also exhibiting a deviation from circularity $\Delta C \leq 0.1$. It is consistent with the shadow of a Kerr black hole as predicted by general relativity (GR). With the detection of the M87* black hole's horizon-scale image[26–28] the black hole shadows have become a physical reality, thus allowing probes into the background theory of gravity as well. The quantitative features are not sufficient to distinguish between black holes in different theories of gravity but using the M87* black hole shadow; one can investigate the viability of black holes in modified theories of gravity (MoG) in explaining the observational data while placing constraints on the black hole parameters using the *EHT* observations.[29]

The shadows cast by black holes in MoG have been found to be smaller and more distorted in comparison with the Kerr black hole shadow.[5,7,9–18] One of the motivations behind the multifarious works on black hole shadow is that by observing the size and deformation of shadow, the spin, mass parameter and possibly other global charges or *hair*-parameters of the black holes can be calculated.[19–22,29–31] The authors in,[23,24] considering the critical impact parameter as an analytical expression of charge, investigated the connection with shadows. In addition, in the context of the Reissner–Nordstrom metric, a tidal charge has been constrained[30] from estimates of shadow done by Doeleman et al.[32] The shadow size in Reissner–Nordstrom spacetime is found to decrease with increasing charge (cf. Figs. 1,2 in,[23] see also a discussion in[25]). Recently, Kocherlakota et al.[33] presented constraints on black hole charge from observations of M87* in 2017. Moreover, the shadows also has a vibrant use in testing theories of gravity.[29,34,35] While the the M87* has been presently inferred to be a black hole via the *EHT* observations,[26–28] there is a possibility that other exotic gravitationally intense objects cast a shadow. The hairy Kerr black holes under consideration are obtained using the gravitational decoupling (GD) approach.[36] It has a source that satisfies the strong energy condition (SEC) thus giving an extended Kerr metric which was termed as Kerr black holes with primary hair by Contreras *et. al.*[36] Hairy black holes are termed as stationary black hole solutions with new global charges, which are not associated with Gauss law.[8,37–39] (See, Ref.[37] for a recent review).

We investigate whether black hole shadow observations can constrain hairy Kerr black holes,[36] which has additional deviation parameter α and primary hair l_0 from the Kerr black hole. Furthermore, the horizons, ergoregions and shadow cast by the hairy Kerr black holes[36] are studied. An investigation of the deviation parameter's effects shows that the hairy Kerr black holes cast smaller and more distorted shadows than the Kerr black hole. Furthermore, within 1σ confidence of the EHT observational data, the parameter space of the hairy Kerr black holes is constrained with the bounds on the shadow observables of M87*.

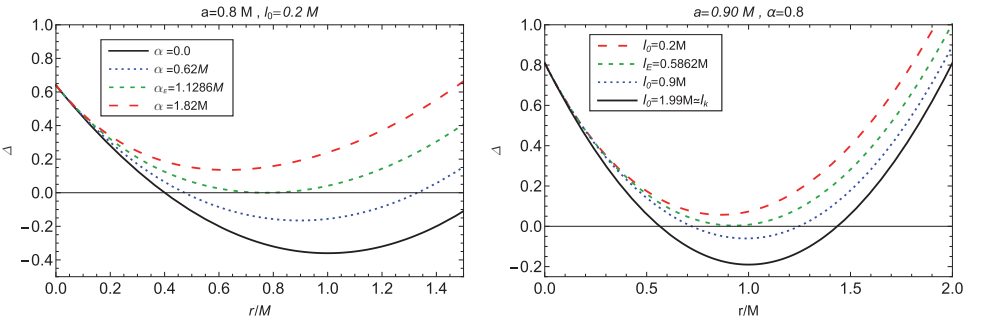

Fig. 1. Horizons of the hairy Kerr black holes are shown with varying α (*left*) and l_0 (*right*) and compared with the Kerr black holes ($\alpha = 0$ or $l \to l_k$).

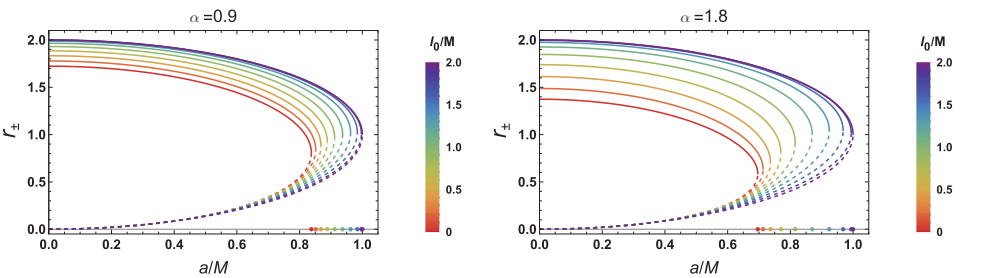

Fig. 2. Event horizon (solid lines) and Cauchy horizon (dashed lines) of hairy Kerr black holes with varying spin a for different values of l_0 and α parameters. The outermost lines are for the Kerr black hole in the limit $l_0 \to l_k$. The extremal spin a_E values are denoted by the colour coded points.

2. Hairy Kerr back holes

The GD approach, which is designed to obtain deformations of the known solutions of GR owing to the additional surrounding sources like dark matter or dark energy,[36,40,41] leads to deformed or hairy Schwarzchild black holes.[36] It has a dimensionless deviation parameter α and primary hair $l_0 \leq 2M$ which also determines the asymptotic flatness. The surrounding matter is described by the conserved stress-energy tensor $S_{\mu\nu}$ that satisfies the SEC. Hence, we consider the rotating counterpart of the spherically symmetric solution described by parameters M, a, l_0 and α, which in the Boyer-Lindquist coordinates reads[36]

$$\begin{aligned} ds^2 = &-\left[\frac{\Delta - a^2\sin^2\theta}{\Sigma}\right]dt^2 - 2a\sin^2\theta\left[1 - \frac{\Delta - a^2\sin^2\theta}{\Sigma}\right]dtd\phi \\ &+\sin^2\theta\left[\Sigma + a^2\sin^2\theta\left(2 - \frac{\Delta - a^2\sin^2\theta}{\Sigma}\right)\right]d\phi^2 + \frac{\Sigma}{\Delta}dr^2 \\ &+\Sigma d\theta^2, \end{aligned} \tag{1}$$

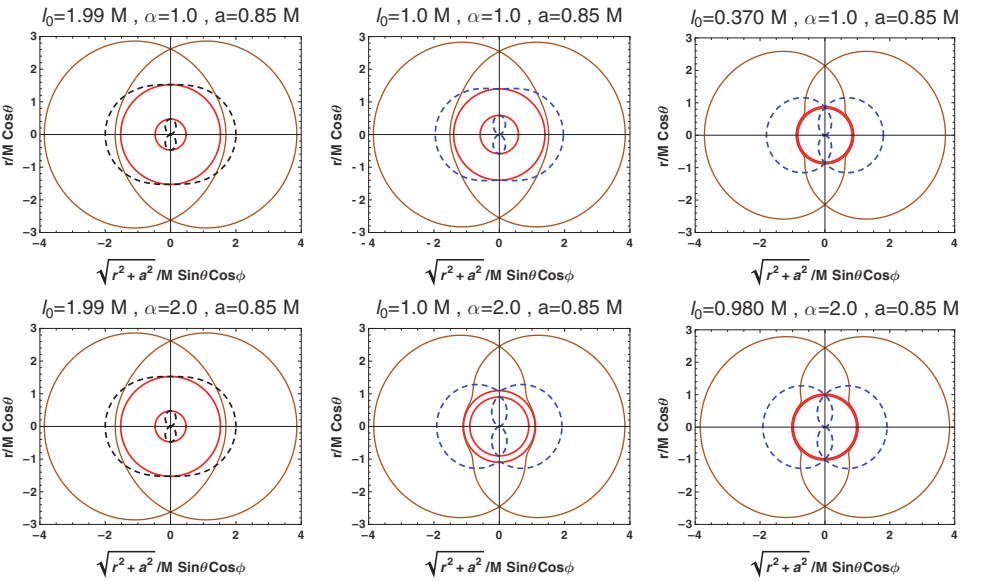

Fig. 3. The cross-section of event horizon (outer red line), SLS (outer blue dotted line) and photon region (bounded within the outer and inner orange lines) of hairy Kerr black holes. The black dotted curves correspond to the event horizon of Kerr black hole ($l_0 \to l_k$).

$$\text{with } \Delta = r^2 + a^2 - 2Mr + \alpha r^2 e^{-r/(M-\frac{l_0}{2})} \text{ and } \Sigma = r^2 + a^2\cos^2\theta.$$

Here α is related to l_0 via $l_0 = \alpha l$ and the metric (1) goes to Kerr in the absence of surrounding fluid ($\alpha = 0$). The metric (1) which is termed as hairy Kerr black holes,[36] is same as Kerr black hole with the Kerr mass M replaced by the mass function,

$$m(r) = M - \frac{\alpha}{2} r e^{-r/(M-\frac{l_0}{2})}.$$

Next, we shall investigate how the primary hair l_0 affects the horizons, photon region as well as shadow of the black hole. The horizons of the metric (1) correspond to spacetime points where $\Sigma \neq 0$ and $g^{\alpha\beta}\partial_\alpha r \partial_\beta r = g^{rr} = \Delta = 0$ and is given by the zeros of

$$r^2 + a^2 - 2Mr + \alpha r^2 e^{-r/(M-\frac{l_0}{2})} = 0. \tag{2}$$

The two roots of Eq. (2) are r_+ outer (event) horizon and r_- the inner (Cauchy) horizon. An analysis of Eq. (2) reveals that, depending on the values of M, a, α and l_0, there can exist a maximum of two distinct real positive roots, or equal roots corresponding respectively to the black holes with Cauchy and event horizons or extremal black holes.

From the horizon structure of the hairy Kerr black holes depicted in Fig. 1, we find that, $l_0 > l_E$ corresponds to hairy Kerr black holes with Cauchy and event horizons whereas $l_0 < l_E$ implies existence of a naked singularity.

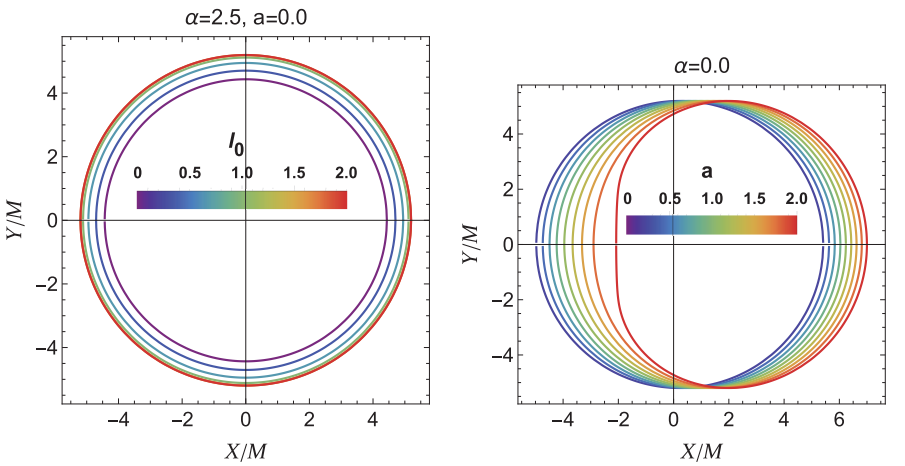

Fig. 4. Shadow geometry of non-rotating hairy black holes with varying l_0 parameter (left) and Kerr black hole ($\alpha = 0$) with varying spin a (right).

Furthermore, the asymptotic time-translational Killing vector, becomes null at the static limit surface (SLS) which yields[9]

$$r^2 + a^2\cos^2\theta - 2Mr + \alpha r^2 e^{-r/(M-\frac{l_0}{2})} = 0. \tag{3}$$

Thus, the real positive solutions ($r^{\pm}_{SLS}$) of Eq. (3) correspond to the radii of the SLS, the larger of the which corresponds to the outer SLS, denoted by r^{+}_{SLS}. Fig. 3 depicts the ergoregion of the hairy Kerr black hole (1) whereby it can be seen that, the increase in parameter l_0 has a diminishing effect on the ergoregion's size and may thus have consequence in the Penrose energy extraction process.[42]

3. Analytic black hole shadow

We use the Hamilton-Jacobi equation to obtain the geodesic equations in the first-order differential form,[43] which for the metric (1) read[44]

$$\Sigma\frac{dt}{d\lambda} = \frac{r^2+a^2}{\Delta}(E(r^2+a^2) - aL_z) - a(aE\sin^2\theta - L_z), \tag{4}$$

$$\Sigma\frac{dr}{d\lambda} = \pm\sqrt{\mathcal{R}(r)}\ , \tag{5}$$

$$\Sigma\frac{d\theta}{d\lambda} = \pm\sqrt{\Theta(\theta)}\ , \tag{6}$$

$$\Sigma\frac{d\phi}{d\lambda} = \frac{a}{\Delta}(E(r^2+a^2) - aL_z) - (aE - \frac{L_z}{\sin^2\theta}), \tag{7}$$

where λ is the affine parameter along the geodesics and the effective potentials $\mathcal{R}(r)$

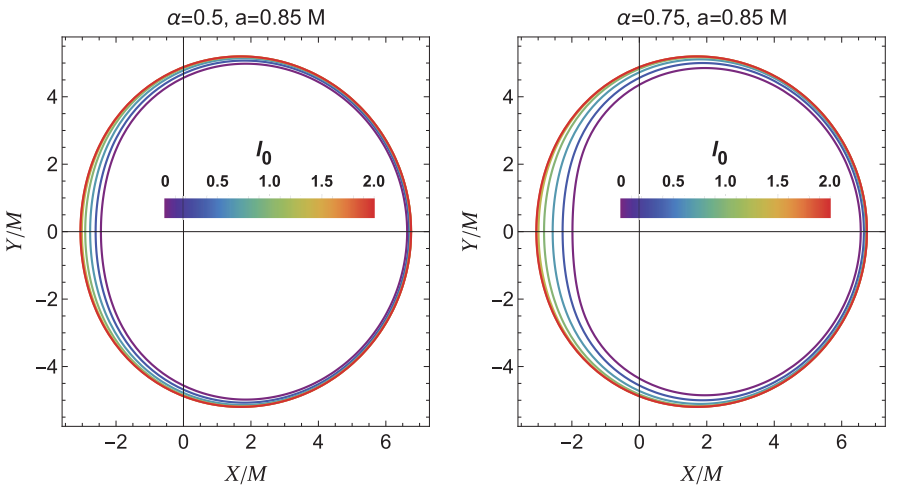

Fig. 5. Shadows of hairy Kerr black holes compared with Kerr black hole shadow (outermost solid curve corresponding to $l_0 \to l_k$).

and $\Theta(\theta)$ for radial and polar motions are given by

$$\mathcal{R}(r) = \Big((r^2+a^2)E - aL_z\Big)^2 - \Delta\Big(\mathcal{K} + (aE - L_z)^2\Big), \tag{8}$$

$$\Theta(\theta) = \mathcal{K} - \left(\frac{{L_z}^2}{\sin^2\theta} - a^2E^2\right)\cos^2\theta\ . \tag{9}$$

The constant $\mathcal{K}$ is the separability constant related to the Carter constant $\mathcal{Q}$ through $\mathcal{Q} = \mathcal{K} + (aE - L_z)^2$.[44] By introducing reduced quantities called impact parameters[44] $\xi = L_z/E$, $\eta = \mathcal{K}/E^2$, the degrees of freedom of the photon motion reduces from three to two. We are interested in the spherical photon orbits[44] whose radius $r = r_p$ are formed at the local extremum of the radial effective potential outside the horizon such that[44,45]

$$\mathcal{R} = \mathcal{R}' = 0 \text{ and } \mathcal{R}'' \leq 0. \tag{10}$$

Solving Eq. (10) we obtain the critical values of impact parameters $(\xi_{crit}, \eta_{crit})$ for the unstable orbits given by,

$$\xi_{crit} = \frac{\left(a^2+r^2\right)\Delta'(r) - 4r\Delta(r)}{a\Delta'(r)},$$

$$\eta_{crit} = \frac{r^2\left(8\Delta(r)\left(2a^2 + r\Delta'(r)\right) - r^2\Delta'(r)^2 - 16\Delta(r)^2\right)}{a^2\Delta'(r)^2}, \tag{11}$$

where $'$ stands for the derivative with respect to the radial coordinate. The Eq. (11) in the limit $\alpha \to 0$ reduces to the critical impact parameter for the Kerr black holes.[19]

The Carter constant is directly related to θ-velocity of the photons and the non-planar or 3D photon orbits only arise for $\eta_{crit} > 0$.[46] The roots of $\eta_{crit} = 0$ give

the radii of prograde (r_p^-) and retrograde (r_p^+) orbits. The exterior photon region, $r_+ < r_p^- < r_p < r_p^+$, of the hairy Kerr black holes is depicted in Fig. 3 as the region enclosed between the inner prograde and the outer retrograde orbits (cf. Fig. 3).

The gravitationally lensed image[47–50] of the photon region appears as a dark region outlined by a bright ring to a distant observer is termed the black hole shadow.[51,52] The shadow has been utilized for the measurement of various black hole parameters like its mass, spin angular momentum as well as other *hairs*,[22,29,35] whereby the black hole shadow is evidently a means to test Einstein's GR in the strong-field regime[13] besides the no hair theorem.[29,53] Assuming a distant observer ($r_o \to \infty$) at an inclination angle θ_0 with the rotation axis of the black hole a stereographic projection of the black hole shadow to the celestial image plane gives the shadow outline in the celestial coordinates (X,Y) as,[19]

$$\begin{aligned} X &= -\,\xi_{crit}\csc\theta_o, \\ Y &= \pm\sqrt{\eta_{crit} + a^2\cos^2\theta_o - \xi_{crit}^2\cot^2\theta_o}\ , \end{aligned} \tag{12}$$

which further gets simplified to $X = -\xi_{crit}$, $Y = \pm\sqrt{\eta_{crit}}$ for an equatorial observer ($\theta_o = \pi/2$). The parametric contour of ($X(r_p)$,$Y(r_p)$) traces the shadow of the hairy Kerr black holes with $m(r) = M - \frac{\alpha}{2} r e^{-r/(M-\frac{l_0}{2})}$.

Interestingly, Zakharov et al.[54] carried out an analysis of critical curve $\eta(\xi)$ which separates scatter and capture of a photon in Kerr metric (cf. see Fig. 2[54] and discussion therein) and considering critical values corresponding to multiple roots of the polynomial describing a radial photon motion as functions of ξ (see also the critical curve in Fig. 34[44]). Subsequently, it was shown[31] that for an equatorial observer for any spin parameter $0 \leq a \leq 1$, the maximum absolute value of Y corresponds to $X = -2a$ and hence, in principle, it is possible to estimate a by measuring the position of the maximum value for Y.[31] Moreover, Bardeen[3] and Chadrasekhar[44] considered the apparent shape of a black hole for spin $a = M$, but they do not suggest using the apparent shape of a black hole as GR test perhaps because the dark region (shadow) is too small to be detectable for all known estimates of black hole masses and distances.

We depict the shadows for the non-rotating hairy black hole ($a = 0$) and Kerr black holes ($\alpha = 0$) (1) in Fig. 4 (cf. Fig. 2[31]) . Further, a comparison of the hairy Kerr black hole shadows with that of the Kerr black hole is shown in Fig. 5. There is a decremental effect in the shadow size from that of the Kerr black hole (cf. Fig. 5) with the decrease in l_0 from the Kerr limit $l_0 = l_k$.

4. Constraints on hairy Kerr black hole parameters from *EHT* observation of M87*

The EHT image of M87* is nearly circular and of crescent shape encompassing a central depression in brightness with a flux ratio $\geq 10 : 1$;[26–28] in terms of root-mean-square deviation from the average shadow radius the circularity deviation

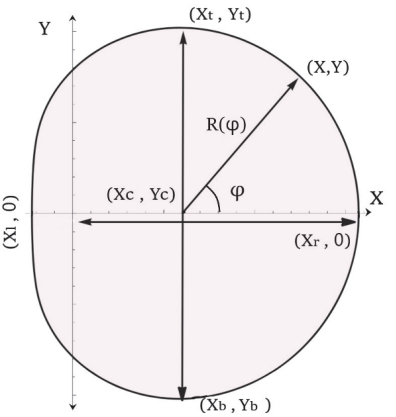

Fig. 6. The coordinates X_l and X_r indicate the most negative and most positive x-coordinates of the shadow while the Y_t, Y_b represent the top most and bottom most points. (X_c, Y_c) is the centre of the shadow and $R(\phi)$ is the polar shadow radius.[55]

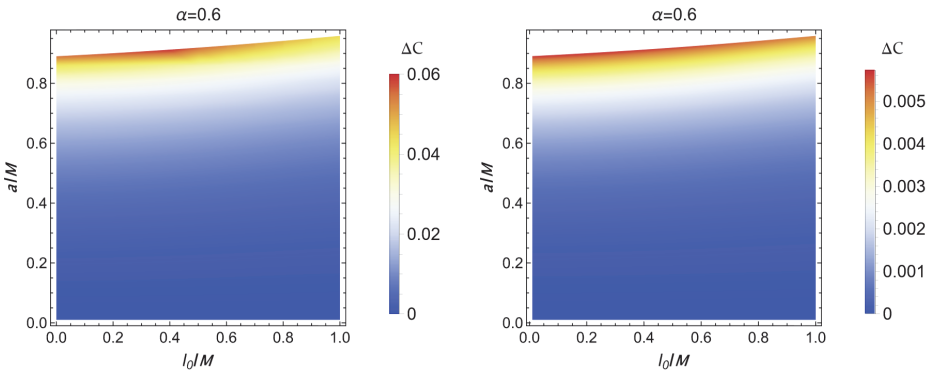

Fig. 7. Circularity deviation observable ΔC for hairy Kerr black hole shadows as a function of parameters (a/M and l_0/M) in agreement with the *EHT* observations of the M87* black hole, $\Delta C \leq 0.1$, is satisfied for the entire parameter space (a/M and l_0/M). The parameters of M87* used are $M = 6.5 \times 10^9 M_\odot$ and $d = 16.8$MPc. The inclination angle is $\theta_0 = 90^\circ$ (*left*) and 17° (*right*). The white region is forbidden for (a/M and l_0/M).

$\Delta C \leq 0.10$ (10%) and the angular size θ_d of the bright emission region in the observed image is $42 \pm 3\mu as$.[26–28]

The shadow outline of an axially symmetric black hole is depicted in Fig. 6 with the boundary of the black hole shadow by the polar coordinates $(R(\varphi), \varphi)$, with origin at the shadow centre (X_c, Y_c) such that $X_c = (X_r - X_l)/2$ and $Y_c = 0$ (cf. Fig. 6). The circularity deviation ΔC, which quantifies deviation from a perfect circle, is defined as[56]

$$\Delta C = \frac{1}{\bar{R}} \sqrt{\frac{1}{2\pi} \int_0^{2\pi} \left(R(\varphi) - \bar{R}\right)^2 d\varphi}, \tag{13}$$

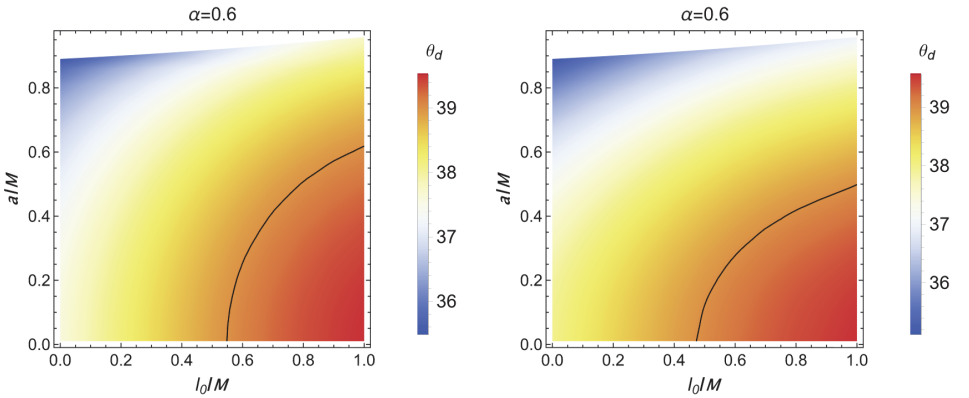

Fig. 8. Angular diameter observable θ_d for hairy Kerr black hole shadows as a function of parameters (a/M and l_0/M). The black solid curve correspond to $\theta_d = 39\mu$as within 1σ region of the measured angular diameter, $\theta_d = 42 \pm 3\mu$as, of the M87* black hole reported by the *EHT*. The parameters of M87* used are $M = 6.5 \times 10^9 M_\odot$ and $d = 16.8$Mpc. The inclination angle is $\theta_0 = 90°$ (*left*) and $17°$ (*right*). The white region is forbidden for (a/M and l_0/M).

with $\bar{R}$ – the average shadow radius.[56] The angular diameter of the shadow θ_d[13] is defined as

$$\theta_d = 2\frac{R_a}{d} \quad , \quad R_a = \sqrt{A/\pi}, \tag{14}$$

Here, φ is the polar angle between the x-axis and the vector connecting the centre (X_c, Y_c) with any point (X, Y) lying on the boundary of the shadow (cf. Fig. 6). where R_a is the areal radius of the shadow. The θ_d together with the ΔC will be useful to perform a comparison between the theoretical predictions for hairy Kerr BH shadows and the *EHT* observations.[56]

Assuming M87* a hairy Kerr black hole, we can calculate ΔC for metric (1) and use the *EHT* observational result $\Delta C \leq 0.1$ to put constraints on the hairy Kerr black hole parameters. The circularity deviation ΔC in the parameter space $(a/M - l_0/M)$ of the hairy Kerr black hole is depicted in Fig. 7. The Fig. 7 clearly indicates that the hairy Kerr black hole shadows of M87* for a given α, satisfy $\Delta C \leq 0.10$ for entire parameter space $(a/M - l_0/M)$ at both the inclination angles. The angular diameter of the shadow is calculated next, which apart from a, l_0, α, θ, depends on mass M and the distance d of the black hole and for the hairy Kerr black holes is depicted in Fig. 8 as function of a and l_0 α taking inclination angle $\theta_0 = 90°, 17°$. The black curves denote the *EHT* bound of 39μas, the 1σ bound of M87* on θ_d, and the region enclosed by it $39\mu as \leq \theta_d \leq 45\mu as$ serves as the parameter space $(a/M - l_0/M)$ consistent with the M87* observations.

5. Conclusions

A thorough analysis reveals that the l_0 and α quantitatively influences the event horizon structure, the ergosphere area, and the spherical photon region around

hairy Kerr black holes. Further, both the α and l_0 parameters are found to alter the shadow shape and size when compared to the Kerr black holes, namely, the shadows are smaller and more distorted, besides, the shadow size decreases, whereas the distortion increases with the decreasing value of parameter l_0.

The circularity deviation $\Delta C \leq 0.1$ is satisfied exhaustively for the entire $(l_0 - a)$ parameter space at both $\theta_0 = 90^\circ$ and $\theta_0 = 17^\circ$ inclination angles. The angular diameter satisfies $\theta_d = 42 \pm 3\mu$as within the 1σ region over a limited $(l_0 - a)$ space. However, the accordant parameter space for $\theta_0 = 17^\circ$ is smaller and more constricted than that at $\theta_0 = 90^\circ$. Thus θ_d puts a tighter bound on the conforming parameter space of the hairy Kerr black hole.

Therefore, our results constrain the hairy Kerr black holes parameters to ensure that the M87* shadow observations do not entirely rule out hairy Kerr black holes whereby the Kerr black hole has been studied in a more general setting, thus shedding light on the effect of surrounding dark matter on the Kerr black holes. The current resolution of the M87* black hole shadow angular diameter is of $\mathcal{O}(\mu$as) makes the distinguishability of the hairy black holes from the Kerr black hole bleak, at least from the present resolution of the *EHT* and the next-generation EHT with higher resolution may pin down the exact constraint. Thus to summarize, with the first direct image of the supermassive black hole M87* *EHT* observation, we have been able to place constraints on the hairy Kerr black hole parameters.

Displacement memory and BMS symmetries

Shailesh Kumar

E-mail: shaileshkumar.1770@gmail.com

This article reviews one of the most intriguing properties of black hole spacetimes known in the literature- *gravitational memory effect*, and its connection with asymptotic symmetries, also termed as Bondi-van der Burg-Metzner-Sachs (BMS) symmetries, emerging near the horizon of black holes. Gravitational memory is a non-oscillatory part of the gravitational wave amplitude which generates a permanent displacement for freely falling test particles or test detectors. We highlight a model scenario where asymptotic symmetries appear as a soldering freedom in the context of stitching of two black hole spacetimes, and examine the impact of the interaction between test detectors and horizon shells. Further, we provide a more realistic approach of computing displacement memory for near-horizon asymptotic symmetries which is analogous to the conventional memory originally obtained at asymptotic null infinity.

Keywords: Memory, Gravitational waves, BMS symmetries (asymptotic symmetries)

1. Introduction

The observational facets of gravitational waves (GWs)[1,2] have opened a new window to look for various aspects of black hole spacetimes; *gravitational memory*[3–8] is one of such intriguing features that has not been detected yet. GW induces a permanent relative change in the position of test detectors by imparting a memory to the configuration. This permanent relative change is referred to as gravitational memory. The term *memory* implies the information or properties of spacetimes from where it is being generated and carried by gravitational waves. The first practical computation of memory's evolution was done by Marc Favata using post-Newtonian formalism where he accounted for all stages of BBH coalescence.[9–12] In this direction, recently, there have been several implications of detecting GW memory using advanced detectors.[13–20]

On the other hand, it has been shown that the gravitational memory is closely related to the asymptotic symmetries of spacetimes originally discovered by Bondi-van der Burg-Metzner-Sachs (BMS) in the early sixties,[21] and such symmetries can also be recovered near the horizon of black holes which motivated us to probe the near horizon properties of black holes. The recent findings in this direction have provided some strong grounds for the information loss puzzle. In the context of asymptotic symmetries, the existence of soft hair on black holes is necessary for charge conservation of supertranslation and superrotation.[7,22–24] As the conservation principles are derived from the long-distance behaviour of fields close to spatial infinity, the presence of black holes should have no effect on them. We know that

the conserved charges can be expressed as bulk integrals over any Cauchy surface. A contribution from the future event horizon should be taken into account for conserved charges as future null infinity is no longer a Cauchy surface in the presence of a classical black hole. In this direction, Strominger and Hawking's latest discovery uses the asymptotic symmetries of the BMS group to prove that information is not lost rather stored in something called as a soft particle. Therefore, soft hair or low-energy quantum excitations may be carried by a black hole and leak information when it evaporates. This brings a direct motivation for the emergence of asymptotic symmetries near the horizon of black holes from conservation perspectives.

Let us understand how memory and BMS symmetries are inter-connected with each other. Classically, for a given spacetime geometry, BMS transformations produce an infinite class of spacetime metrics that are physically unique or distinct. Assume that BMS transformations act on a given metric $g_{\mu\nu}(x^\mu)$ with $x^\mu = (x^0, x^i)$, i.e., one time and three spatial coordinates. Such an action on the metric generates a completely different metric.

$$g_{\mu\nu}(x^\mu) \xrightarrow{\text{BMS transformation}} \tilde{g}_{\mu\nu}(x^\mu).$$

The metric $g_{\mu\nu}(x^\mu)$ and $\tilde{g}_{\mu\nu}(x^\mu)$ are distinct and this relative change implies the generation of *GW memory*, and also motivates us to seek for a connection between memory and BMS symmetries. This change can be understood in the following way- GWs generated from a black hole spacetime carrying information or properties in terms of BMS parameters would interact with the detector setup placed at the asymptotic null infinity, this would induce a permanent relative change in the initial configuration of the setup. A similar setup can also be considered at a place near the horizon of a black hole. A persistent effect similar to that of null-infinity may again be observed. It provides a physical meaning to the inter-connection between GW memory and asymptotic symmetries emerging near the horizon of black holes. Technically, $g_{\mu\nu}(x^\mu)$ can be thought of as a metric of a given asymptotically flat spacetime and $\tilde{g}_{\mu\nu}(x^\mu)$ is the resultant metric appears as a consequence of the interaction between GWs and detectors which implies a net relative change in the configuration and gives a definition to the memory. Briefly, if we have two nearby timelike geodesics or inertial detectors described by the tangent vector T^μ together with a deviation vector s^μ, and let us position them at the future null infinity. The evolution of the deviation vector before and after the interaction with gravitational waves will be captured in the geodesic deviation equation (GDE), written as

$$\frac{D^2 s^\mu}{d\tau^2} = -R^\mu{}_{\delta\sigma\lambda} T^\delta T^\lambda s^\sigma. \tag{1}$$

The solution of the GDE will give us a permanent relative change in the displacement vector s^μ which can further be related to supertranslation and will implicate the achievement of *BMS displacement memory effect*. Our study provides an analogous effect and its connection with asymptotic symmetries for near the horizon of black holes.

There are two methods to recover asymptotic symmetries near the horizon of a black hole. As a recent progress, Donnay et al. showed the first way of obtaining such symmetries near the horizon of a stationary black hole[25] with asymptotic form of the Killing vectors preserving the boundary conditions. It turns out that the near-horizon region of a stationary black hole spacetime induces supertranslations including semi-direct sum with extended asymptotic symmetry superrotations which is being represented by Virasoro algebra. Hence, one can recover asymptotic symmetries that would mimic the ones originally obtained at asymptotic null infinity[25,26] by preserving the near-horizon asymptotic structure of black holes. The second method for recovering asymptotic symmetries deals with the soldering of two spacetimes across a common null hypersurface.[27,28] It has been shown that we can stitch them in infinite ways by demanding that the induced metric remains invariant under the translations generated by the null generators of the shell.[27,28] The freedom for the choice of the intrinsic coordinates on null hypersurface in the null-direction is termed as *soldering freedom*, and also known as *BMS-like soldering freedom*. Since these appear as a metric preserving transformations, hence, known as BMS-like symmetries or BMS-like transformations. We shall discuss the related details in section 2.

The article is organized as follows. In section 2, we discuss the intrinsic formulation of null shells placed at the horizon and how near-horizon asymptotic symmetries are recovered in the context of stitching of two black hole spacetimes. Further, in section 3.1, we show how horizon shells carrying memory affect the displacement between two nearby test detectors or test particles for Schwarzschild and Extreme Reissner Nordström (ERN) black holes. We have also studied the impact of interaction between null geodesics and horizon shells; since we shall be completely focusing on timelike geodesics in this article, we do not include the discussion on null geodesics crossing the horizon shells. However, the study can be found in.[31,32] We further consider a more realistic approach in section 3.2 for determining the displacement memory effect and its connection with near-horizon asymptotic symmetries. In the end, we conclude our findings in section 4 by providing some remarks on possible future outlooks to our studies which might be relevant from theoretical as well as observational perspectives.

2. Horizon shell and asymptotic symmetries

In general relativity, a shell is a geometric configuration that can be used to investigate the propagation of thin distribution of null matter (e.g. neutrino) and impulsive gravitational waves (IGWs). The thin surface layer of null matter together with impulsive waves is precisely referred to as *thin-shell* or *thin null shell*.[29,30] The generated impulsive signals are usually produced during violent astrophysical phenomena like supernova explosions or coalescence of black holes. If we stitch two black hole spacetimes along a common null hypersurface which also happens to be the horizon of black holes, and stitching is consistent with *junction conditions*, we

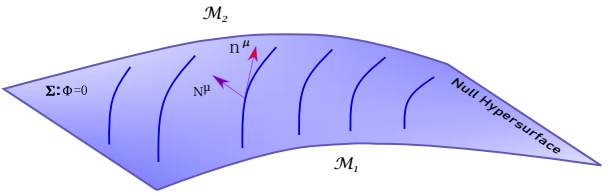

Fig. 1. Null hypersurface Σ separating manifolds $\mathcal{M}_{1,-}$ and $\mathcal{M}_{2,+}$ each with a different metric.

obtain *horizon shell*. The soldering formalism shows that the stess-energy tensor of the stitched spacetime satisfying Einstein field equation carries a singular term proportional to the Dirac delta distribution function, given by

$$T_{\mu\nu} = T^{+}_{\mu\nu}\mathcal{H}(\Phi) + T^{-}_{\mu\nu}\mathcal{H}(-\Phi) + S_{\mu\nu}\delta(\Phi), \tag{2}$$

where $\mathcal{H}(\Phi)$ is a Heaviside step function for a given null surface $\Sigma \equiv \Phi = 0$. The last term of Eq. (2) corresponds to the stress-energy tensor of the null surface, and further investigation on the same shows the generation of *impulsive gravitational wave* or thin surface layer of null matter or a mixture of both. The null hypersurface, representing the history of impulsive lightlike signals, separates spacetime manifold into two parts $(\mathcal{M}_1, \mathcal{M}_2)$ or $(\mathcal{M}_-, \mathcal{M}_+)$ as depicted in the Fig. 1 each with a different metric. n^μ is a null-normal or a generator of the null hypersurface, and N^μ is a transverse or auxiliary normal which is not tangent to the null surface, satisfying $n \cdot N = -1$. N^μ carries the transversal properties of Σ. One can study the intrinsic quantities of a horizon shell known as surface energy density (μ), surface current (J^A) and surface pressure (p) in terms of *transverse curvature* by analyzing the stress tensor on the null surface. The intrinsic quantities can be written in the following form

$$\mu = -\frac{1}{8\pi}\sigma^{AB}[\mathcal{K}_{AB}] \;\; ; \;\; j^A = \frac{1}{8\pi}\sigma^{AB}[\mathcal{K}_{VB}] \;\; ; \;\; p = -\frac{1}{8\pi}[\mathcal{K}_{VV}], \tag{3}$$

where '[ ]' denotes the difference between a quantity computed on the null surface Σ for both sides $\mathcal{M}_{1,2}$ separately. We notice that the null shell quantities depend on the induced metric σ^{AB} and jump in the extrinsic curvature $\mathcal{K}_{AB}$[a]. The other related details can be found in.[27,30–32]

An induced tensor field γ_{ab} on Σ is related to the jump of the induced metric g_{ab} and transverse normal N^μ which helps us to examine the intrinsic formulation of the horizon shell. The tensor field γ_{ab} can be written in terms of the jump in the derivative of the induced metric along the auxiliary normal N^μ which can further be written in terms of transverse curvature, i.e., $\gamma_{ab} = N^\mu[\partial_\mu g_{ab}] = 2[\mathcal{K}_{ab}]$. The analysis for intrinsic expression of stress tensor ensures that there is a part of γ_{ab}

[a]We have taken Kruskal-like coordinates. Also, Capital Latin letters denote spatial or spherical coordinates of the 2-sphere metric, and lower Latin letters denote hypersurface coordinates.

which does not contribute to stress-energy tensor. We denote this non-contributing part as $\hat{\gamma}_{ab}$. In general, one can write down γ_{ab} containing both null matter ($\bar{\gamma}_{ab}$) and GW degree of freedom ($\hat{\gamma}_{ab}$) in the following way

$$\gamma_{ab} = \hat{\gamma}_{ab} + \bar{\gamma}_{ab}, \tag{4}$$

with

$$\hat{\gamma}_{ab} = \gamma_{ab} - \frac{1}{2} g_*^{cd} \gamma_{cd} g_{ab} - 2n^d \gamma_{d(a} N_{b)} + \gamma^\dagger N_a N_b \tag{5}$$

$$\bar{\gamma}_{ab} = 16\pi \Big(g_{ac} S^{cd} N_d N_b + g_{bc} S^{cd} N_d N_a - \frac{1}{2} g_{cd} S^{cd} N_a N_b - \frac{2}{2} g_{ab} S^{cd} N_c N_d \Big), \tag{6}$$

where $\gamma^\dagger = \gamma_{cd} n^c n^d$, and g_*^{ab} is the pseudo-inverse of g_{ab}, i.e., $g_*^{ab} g_{bc} = \delta_c^a - n^a N_c, g_*^{cd} \gamma_{cd} = g^{AB} \gamma_{AB}$. The $\hat{\gamma}_{ab}$ carries the pure impulsive gravitational wave degree of freedom whereas $\bar{\gamma}_{ab}$ contains the null matter part of the horizon shell. In general, a null shell is being considered the combination of both IGWs and null matter. Further, using the expressions of intrinsic quantities of the null surface together with $\hat{\gamma}_{ab}$ and $\bar{\gamma}_{ab}$, in Kruskal coordinates, one obtains,

$$\bar{\gamma}_{VB} = 16\pi g_{BC} S^{VC} \;\; ; \;\; \bar{\gamma}_{AB} = -8\pi S^{VV} g_{AB}. \tag{7}$$

Now, we shall examine the interaction of such impulsive lightlike signals carrying BMS parameters on timelike geodesics. Let us first investigate the appearance of BMS symmetries in gluing formalism.

2.1. *Emergence of asymptotic symmetries*

Here, we investigate the emergence of near-horizon asymptotic symmetries in the context of soldering of two black hole spacetimes. This, in gluing formalism, can be achieved via obtaining the freedom in the choice of intrinsic coordinates along the null direction. The soldering freedom of stitching the two spacetimes along a common null surface provides BMS-like transformation on the horizon shell. It emerges as a coordinate transformation which preserves the induced metric on the null hypersurface Σ. This implies us to figuring out the Killing vectors of the hypersurface metric in a suitable coordinate system.[27,28] Therefore, the analysis is based on the Lie derivative of the induced metric along the Killing direction (say $Z^a \partial_a$ with components Z^a). We consider Kruskal coordinates (U, V, x^A) with coordinates (V, x^A) on Σ. Further, we also consider the metric with $g_{aV} = 0$. Therefore, the Killing equation for spatial metric g_{AB} is

$$\mathcal{L}_Z g_{AB} = 0 \implies Z^V \partial_V g_{AB} + Z^C \partial_C g_{AB} + (\partial_A Z^C) g_{CB} + (\partial_B Z^C) g_{AC} = 0. \tag{8}$$

Now, we may separately examine the emergence of near-horizon BMS symmetries-supertranslation and superrotation.

2.1.1. *Supertranslation*

The first special case is when metric does not depend on V parameter, i.e., $\partial_V g_{AB} = 0$. This induces a new type of translation which has angle dependent notion, termed as *Supertranslation*. It is similar to the one obtained at asymptotic null infinity for asymptotically flat spacetimes. Keeping in mind the impact of the Z-generated transformations on the null normal n^a of Σ, as a result, Eq. (8) gives

$$\partial_V Z^V = 0 \implies V \longrightarrow V + T(x^A) \ : \ BMS \ Supertranslation \tag{9}$$

This is instantly indentified as a supertranslation in the literature with $T(x^A)$ being a supertranslation parameter, where $x^A = (\theta, \phi)$. It is interpreted as an angle dependent translation, hence named *supertranslation*. The soldering group that keeps this structure preserved is still infinite dimensional. Let us now turn our discussion to investigate the extended form of asymptotic symmetry.

2.1.2. *Superrotation*

A new type of symmetry labeled as *superrotation* has just been discovered in an extended form of BMS symmetries near the horizon of black holes which mimics the one obtained at asymptotic null infinity.[25,27,28,33,34] It is a local conformal transformation of the spatial slice of the metric, or local conformal transformation of celestial sphere at null infinity.[22,33] Let us determine the extended BMS symmetry by considering the case when the spatial slice of the metric depends on the V parameter, i.e., $\partial_V g_{AB} \neq 0$. The analysis begins with the Eq. (8) in search of possible non-trivial soldering freedoms. If one performs the conformal transformation in spatial coordinates represented in complex coordinates via $z \longrightarrow f(z)$ and $\bar{z} \longrightarrow \bar{f}(\bar{z})$ such that the Eq. (8) can be written in the following way

$$Z^V \partial_V g_{AB} + \Omega(x^A) g_{AB} = 0, \tag{10}$$

where $x^A = (z, \bar{z})$ and $\Omega(x^A)$ denotes the conformal factor. We have the equation whose feasible solution can be written as, $g_{AB} = r^2(U, V)\tilde{g}_{AB}(x^A)$. It gives a suitable choice along V direction, i.e., $Z^V (= -\frac{V\Omega(x^A)}{2})$ which compensates the conformal transformation. This ensures that the metric remains preserved under such transformations. Thus, the analysis gives rise metric preserving extended BMS transformations known as *superrotation*-like symmetries.

3. Displacement memory and asymptotic symmetries

As a first approach, we wish to examine the relative change in the displacement vector between two nearby timelike geodesics which arises due to interaction with impulsive lightlike signals. We also discuss the appearance of near-horizon asymptotic symmetries in the context of soldering of two ERN and Schwarzschild spacetimes. Second, we would be considering a more realistic approach of computing displacement memory which is analogous to the one obtained at asymptotic null infinity. Let us first start with the case where horizon shell interacts with test detectors.

3.1. *Memory & BMS symmetries due to impulsive lightlike signals*

Cataclysmic processes such as black hole mergers and supernovae explosions produce shockwave type of gravitational radiations. We wish to estimate the finite difference in the displacement vector between two nearby timelike test particles or geodesics upon crossing the horizon shell[b]. It turns out that the asymptotic symmetries, associated with impulsive lightlike signals, leave footprints on test particles upon passing through them. As a result, we studied the effects of horizon shell for Schwarzschild and extreme RN spacetimes on the separation vector of two nearby timelike geodesics. The displacement between the geodesics is identified by supertranslation parameter which gives us *Supertranslation memory effect*. Let us consider a congruence having T^μ to be a tangent vector with $T\cdot T=-1$. A displacement or separation vector between two test particles is X^μ satisfying $T\cdot X=0$. Thus one can compute the relative change in the separation vector before and the passage of impulsive lightlike signals by analyzing the GDE Eq. (1). Riemann tensor is the memory generating factor for the given configuration. The solution of the GDE will generate a non-vanishing finite change in the deviation vector upon interacting with IGWs. Following the basic framework of the analyses from,[29,31,32] we use the expressions written in section 2 and $X^a=\tilde{g}^{ab}X_b$, we obtain components of deviation vectors as

$$X_V = 8\pi U g_{BC} S^{VC} X^B_{(0)} \tag{11}$$

$$X_A = X_{A(0)} + \frac{U}{2}\gamma_{AB}X^B_{(0)} + UV^-_{(0)A}, \tag{12}$$

where $V^-_{(0)a}=\frac{dX^-_a}{dU}\Big|_{U=0}$, and $\tilde{g}_{ab}=g_{ab}+(T_{(0)\mu}e^\mu_a)(T_{(0)\nu}e^\nu_b)$ with e_a defined as a triad on the null surface. The $X^B_{(0)}$ is some function evaluated on the null surface, and it is denoted by subscript (0). It is to note that when S^{VC} is nonzero, then we have $X_V\neq 0$. This implies that the particle will be displaced off from the initial two dimensional surface. On the other hand, if $S^{VC}=0$, the component X_V vanishes which means that the particle will reside on the initial two dimensional surface but with a relative displacement. In this particular consideration, the nonzero displacement vector X_A is written as

$$X_A = (1-4\pi U S^{VV})\Big(g_{AB}+\frac{U}{2}\hat{\gamma}_{AB}\Big)X^B_{(0)}. \tag{13}$$

The factor γ_{AB} is the one which carries the BMS memory part of the wave, and generates the distortion effect on the test particles. This sets our first goal to investigate the memory signal arises in the context of soldering of two black hole spacetimes. Further, we show our studies for extreme RN and Schwarzschild black holes. Let us understand these two cases separately.

[b]The study (B-memory) of interaction between null congruence and horizon shell can be found in Bhattacharjee et al.[31,32]

3.1.1. *Extreme RN case (ERN)*

As we know that 70% astrophysical black holes are near extremal and many supermassive black holes are also near extremal.[35–38] Further, Strominger and Vafa[39] determined the Bekenstein-Hawking area-entropy relation for extreme black hole. So extreme black holes are important from experimental as well as theoretical perspectives. Here, we investigate the asymptotic symmetries together with intrinsic properties of the shell and its interaction with test detectors in terms of BMS parameters. It is known that Carter investigated the maximal analytic extension of RN black hole for $e^2 = M^2$.[40] As the Carter's metric is not C^1 i.e. the first derivative of the metric component is discontinuous. Secondly, he certainly did a conceptual analysis without providing the exact Kruskal analogue for the extreme case. For our purpose, it is important to have an exact form of the Kruskal metric which enables us to write $U = 0$ on the horizon. This helps us to perform off-shell extension of the soldering transformation without any obscurities. Therefore, we adopt a Kruskal extension that unambiguously places the shell at $U = 0$, and also better suited for memory effect. The ERN metric in Kruskal coordinates can be written as[41]

$$ds^2 = -\frac{2M}{r^2}\psi(V)' dU dV + r^2(U)(d\theta^2 + \sin^2\theta d\phi^2), \tag{14}$$

where, $\psi(V)'$ is a regular, defined as, $\psi(V) = 4M\Big(lnV - \frac{M}{2V}\Big)$. Also $U = -(r - M)$ where $r = M$ is the horizon.

Immediately, by looking at the spherical part of the metric, we observe that supertranslation-like symmetries can be recovered, written as: $V \longrightarrow V + T(\theta, \phi)$. We also find that coordinate r is independent of V, thus interestingly, ERN consideration does not induce the superrotation-like symmetries whereas it is not the case with Schwarzschild discussed in section 3.1.2. For explicit details, we refer to Bhattacharjee et al.[32]

Further, we examine some measurable effects on timelike test particles due to interaction with horizon shell of ERN spacetime. In this process, we first extend the soldering transformation off the horizon shell to the linear order in U. The transformations are give by[31]

$$U_+ = UC(V, x^A) \;\; ; \;\; V_+ = F(V, x^A) + UA(V, x^A) \;\; ; \;\; x^A_+ = x^A + UB^A(V, x^A), \tag{15}$$

where $x^A \equiv (\theta, \phi)$, with

$$C = \frac{\partial_V \psi(V)}{\partial_V \psi(F)} \;\; ; \;\; A = \frac{M^2}{2}\frac{F_V}{\partial_V \psi(V)}\sigma_{AB}B^A B^B \;\; ; \;\; B^A = \partial_V \psi(V)\frac{1}{M^2 F_V}\sigma^{AB}F_B. \tag{16}$$

Here, σ_{AB} denotes the unit 2-sphere metric. One side of the spacetime $\mathcal{M}_-$ is completely ERN and the another side of the spacetime $\mathcal{M}_+$ is off-shell extended with the transformations (15). The process of obtaining the intrinsic quantities is

known as *off-shell extension of the soldering transformations*. It is to note here that one can also obtain the intrinsic properties of the horizon shell using *extrinsic curvature algorithm*. Both the results would exactly match. The benefit of the later approach is that it makes the computational algebra significantly simplified. As a result, we find that the surface current (j^A) together with surface energy density (μ) and pressure (p) is nonvanishing, and can be expressed in terms of supertranslation parameter $T(\theta, \phi)$. For example, the surface current is given by

$$j^A = \frac{1}{8M^2\pi}\sigma^{AB}\Big(T_B\frac{\psi(T)''}{\psi(T)'}\Big). \tag{17}$$

The expressions for μ and p can also be found in.[32] The presence of nonzero surface current induces a finite change in the X_V component of the deviation vector, i.e., $X_V \neq 0$; therefore, test particles get displaced off the initial 2-dimensional surface with a relative change in the displacement vector. The X_θ component is given by

$$X_\theta = X_{\theta(0)} + \frac{U}{2}\Big(\gamma_{\theta\theta}X^\theta_{(0)} + \gamma_{\theta\phi}X^\phi_{(0)}\Big) + UV^-_{(0)\theta}, \tag{18}$$

where,

$$\gamma_{\theta\theta} = 2\psi(V)'\Big(T_{\theta\theta} + \frac{T_\theta^2\psi(T)''}{\psi(T)'} - \frac{M}{\psi(T)'} + \frac{M}{\psi(V)'}\Big) \tag{19}$$

$$\gamma_{\theta\phi} = \gamma_{\phi\theta} = 2\psi(V)'\Big(\frac{T_\theta T_\phi}{\psi(T)'}\psi(T)'' + T_{\theta\phi} - T_\phi\cot\theta\Big). \tag{20}$$

This helps in determining GW degree of freedom γ_{ab}. One can determine X_ϕ component in a similar way. We notice that the deviation is written in terms of supertranslation parameter $T(\theta, \phi)$. The integration with respect to the geodesic parameters would give rise the displacement memory which would mimic the one obtained at null infinity. The Fig. 2 depicts the ultimate result of the test particles getting displaced off from the initial spatial slice with a comparison on Schwarzschild discussed in the section below. This completes our analyses of examining the role of near-horizon asymptotic symmetries on test particles upon interacting with impulsive lightlike signals together with the intrinsic properties of ERN horizon shell.

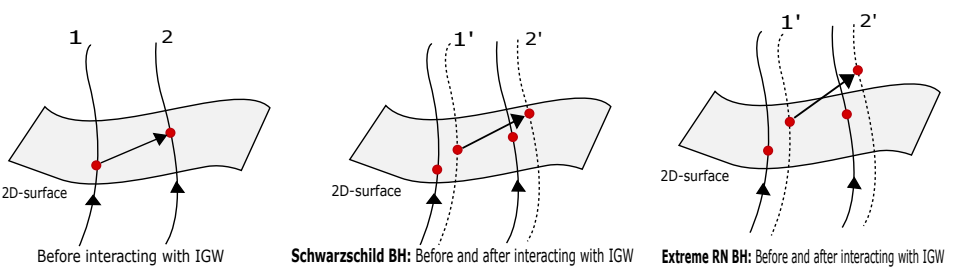

Fig. 2. Timelike geodesics 1 & 2 get displaced upon interacting with IGW, depicted as 1' & 2' with a new relative displacement vector.

3.1.2. *Schwarzschild case*

Now, we start with the Schwarzschild spacetime in order to examine the intrinsic formulation of the horizon shell and study the interaction with test particles.[31] Let us write down the metric in Kruskal coordinates,

$$ds^2 = -2G(r)dUdV + r^2(U,V)(d\theta^2 + \sin^2\theta d\phi^2), \tag{21}$$

where, $G(r) = \frac{16M^3}{r}$ and $UV - \Big(\frac{r}{2M} - 1\Big)e^{r/2M}$. The horizon is defined as $U = 0$. One can clearly see the supertranslation-like transformation, written as $V \longrightarrow V + T(\theta,\phi)$. Further, we notice that spherical part of the metric can be written as $\gamma_{\zeta\bar{\zeta}} = r^2\frac{d\zeta d\bar{\zeta}}{(1+\zeta\bar{\zeta})^2}$, and given the conformal transformations as discussed in (2.1.2), in contrast to ERN spacetime, we obtain superrotations for the null shell placed just outside the horizon $U = \epsilon$ with a compensation along null direction V which makes sure that the soldering transformations also preserve the form of the metric. These transformations mimic the ones originally obtained at asymptotic null infinity. We also compute the intrinsic quantities of the horizon shell which contain supertranslation parameter $T(\theta,\phi)$, can be seen in Bhattacharjee et al.[31]

Next, we show the non-vanishing finite change in the components of the deviation or displacement vector between two nearby timelike geodesics upon passing through the horizon shell. We follow Blau et al.[27] to extend the soldering transformations off the horizon shell in order to compute the induced tensor field γ_{ab}. The computation of the deviation vectors further require the GW degree of freedom which can be expressed as

$$\hat{\gamma}_{\theta\phi} = 2\nabla^{(2)}_{\theta}\partial_{\phi}T(\theta,\phi) \;\; ; \;\; \hat{\gamma}_{\theta\theta} = 2\Big(\nabla^{(2)}_{\theta}\partial_{\theta}T(\theta,\phi) - \frac{1}{\sin^2\theta}\nabla^{(2)}_{\phi}\partial_{\phi}T(\theta,\phi)\Big), \tag{22}$$

where $T(\theta,\phi)$ is a supertranslation parameter. Thus the framework of section 2 and section 3.1 generates the θ-component of the deviation vector,

$$\begin{aligned} X_{\theta} =& \Big(1 + \frac{U}{8m^2}(\nabla^2 T(\theta,\phi) - T(\theta,\phi)\Big)\Big(\Big(4m^2 + U(\nabla^{(2)}\partial_{\theta}T(\theta,\phi) \\ &- \frac{1}{\sin^2\theta}\nabla^{(2)}_{\phi}\partial_{\phi}T(\theta,\phi))\Big)X^{\theta}_{(0)} + U\nabla^{(2)}_{\theta}\partial_{\phi}T(\theta,\phi)X^{\phi}_{(0)}\Big). \end{aligned} \tag{23}$$

The X_{ϕ} component can also be computed in the similar way which again carries supertranslation parameter. It turns out that the surface current vanishes, i.e., $J^A = 0$, hence the test particles will remain on the spatial slice of the metric since $X_V = 0$, but with a relative change in the displacement as it can clearly be seen in Fig. 2, and opposes the result of ERN spacetime. Therefore, the nonvanishing displacement vector X_A depicts the BMS displacement memory in the context of soldering of two Schwarzschild spacetime geometries. One can further integrate Eq. (23) with respect to the parameter of the geodesics in order to have the explicit form of the displacement memory. Next, we shall discuss a more realistic approach of estimating the displacement memory which is analogous to the far region analysis.

3.2. *Memory and BMS symmetries: Analogous to far region*

In this section, we adopt a more realistic approach of computing displacement memory near the horizon of black holes and its possible connection with asymptotic symmetries. The analysis of this section is independent of section 2, i.e., it is not based on soldering of black hole spacetimes. We study displacement memory for non-extremal (fixed temperature) and extremal (zero temperature) black holes.[42] This shows an analogous effect of conventional GW-memory which was originally established at asymptotic null infinity (I^+). The emergence of asymptotic symmetries near the horizon of black holes (not in the context of null shell formalism) has been established by.[25,34] In this respect, we are interested in measuring the permanent relative change in the deviation or displacement of the test detectors induced due to the interaction with GW, and its connection with near-horizon BMS symmetries. In this realistic approach, as it can be seen in the schematic diagram below, the detectors are being placed near the horizon of a black hole ($\mathcal{H}^+$), and we estimate a relative change in the deviation vector of configuration before and after the passage of GWs. The displacement vector S^μ between the detector setup or geodesics evolves according to GDE Eq. (1). Let us consider the general form of the 4-dimensional near-horizon metric[26,43]

$$ds^2 = g_{vv}dv^2 + 2\kappa dvd\rho + 2g_{vA}dvdx^A + g_{AB}dx^Adx^B, \tag{24}$$

with following fall-off conditions for the horizon $\rho = 0$:

$$\begin{aligned} g_{vv} &= -2\kappa\rho + \mathcal{O}(\rho^2) \quad ; \quad k = 1 + \mathcal{O}(\rho^2) \\ g_{vA} &= \rho\theta_A + \mathcal{O}(\rho^2) \quad ; \quad g_{AB} = \Omega\gamma_{AB} + \rho\lambda_{AB} + \mathcal{O}(\rho^2) \end{aligned}$$

where θ_A, Ω and λ^{AB} are functions of (v, x^A). For computational purpose, we consider Ω to be unity. γ_{AB} represents the 2-sphere metric. In stereographic coordinates, $x^A = (\zeta, \bar{\zeta})$, the 2-sphere metric is $\gamma_{AB}dx^Adx^B = \frac{4}{(1+\zeta\bar{\zeta})^2}d\zeta d\bar{\zeta}$. The asymptotic Killing vectors preserving fall-off boundary conditions together with the charges

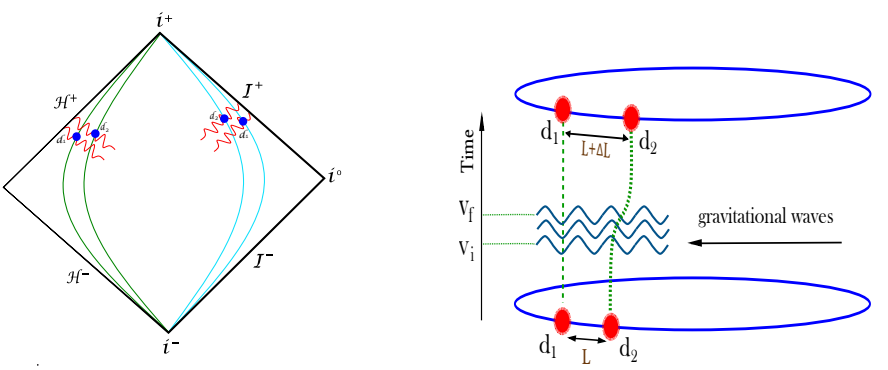

Fig. 3. Schematic diagrams depicting displacement memory effect for the detectors d_1 and d_2. Separation L gets modified permanently before and after the passage of GWs depicted as $L + \Delta L$.

can be found in Donnay et al.[26] It turns out that the variation of κ along Killing direction, when fixed temperature configuration considered, generates a copy of supertranslation together with a superrotation.[25,26] We use this fact in section 3.2.1. Let us consider the fixed temperature configuration first in order to compute displacement memory.

3.2.1. *Memory: Fixed temperature configuration*

The fixed temperature configuration enables us to take κ non-zero but constant. With this consideation, the solution of the GDE for the given metric is[42]

$$\Delta S^{\bar{\zeta}} = \frac{\rho(1+\zeta\bar{\zeta})^2}{4}\Big((\Delta\lambda_{\zeta\bar{\zeta}}S^{\bar{\zeta}} + \Delta\lambda_{\zeta\zeta}S^{\zeta}) - \kappa(\Delta v)^2(\mathcal{H}S^{\bar{\zeta}} + \mathcal{G}S^{\zeta})\Big) + \mathcal{O}(\rho^2), \quad (25)$$

where $S^{\bar{\zeta}}$ and S^{ζ} denote the $\bar{\zeta}$ and ζ components of the deviation vector. Here, we have also used the vA-component of the Einstein field equation, the $\mathcal{O}(\rho^0)$ term gives $\partial_v\theta_A = 0 \;\Rightarrow\; \theta_A = \mathcal{C}(x^A)$. Using vv-component of the Einstein field equation, we replace changes $\Delta\lambda_{AB}$ in Eq. (25) to obtain an explicit form of the memory which also ensures that λ_{AB} can be written in terms of θ_A. The resultant displacement memory is

$$\Delta S^{\bar{\zeta}} = \frac{\rho(1+\zeta\bar{\zeta})^2}{4}\Big(\Big((\kappa\tilde{G}\Delta v - \frac{2aQ}{(1+\zeta\bar{\zeta})^2})S^{\bar{\zeta}} + \kappa\tilde{B}S^{\zeta}\Big)\Delta v - \kappa(\Delta v)^2(\mathcal{H}S^{\bar{\zeta}} + \mathcal{G}S^{\zeta})\Big) + \mathcal{O}(\rho^2), \quad (26)$$

where $\tilde{G}, Q, \tilde{B}, \mathcal{H}$ and $\mathcal{G}$ are functions of $(\zeta, \bar{\zeta})$, also $\mathcal{H}$ is written in terms of metric parameter θ_A. Thus the analyses suggest that the displacement memory is restored in terms of metric parameters. This completes our study of achieving the displacement memory near the horizon of non-extremal black holes. Further, we relate it with the asymptotic symmetries.

Relation with BMS symmetry: We show the explicit relation between BMS symmetries and displacement memory. One can obtain the variation of the metric parameters λ_{AB}, θ_A and κ along the Killing direction. Since the the memory (25) or (26) is independent of v coordinate, we only mention the relevant expression of λ_{AB}-variation,[26] given by

$$\mathcal{L}_\chi\lambda_{AB} = f\partial_v\lambda_{AB} - \lambda_{AB}\partial_v f + \mathcal{L}_Y\lambda_{AB} + \theta_A\partial_B f + \theta_B\partial_A f - 2\nabla_A\nabla_B f. \quad (27)$$

On the other hand, the v component of the Killing vector for the fixed temperature configuration generates two sets of supertranslations $T(\phi)$ and $X(\phi)$, i.e.,

$$f(v, x^A) = T(x^A) + e^{-\kappa v}X(x^A). \quad (28)$$

Also, the Lie derivative of g_{vA} along Killing direction yields superrotation $Y^A(x^A)$.[26]

Now, in order to make the variation of λ_{AB} along the killing direction independent of v, we set v coefficients to be zero. Using the general solutions of λ_{AB} from relevant component of Einstein field equations, and for computational simplification switching off the supertranslation parameter T, we obtain $Y^{\zeta}(\zeta) = \tilde{a}e^{-\int \frac{\tilde{w}}{\tilde{p}} d\zeta}$ as a solution. where, $\tilde{w}$ and $\tilde{p}$ are functions of $(\zeta, \bar{\zeta})$ and $\tilde{a}$ appears as an integration constant; it would be a function of $\bar{\zeta}$ with respect to ζ differential equation. Similarly, one can also find the solution for $Y^{\bar{\zeta}}(\bar{\zeta})$. Therefore, we can find a solution for Y^A that will induce the desired shift in the displacement vector, and serves our purpose of establishing relation between displacement memory and asymptotic symmetries near the horizon of black holes.

3.2.2. *Memory: Zero temperature configuration & BMS symmetries*

We have also provided an explicit approach for zero-temperature configuration (extremal consideration). For this, the metric coefficients remain same as appear in the non-extreme case except the g_{vv} component which becomes $\mathcal{N}(\zeta, \bar{\zeta})\rho^2 + \mathcal{O}(\rho^3)$. The displacement memory with this consideration can be achieved by setting $\kappa = 0$ in Eq. (25), and written as

$$\Delta S_E^{\bar{\zeta}} = \frac{\rho}{4}(1 + \zeta\bar{\zeta})^2(\Delta\lambda_{\zeta\bar{\zeta}} S_E^{\bar{\zeta}} + \Delta\lambda_{\zeta\zeta} S_E^{\zeta}) + \mathcal{O}(\rho^2), \tag{29}$$

where subscript E stands for the change in the displacement vector for *extremal* or *zero temperature* configuration. One can again take the variation of λ_{AB} along Killing direction and obtain set of differential equations similar to the fixed-temperature analyses. The related details can be found in Bhattacharjee et al.[42]

3.2.3. *Memory & BMS symmetries: for a less generic form of the metric*

In this section, we consider a less generic form of the full metric (24) by setting $g_{vA} = 0$ which can be regarded as an asymptotic form of a metric near the horizon of a spherically symmetric black hole deformed in the spatial sector. The displacement memory for this setup can be computed in similar way as obtained for the full metric.

We find that the fixed temperature configuration does not produce very interesting result. However, the displacement memory is written in terms of $\Delta\lambda_{AB}$, and further set of conditions can be obtained in order to have the connection with BMS symmetries. The interesting finding appears if we consider zero temperature configuration. The change in the displacement vector is written in terms of $\Delta\lambda_{AB}$. Using the vv-component of Einstein field equation, the displacement memory is given by

$$\Delta S_E^{\bar{\zeta}} = \frac{\rho}{4}(1 + \zeta\bar{\zeta})^2 H(\zeta, \bar{\zeta})\Delta v S_E^{\bar{\zeta}} + \mathcal{O}(\rho^2). \tag{30}$$

We notice that the displacement memory is proportional to ρ whereas in the far region case[22] the memory is proportional to $\frac{1}{r}$. This implies that the displacement memory near the horizon of black holes is mimicking the one obtained null infinity.

One can further relate it with the BMS symmetries. It turns out that if we freeze off the superrotation, we have an exact solution: $X(\zeta, \bar{\zeta}) = X_1(\zeta) + X_2(\bar{\zeta})$. Hence, there is a supertranslation $X(\zeta, \bar{\zeta})$ that can induce the same shift in the displacement memory. We have also considered the three dimensional analyses for extreme and non-extreme cases, and its connection with near-horizon BMS symmetries in Bhattacharjee et al.[42]

4. Discussion and outlook

The primary motivation of this article is to provide a review study on the displacement memory effect near the horizon of black holes and its connection with asymptotic symmetries which is similar to the one established at null infinity for asymptotically flat spacetimes. In this respect, we started with a brief introduction of the intrinsic formulation of null shell. As a result, we show that the supertranslation-like transformations can be achieved in the context of soldering of two black hole spacetimes. We explicitly provided the results for Schwarzschild and ERN cases. However, interestingly, superrotation can not be recovered for ERN spacetime whereas it can be recovered for Schwarzschild. Further, as a result of interaction between horizon shell and test particles, we find that the particles remain on the initial 2-dimensional surface for Schwarzschild consideration as surface current is zero whereas for ERN spacetime, particles get displaced off from the initial 2-dimensional surface. We compute the components of deviation vectors which carry the supertranslation parameter ensuring that the memory can be obtained in terms of BMS parameters.

We have provided a detailed description of GW memory effect near the horizon of black holes as a more realistic approach which is analogous to the one obtained at null infinity. As a major distinguishing feature in order to establish a connection with asymptotic symmetries, we observed that there are two supertranslation parameters $T(x^A)$ and $X(x^A)$ and one superrotation $Y^A(x^A)$ in near horizon analyses whereas there is only one supertranslation in the far region case. We also notice that $\Delta\lambda_{AB}$ is the data available to be considered in the detection which mimics the data C_{zz} present near the null infinity.[22] The form of the GDE is also quite different with respect to the far region case. These are the brief and major distinguishing features between displacement memory obtained near the horizon of black holes and at asymptotic null infinity, together with its possible connection to BMS symmetries.

The observational features of GW will be extremely useful in investigating the signatures of the asymptotic symmetries in displacement memory effect. As a result, we might be able to look into such symmetries in greater detail as a firm evidence in near future. The theoretical aspects of our study might help as a model framework in the detection prospects of the near-horizon BMS memory effect. It is expected that present-day detectors like LIGO might not be able to play a crucial role in the detection prospects. We hope that advanced detectors like aLIGO or LISA might be able to capture this effect as LISA is looking for a much longer wavelength

opening up the detection realm to a wider range of gravitational wave sources. In this direction, building up the theoretical framework of post-Newtonian (PN) formalism having relevance for asymptotic symmetries, it is interesting to investigate the contribution of supertranslation-like symmetries in non-oscillatory signals of the gravitational wave polarizations. This would surely provide a more direct approach to gravitational wave data analysts in order to search for asymptotic symmetries in GW memory signal.

The alternative approach of detecting astrophysical signatures of asymptotic symmetries from gravitational lensing might not be an appropriate direction as supertranslated geometry of the spacetime will not lead to any deviations from standard results in general relativity for static configurations.[44] The underlying reason to the problem is that given a supertranslated Schwarzschild black hole, one can always choose a coordinate patch in a finite solid angular range where the metric will be given by the Schwarzschild. Hence, the signatures of asymptotic symmetries seem to be difficult from gravitational lensing. However, we still have a hope to detect such symmetries in black hole shadows and lensing if we have a dynamically evolving spacetime, and in this consideration, it is not sure whether one can again have some coordinate transformations which would give rise to indistinguishable features. So this might set a stronger grounds for detecting the asymptotic symmetries through deflection angle approach and black hole shadows. Interestingly, it is not difficult to understand that why gravitational memory is suitable for detecting such symmetries, because it appears as a physical effect where initial and final vacua differ by a BMS supertranslation. On another hand, the post-Newtonian tidal environment analysis especially in terms of BMS symmetries can also be explored from BMS-detection prospects.

Furthermore, as we have been investigating the issues from classical perspectives, the quantum memory effect has also got considerable attention in very recent, and it is yet to be explored extensively. This would certainly give a new meaning to the quantum treatment of the memory to catch on to the hawking information paradox. We know that the displacement memory is induced by the radiative energy flux, and it has been shown that there exists a new kind of gravitational memory- *spin memory effect* which is sourced by angular momentum flux.[45] It is interesting to examine the signatures of asymptotic symmetries in the context of spin memory effect near the horizon of black holes from BMS-detection point of view. Further, the algebra of asymptotic symmetries on null surface situated at a finite location of the manifold might determine some fascinating role of symmetries on GW memory.

Acknowledgement

I would like to express my sincere thanks to Srijit Bhattachrajee for proofreading this article and sharing his stimulating ideas during the preparation of the draft. I would also like to thank Arpan Bhattacharyya for illuminating discussions.

We derive and critically examine the consequences that follow from the formation of a regular black or white hole horizon in finite time of a distant observer. In spherical symmetry, only two distinct classes of solutions to the semiclassical Einstein equations are self-consistent. Both are required to describe the formation of physical black holes and violate the null energy condition in the vicinity of the outer apparent horizon. The near-horizon geometry differs considerably from that of classical solutions. If semiclassical physics is valid, accretion into a black hole is no longer possible after the horizon has formed. In addition, the two principal generalizations of surface gravity to dynamical spacetimes are irreconcilable, and neither can describe the emission of nearly-thermal radiation. Comparison of the required energy and timescales with established semiclassical results suggests that if the observed astrophysical black holes indeed have horizons, their formation is associated with new physics.

Keywords: Black holes; white holes; general relativity; semiclassical gravity; quantum aspects of black holes; energy conditions; surface gravity.

1. Introduction

Our current understanding of ultra-compact objects (UCOs) can be summarized as follows: the existence of astrophysical black holes (ABHs) — dark massive compact objects — is established beyond any reasonable doubt. However, it is unclear when, how, or if at all these UCOs develop the standard black hole attributes, such as horizons and singularities. A large number of models, often with deliberately designed features (or lack thereof), purport to describe ABHs. Translating the differences between these models into potentially observable differences between the signals received from the black hole candidates they describe is one of the most exciting topics in gravitational physics research.[1,2]

There is no unanimously agreed upon definition of a black hole.[3] The salient feature of a mathematical black hole (MBH)[4] is the event horizon that separates our outside world from an inaccessible interior. However, event horizons are global

teleological entities that are — even in principle — unobservable,[5,6] and observational, numerical, and theoretical studies focus on other characteristics of black holes. A trapped region is a spacetime domain where both ingoing and outgoing future-directed null geodesics emanating from a spacelike two-dimensional surface with spherical topology have negative expansion.[7–9] Its evolving outer boundary is the apparent horizon. This definition captures the most fundamental feature of black holes as spacetime regions that nothing, not even light, can escape. It is also local, and thus physically observable: the escape is not possible now, but the notion of "now" depends on the observer. Following the characterization scheme of Ref. 4, we refer to a trapped spacetime region that is bounded by an apparent horizon as a physical black hole (PBH).[10]

Although it cannot be observed, the event horizon is a useful asymptotic concept, and in many situations it is reasonable to assume that MBHs provide a good description of certain aspects of ABHs. Indeed, the predictions of various alternatives to black holes are most often compared with the standard Schwarzschild/Kerr paradigm.[1,2] However, using this asymptotic concept at finite times is logically unsatisfactory, and in the situations we consider below cannot be sustained.

Another question is whether the asymptotic picture is adequate to describe the relevant geometric and physical properties of black holes. We first formalize the minimal assumptions that underpin the widely used black hole notions presented in Fig. 1, namely regularity of the apparent horizon and its finite-time formation according to the clock of a distant observer. In spherical symmetry, these two assumptions uniquely determine the formation scenario for PBHs and suffice to provide an exhaustive description of their near-horizon geometry. Its properties are the subject of this contribution. We now outline the motivation and justification for these requirements.[10]

In classical general relativity (GR) non-spacelike singularities destroy predictability. According to the weak cosmic censorship conjecture,[16,17] spacetime singularities are concealed by event horizons. Quantum gravitational effects are expected to become important when the spacetime curvature is sufficiently strong,[8,18] i.e. when the Kretschmann scalar $\mathcal{K} := R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}$ reaches the Planck scale, that is $\mathcal{K} \gtrsim l_{\mathrm{P}}^{-4}$. The near-horizon geometry is believed to be well-described by semi-classical physics. Nontrivial quantum effects are obtained within the framework of quantum field theory in curved spacetime.[18] One of its most spectacular predictions is Hawking radiation: it not only completed black hole thermodynamics,[8,19] but has given rise to the infamous information loss paradox.[12] Regular (singularity-free) black holes were introduced to altogether eliminate singularities in classical gravitational collapse or as a way to resolve the problem of information loss.[4,20,21] Leaving aside the interior structure of black holes, we formulate the regularity criterion as the absence of curvature singularities at the apparent horizon. A precise mathematical formulation[10] is provided in Sec. 2.

To be considered a genuine physical object rather than merely a useful mathematical tool, the horizon must form in finite time of a distant observer, and there

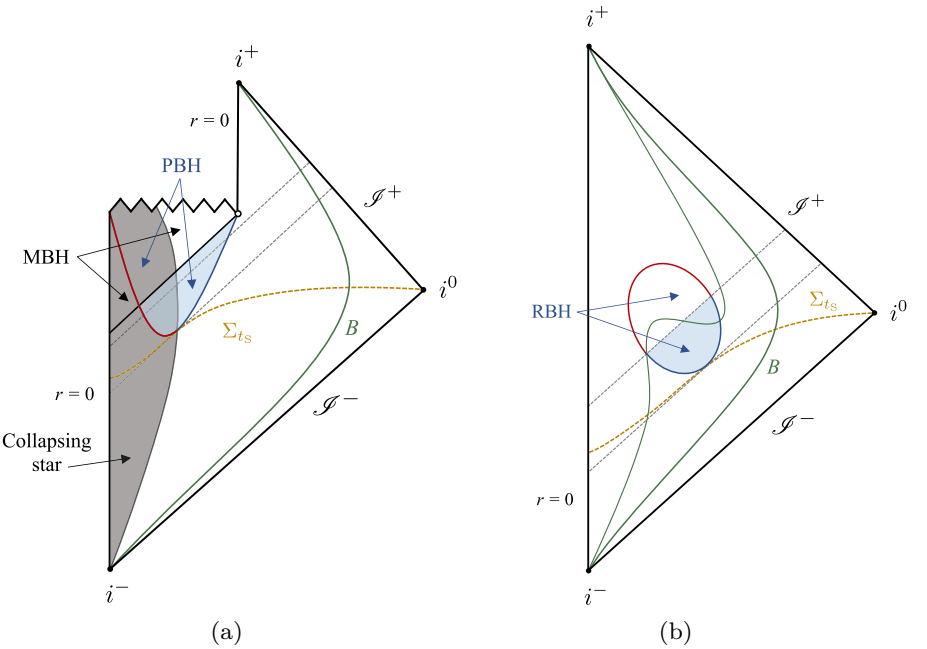

Fig. 1. Schematic Carter–Penrose diagram of the conventional formation and evaporation of (a) a black hole, and (b) a RBH. The outer apparent horizon $r_g(t)$ and the inner apparent horizon $r_{\rm in}(t)$ form the boundary of a PBH and are shown in blue and red, respectively. The equal time surface Σ_{t_S} is drawn as a dashed orange line. It is null at $\big(t_S, r_g(t_S)\big)$ and spacelike everywhere else.[11] The trajectory of a distant observer Bob is indicated in green and labeled "B". Dashed grey lines correspond to outgoing radial null geodesics. (a) Diagrams of this type are elaborations of the original sketch by Hawking, see Fig. 5 of Ref. 12. Spacetime regions corresponding to PBH (MBH) solutions are indicated by blue (black) arrows. Light signals emitted from the quantum ergosphere[13] (indicated by the light blue shading), i.e. from within the trapped region, but outside of the event horizon, reach $\mathscr{I}^+$ and are detected by Bob in his finite proper time. The collapsing matter and its surface are shown as in conventional depictions of the collapse. However, the matter in the vicinity of the outer apparent horizon $\big(t, r_g(t)\big)$ violates the NEC for $t \geqslant t_S$. Moreover, the energy density, pressure, and flux as seen by an infalling observer Alice vary continuously across it, and the equation of state dramatically differs from that of normal matter that may have been used to model the initial EMT of the collapse. (b) The asymptotic structure of a simple RBH spacetime[14] coincides with that of Minkowski spacetime. Conditions for the smooth joining of the inner and outer apparent horizon are described in Ref. 15. An unmarked green line represents a hypersurface $r = \text{const}$ that passes through the RBH.

should be some potentially (at least in principle) observable consequences of its formation. Moreover, if black holes do indeed emit Hawking radiation, and their evolution roughly resembles that of Fig. 1(a), then the apparent horizon forms in finite time t_S of a distant observer. We note that, as illustrated in Fig. 1(a), the outer apparent horizon is located outside of the event horizon.[8,12] Hence all signals that are emitted from the so-called quantum ergosphere[13,15] — part of the trapped region that lies outside of the event horizon — reach future null infinity $\mathscr{I}^+$. In addition, models of transient (even if long-lived) regular black holes (RBHs) imply

the finite-time formation and disappearance of the trapped region, as depicted in Fig. 1(b). This leads to our second requirement: the finite-time formation of an apparent horizon according to a distant observer.

Working in the framework of semiclassical gravity, we use classical notions (horizons, trajectories, etc.) and describe dynamics via the Einstein equations $G_{\mu\nu} = 8\pi T_{\mu\nu}$. We do not assume any specific matter content nor a specific quantum state ω that produces the expectation values of the energy-momentum tensor (EMT) $T_{\mu\nu} := \langle \hat{T}_{\mu\nu} \rangle_\omega$. Note that this EMT describes the total matter content — both the original collapsing matter and the produced excitations. We do not assume the presence of Hawking-like radiation, an event horizon, or a singularity. To simplify the exposition we work in asymptotically flat spacetimes, even if it is not essential for the resulting near-horizon geometries.

2. Spherically symmetric solutions

It is convenient to use Schwarzschild coordinates to impose the two assumptions described above. Their coordinate singularities allow us to identify the admissible solutions. A general spherically symmetric metric in four spacetime dimensions is given by

$$ds^2 = -e^{2h(t,r)} f(t,r) dt^2 + f(t,r)^{-1} dr^2 + r^2 d\Omega_2. \tag{1}$$

These coordinates provide geometrically preferred foliations with respect to Kodama time, a natural divergence-free preferred vector field.[9,22] In asymptotically flat spacetimes the time t represents the proper time of a distant static observer. Using the advanced null coordinate v, the metric is written as

$$ds^2 = -e^{2h_+} \left(1 - \frac{C_+}{r}\right) dv^2 + 2e^{h_+} dv dr + r^2 d\Omega_2. \tag{2}$$

The Misner–Sharp (MS) mass $C(t,r)/2$[9,23] is invariantly defined via

$$f(t,r) := 1 - C/r := \partial_\mu r \partial^\mu r, \tag{3}$$

and thus $C(t,r) \equiv C_+\big(v(t,r), r\big)$. The functions $h(t,r)$ and $h_+(v,r)$ play the role of integrating factors in coordinate transformations, such as

$$dt = e^{-h}(e^{h_+} dv - f^{-1} dr). \tag{4}$$

The apparent horizon is located at the Schwarzschild radius $r_g(t) \equiv r_+(v)$ that is the largest root of $f(t,r) = 0$.[9,24] In (v,r) coordinates the tangents to ingoing and outgoing radial geodesics are given by

$$l^\mu_{\text{in}} = (0, -e^{-h_+}, 0, 0), \qquad l^\mu_{\text{out}} = (1, \tfrac{1}{2} e^{h_+} f, 0, 0), \tag{5}$$

respectively. They are normalized to satisfy $l_{\text{in}} \cdot l_{\text{out}} = -1$, and their corresponding expansions are

$$\vartheta_{\text{in}} = -\frac{2e^{-h_+}}{r}, \qquad \vartheta_{\text{out}} = \frac{e^{h_+} f}{r}, \tag{6}$$

thus identifying the domain $r \leqslant r_+ \equiv r_g$ as a PBH.

Using the retarded null coordinate u, the metric is written as

$$ds^2 = -e^{2h_-}\left(1 - \frac{C_-}{r}\right)du^2 - 2e^{h_-}dudr + r^2 d\Omega_2. \tag{7}$$

In (u, r) coordinates the tangents to ingoing and outgoing radial geodesics are given by

$$l^\mu_{\text{in}} = (1, -\tfrac{1}{2}f(u,r)e^{h_-(u,r)}, 0, 0), \qquad l^\mu_{\text{out}} = (0, e^{-h_-(u,r)}, 0, 0), \tag{8}$$

respectively. Again, the tangents are normalized by $l_{\text{in}} \cdot l_{\text{out}} = -1$, and their respective expansions are given by

$$\vartheta_{\text{in}} = -\frac{e^{h_-}f}{r}, \qquad \vartheta_{\text{out}} = \frac{2e^{-h_-}}{r}. \tag{9}$$

As a result, the domain $r \leqslant r_- \equiv r_g$ is a white hole and the Schwarzschild radius is the location of the anti-trapping horizon. As in the case of the maximally extended Schwarzschild solution, these two scenarios describe different physical settings.

The Schwarzschild coordinates become singular as $r \to r_g$. We extract information about the EMT and therefore about the near-horizon geometry by studying how various divergences cancel to produce finite curvature scalars. Singular points are identified through the presence of incomplete geodesics in their vicinity and are excluded from manifolds representing the spacetime. These geodesics are inextendible in at least one direction, but the range of their generalized affine parameter (proper time for timelike geodesics) is bounded.[7,17,25,26] We focus on curvature singularities and formalize the regularity requirement as the demand that curvature scalars built from polynomials of Riemann tensor components are finite. This condition corresponds to the absence of essential scalar curvature singularities. More stringent conditions that involve higher covariant derivatives or regularity of individual components are not imposed.

In a general four-dimensional spacetime, there are 14 algebraically independent scalar invariants that can be constructed from the Riemann tensor.[27] We use two quantities that are expressed straightforwardly from components of the EMT, namely

$$\tilde{\mathrm{T}} := T^\mu{}_\mu\,, \qquad \tilde{\mathfrak{T}} := T_{\mu\nu}T^{\mu\nu}. \tag{10}$$

The Einstein equations relate them to the curvature scalars as $\tilde{\mathrm{T}} \equiv -\mathcal{R}/8\pi$ and $\tilde{\mathfrak{T}} \equiv R^{\mu\nu}R_{\mu\nu}/64\pi^2$, where $R_{\mu\nu}$ and $\mathcal{R}$ are the Ricci tensor and Ricci scalar, respectively. In spherical symmetry, if the two scalars of Eq. (10) are finite, then the rest are finite as well.[28]

It is convenient to introduce

$$\tau_t := e^{-2h}T_{tt}\,, \qquad \tau_t{}^r := e^{-h}T_t{}^r\,, \qquad \tau^r := T^{rr}. \tag{11}$$

The three Einstein equations for G_{tt}, $G_t{}^r$, and G^{rr} can then be written as

$$\partial_r C = 8\pi r^2 \tau_t / f, \tag{12}$$

$$\partial_t C = 8\pi r^2 e^h \tau_t{}^r, \tag{13}$$

$$\partial_r h = 4\pi r \left(\tau_t + \tau^r\right) / f^2. \tag{14}$$

Since $T^\theta{}_\theta \equiv T^\varphi{}_\varphi$ in spherical symmetry, the two scalars have the form

$$\tilde{\mathrm{T}} = \mathrm{T} + 2T^\theta{}_\theta, \qquad \tilde{\mathfrak{T}} = \mathfrak{T} + 2\big(T^\theta{}_\theta\big)^2, \tag{15}$$

where

$$\mathrm{T} := \left(\tau^r - \tau_t\right) / f, \qquad \mathfrak{T} := \left((\tau^r)^2 + (\tau_t)^2 - 2(\tau_t{}^r)^2\right) / f^2. \tag{16}$$

The curvature scalars are finite even if the individual terms are divergent in one of the two possible cases. The three effective EMT components τ_a, $a \in \{_t, _t{}^r, ^r\}$, may result in finite T and $\mathfrak{T}$, with $T^\theta{}_\theta$ [$G^\theta{}_\theta/8\pi$ with the metric functions that solve Eqs. (12)–(14)] being finite as well, or all four non-zero components $T^\mu{}_\nu$ may diverge, but these divergences cancel to produce the finite scalars of Eq. (15). We first describe the former possibility and then explain why the latter possibility is not realized.

A priori, to ensure that T and $\mathfrak{T}$ remain finite as $r \to r_g$, the effective EMT components τ_a must either diverge according to the same power law f^k, $k < 0$, converge to finite limits ($k = 0$), slowly converge to zero ($0 < k < 1$), or converge to zero with a variety of possible exponents k_a, $k_a \geqslant 1$. It was shown that only two classes of dynamic solutions (with the leading terms in the functions τ_a scaling as f^k, $k = 0, 1$) satisfy the regularity conditions.[29,30] The component $T^\theta{}_\theta$ is either finite due to the Einstein equations (or, possibly, due to some additional constraints on the functions C and h), resulting in admissible solutions, or divergent, indicating the inadmissibility of the solution as $T^\theta{}_\theta$ cannot have the same leading divergence as τ_a / f.[29] Moreover, a slow divergence (or a faster convergence of either τ_t or τ^r) is incompatible with Eqs. (13) and (14). Hence finite values of the two functions of Eq. (16) are a necessary condition to ensure that the curvature scalars are finite. We now briefly summarize the properties of the admissible solutions.

2.1. *Generic solution ($k = 0$)*

In principle, the solutions with $k = 0$ allow for $\tau_t \to \tau^r \to \mp\Upsilon^2$, $\tau_t{}^r \to \mp\Upsilon^2$ for some $\Upsilon(t) > 0$, but only

$$\tau_t \approx \tau^r = -\Upsilon^2 + \mathcal{O}(\sqrt{x}), \tag{17}$$

$$\tau_t{}^r = \mp\Upsilon^2 + \mathcal{O}(\sqrt{x}), \tag{18}$$

where $x := r - r_g$ denotes the coordinate distance from the horizon, describe valid solutions: taking $\tau_t \to \tau^r \to +\Upsilon^2$ results in complex-valued solutions of Eqs. (12)–(14) (see Ref. 31 for details).

The negative sign in the leading term of τ_t and τ^r leads to the violation of the null energy condition (NEC)[7,32,33] in the vicinity of the apparent horizon, i.e. a future-directed outward (inward) pointing radial null vector ℓ^μ does not satisfy $T_{\mu\nu}\ell^\mu\ell^\nu \geqslant 0$ for the contracting (expanding) Schwarzschild radius r_g.[31] An immediate consequence of this result is that accreting Vaidya black hole solutions in (v, r) coordinates cannot describe PBHs as they satisfy the NEC.[31]

The metric functions that solve Eqs. (12) and (14) are

$$C = r_g - 4\sqrt{\pi} r_g^{3/2} \Upsilon \sqrt{x} + \mathcal{O}(x), \tag{19}$$

$$h = -\frac{1}{2} \ln \frac{x}{\xi} + \mathcal{O}(\sqrt{x}), \tag{20}$$

where $\xi(t)$ is determined by the choice of time variable and the higher-order terms depend on the higher-order terms in the EMT expansion.[34] Eq. (13) must then hold identically. Both sides contain terms that diverge as $1/\sqrt{x}$, and their identification results in the consistency condition

$$r_g'/\sqrt{\xi} = 4\varepsilon_\pm \sqrt{\pi r_g}\, \Upsilon, \tag{21}$$

which describes the expansion or contraction of the Schwarzschild sphere depending on the sign of $\varepsilon_\pm = \pm 1$.

Useful information can be obtained by working with retarded and advanced null coordinates that result in regular metric functions.[31] If $r_g' > 0$, this is achieved by using the retarded null coordinate u. For $r_g' < 0$, the advanced null coordinate v leads to

$$C_+(v, r) = r_+(v) + \sum_{i \geqslant 1}^{\infty} w_i(v)(r - r_+)^i, \tag{22}$$

$$h_+(v, r) = \sum_{i \geqslant 1}^{\infty} \chi_i(v)(r - r_+)^i, \tag{23}$$

for some functions $w_i(v)$, $\chi_i(v)$, where $w_1 \leqslant 1$ due to the definition of r_+. This is the general form of the metric functions in (v, r) coordinates that ensures finite curvature scalars at the apparent horizon if $r_g' < 0$.[29] The components of the EMT in (v, r) and (t, r) coordinates are related by

$$\theta_v := e^{-2h_+} \Theta_{vv} = \tau_t\,, \tag{24}$$

$$\theta_{vr} := e^{-h_+} \Theta_{vr} = \left(\tau_t{}^r - \tau_t\right)/f, \tag{25}$$

$$\theta_r := \Theta_{rr} = \left(\tau^r + \tau_t - 2\tau_t{}^r\right)/f^2, \tag{26}$$

where $\Theta_{\mu\nu}$ labels the EMT components in (v, r) coordinates, which are finite. Hence $r_g' < 0$ corresponds to an evaporating PBH. Similarly, (u, r) coordinates are regular at the anti-trapping horizon r_g of an expanding white hole, $r_g' > 0$.[10,31]

The limiting form of the (tr) block of the EMT as $r \to r_g$ is

$$T^a{}_b = \begin{pmatrix} \Upsilon^2/f & -\varepsilon_\pm e^{-h} \Upsilon^2/f^2 \\ \varepsilon_\pm e^h \Upsilon^2 & -\Upsilon^2/f \end{pmatrix}, \qquad T_{\hat{a}\hat{b}} = \frac{\Upsilon^2}{f} \begin{pmatrix} -1 & \varepsilon_\pm \\ \varepsilon_\pm & -1 \end{pmatrix}, \tag{27}$$

where the second expression is written in the orthonormal frame. It makes the violation of the NEC particularly transparent.

In the test-field limit[18] quantum fields propagate on a given gravitational background, but the resulting EMT is not permitted to backreact on the geometry via the Einstein equations. It is instructive to compare the tensor of Eq. (27) with explicit results obtained in the test-field limit. Out of the three popular choices for the vacuum state,[8,18] only the Unruh vacuum results in an EMT with nonzero T_{tr} components. The state itself corresponds to the requirement that no particles impinge on the collapsing object from infinity.[35] In the context of a static maximally extended spacetime, its counterpart is a state with unpopulated modes at past null infinity and the white hole horizon.[8,18] Using various semi-analytical and numerical methods that are based on conformally coupled fields[36] and minimally coupled scalar field,[37] the expectation values of the renormalized components T_{tt}, $T_t{}^r$, and T^{rr} have been determined explicitly. They approach the same negative value as $r \to r_g$.

The experiences of observers in the vicinity of the apparent horizon depend on their trajectories. A static observer finds that the energy density $\rho := T_{\mu\nu}\, u^\mu u^\nu = -T^t_{\ t}$, pressure $p := T_{\mu\nu}\, n^\mu n^\nu = T^r_{\ r}$, and flux $\phi := T_{\mu\nu}\, u^\mu n^\nu$ diverge at the apparent horizon, where u^μ denotes the four-velocity and n^μ the outward-pointing radial spacelike vector. The experience of a radially-infalling observer Alice moving on the trajectory $x^\mu_{\rm A}(\tau) = (t_{\rm A}, r_{\rm A}, 0, 0)$ is different, and also differs from the infall into a classical eternal black hole.

First, crossing the apparent horizon of a PBH happens not only at some finite proper time τ_0, but also at a finite time $t_0(\tau_0)$, $r_g\big(t_0(\tau_0)\big) = r_{\rm A}(\tau_0)$ according to the clock of a distant Bob. This is particularly easy to see for radial null geodesics, where

$$\frac{dt}{dr} = -\frac{e^{-h(t,r)}}{f(t,r)} \to \pm\frac{1}{|r_g'|} \tag{28}$$

at $r = r_g$, the rhs is obtained using Eqs. (19)–(21),[29] and the upper (lower) signature corresponds to an outgoing (ingoing) null ray. We use this result in our estimate of the formation time in Sec. 4, and in showing that the simple generalizations of surface gravity to nonstationary spacetimes fail for PBHs (Sec. 3.2).

It is possible to find explicit relations between (t, r) and (v, r) coordinates in the vicinity of the apparent horizon,[30] namely

$$x(r_+ + y, v) = r_+ + y - r_g\big(t(v, r_+ + y)\big) = -r_g'' y^2/(2r_g'^2) + \mathcal{O}(y^3), \tag{29}$$

which relates the coordinates $x := r - r_g(t)$ and $y(r, v) := r - r_+(v)$. Another useful relation[38] is

$$w_1 = 1 - 2\sqrt{2\pi r_g^3 |r_g''|}\,\frac{\Upsilon}{|r_g'|}. \tag{30}$$

For an evaporating PBH ($r_g' < 0$) the energy density, pressure, and flux in Alice's frame are finite. However, upon approaching the anti-trapping horizon of an

expanding white hole ($r_g' > 0$), Alice encounters a firewall,

$$\rho_{\rm A} = T_{\mu\nu}\, u^\mu_{\rm A} u^\nu_{\rm A} = -\frac{\dot{r}^2_{\rm A}}{4\pi r_g X} + \mathcal{O}(1/\sqrt{X}), \tag{31}$$

where $X := r_A(\tau) - r_g\big(t_{\rm A}(\tau)\big)$,[28] which may be another indication of the instability[8] of such objects.

Violations of the NEC are bounded by quantum energy inequalities.[33,39] Outside of the singularities the lower bounds were shown to exist for the energy density $\langle \hat{T}_{\mu\nu} \rangle_\omega u^\mu u^\nu$ and its smeared averages. These are known to be state-independent for free fields. For spacetimes of small curvature, explicit bounds for a geodesic observer were derived in Ref. 40. A finite bound is violated by the $1/f^2$ divergence of the energy density that results in the logarithmic divergence of its smeared time average provided that the radial velocity does not go to zero.[11,29] However, this is not true for geodesics, and thus the inequality of Ref. 40 is inapplicable.

Observers that have crossed the apparent horizon but change their mind before traversing the quantum ergosphere can exit the black hole before it evaporates. Their experiences at the apparent horizon are more involved: for a geodesic observer that attempts to cross the apparent horizon from the inside, the energy density also diverges. However, it does so according to a weaker $1/f$ law, and thus the integrated energy density remains finite.

2.2. *Extreme solution ($k = 1$)*

The static solution with $k = 0$ is impossible, as in this case $\mathfrak{T}$ would diverge at the apparent horizon. Consequently, EMT components that allow for static solutions must behave differently. Many models of static nonsingular black holes assume finite values of energy density and pressure at the horizon.[4,21] With respect to the scaling behavior f^k of the effective EMT components of Eq. (11) this is the $k = 1$ solution, with

$$\tau_t \to E(t) f, \qquad \tau_t{}^r \to \Phi(t) f, \qquad \tau^r \to P(t) f, \tag{32}$$

where $\rho = E$ and $p = P$ at the apparent horizon. Any two functions can be expressed algebraically in terms of the third, and $8\pi r_g^2 E \leqslant 1$ to ensure that $C(t, r) - r_g > 0$ for $r > r_g$.

Only the extreme value of $E = (8\pi r_g^2)^{-1}$ corresponds to non-extreme dynamic black holes (i.e. those with $r_g \neq$ const whose trapped regions have nonzero volume).[30] As a result

$$C(t, r) = r - c_{32}(t) x^{3/2} + \mathcal{O}(x^2) \tag{33}$$

for some coefficient $c_{32}(t) > 0$, setting via Eq. (32) the scaling of other leading terms in the EMT. Consistency of Eqs. (13) and (14) implies $P = -E = -1/(8\pi r_g^2)$ and $\Phi = 0$. From the next-order expansion we obtain

$$h = -\frac{3}{2} \ln \frac{x}{\xi} + \mathcal{O}(\sqrt{x}), \tag{34}$$

as well as the consistency relation

$$r_g' = \varepsilon_\pm c_{32} \xi^{3/2} / r_g, \tag{35}$$

where the case $\varepsilon_\pm \equiv -1$ ($\varepsilon_\pm \equiv +1$) describes an evaporating PBH (an expanding white hole). The NEC violation is more subtle than in the $k = 0$ case. At $r = r_g(t)$ itself the NEC is marginally satisfied, as

$$T_{\hat{a}\hat{b}} = \frac{1}{8\pi r_g^2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{36}$$

However, the NEC is violated for some $x > 0$, as for both incoming and outgoing directions $l_{\rm in}$, $l_{\rm out}$, we have

$$T_{\hat{a}\hat{b}} l^{\hat{a}} l^{\hat{b}} = -\frac{3 c_{32} \sqrt{x}}{8\pi r_g^2} + \mathcal{O}(x). \tag{37}$$

Solutions with a time-independent apparent horizon or general static solutions do not require $w_1 = 1$ to satisfy Eqs. (24)–(26). Since $r_+(v) = r_g(t) = \text{const}$, it is possible to have non-extreme solutions. Then Eq. (13) implies $\Phi = 0$ and the identity $E = -P$ follows from Eq. (26), leading to a regular function $h(t, r)$. However, in this case Eq. (4) indicates that the apparent horizon cannot be reached in finite time t.

The curvature scalars of the solutions we have considered so far were rendered finite thanks to the constraint that Eq. (13) imposes on the dynamic behavior via Eqs. (21) and (35). For example, the Ricci scalar of the solution with $C(t, r)$ given by Eq. (33) includes the potentially divergent term

$$R_{\rm div} = \frac{3}{4\sqrt{x}} \left(\frac{r_g r_g'^2}{c_{32} \xi^3} - \frac{c_{32}}{r_g} \right) \tag{38}$$

that vanishes upon substitution of Eq. (35). However, a metric with $C(t, r) = r + c_2 x^2 + \ldots$ and the same $h(t, r)$ of Eq. (34), while being a solution of the Einstein equations, has a finite value of the Ricci scalar only in the static case $r_g' = 0$, as in this case

$$R_{\rm div} = -\frac{3 r_g r_g'^2}{c_2 \xi^3 x}. \tag{39}$$

3. Implications

The solutions described in Sec. 2 have many remarkable properties, and their near-horizon geometry differs considerably from that of Schwarzschild black hole spacetimes. First, we mention an immediate mathematical consequence of the firewall that we have described. The divergence of $\rho_{\rm A}$ [see Eq. (31)] points to the presence of a matter singularity. As a result, we observe that if an apparent/anti-trapping horizon forms, it is a surface with an intermediate singularity. The appearance of a negative energy firewall is the counterpart to arbitrarily large tidal forces that

could tear apart an observer falling into such a singularity. In these cases the fate of an observer depends on the integrated tidal stress.[8,41]

Consider observers attempting to enter an expanding white hole or exit an evaporating PBH.[10] In the former case, the radial velocity $\dot{R} < 0$ on a geodesic trajectory reverses the sign at some finite $R - r_g$ due to the divergent radial acceleration, and in fact the energy density remains finite. On the other hand, a massive test particle exits a PBH with $\dot{R} = 0$ and the energy density diverges, but its integrated smeared version remains finite.[11]

Since all curvature scalars remain finite, it is instructive to check the Ricci spinors

$$\Phi_{00} = \tfrac{1}{2}R_{11}, \quad \Phi_{22} = \tfrac{1}{2}R_{22}, \quad \Phi_{11} = \tfrac{1}{4}(R_{12} + R_{34}). \tag{40}$$

Using the natural Newman–Penrose tetrad that is built from the two null vectors of Eq. (5) and a pair of complex-conjugate vectors m^μ and $\bar{m}^\mu := m^{\mu *}$,

$$m = \frac{1}{\sqrt{2}r}\partial_\theta + \frac{i}{\sqrt{2}r\sin\theta}\partial_\phi, \qquad m \cdot \bar{m} = 1, \tag{41}$$

we find that the values of all nonzero spinors are finite at the apparent horizon. However, given the freedom of choice of these vectors $l^\mu_{\rm out} \to A l^\mu_{\rm out}$, $l^\mu_{\rm in} \to l^\mu_{\rm in}/A$, the values of the spinors Φ_{00} and Φ_{22} depend on this choice. By choosing $A = f(v, r)$ (this form of the tangent vectors may appear more natural in (t, r) coordinates), we find

$$\Phi_{00} \propto f, \qquad \Phi_{22} \propto f^{-1}, \tag{42}$$

again demonstrating that the apparent/anti-trapping horizon is a surface of intermediate singularity.[11]

3.1. *Black hole formation*

Consider now possibilities for horizon formation. The properties of the self-consistent solutions of the Einstein equations that we have described above lead to the identification of a unique scenario for black hole formation.[29,30] We consider only evaporating PBHs ($r_g' < 0$) due to the implications of the results presented in Sec. 2.1. Working in (v, r) coordinates, we assume that the first marginally trapped surface appears at some $v_{\rm S}$ at $r_+(v_{\rm S})$ that corresponds to a finite value of $t_{\rm S}$. For $v \leqslant v_{\rm S}$, the MS mass in its vicinity can be described by modifying Eq. (22) as

$$C(v, r) = \Delta(v) + r_*(v) + \sum_{i \geqslant 1}^{\infty} w_i(v)(r - r_*)^i, \tag{43}$$

where $r_*(v)$ corresponds to the maximum of $\Delta_v(r) := C(v, r) - r$, and the deficit function $\Delta(v) := C(v, r_*) - r_*(v) \leqslant 0$. At the advanced time $v_{\rm S}$, the location of the maximum corresponds to the first marginally trapped surface, $r_*(v_{\rm S}) = r_+(v_{\rm S})$, and $\sigma(v_{\rm S}) = 0$. For $v \geqslant v_{\rm S}$, the MS mass is described by Eq. (22). For $v \leqslant v_{\rm S}$, the (local) maximum of $\Delta_v(r)$ is determined by $\Delta_v(r)/dr = 0$, hence $w_1(v) - 1 \equiv 0$.

There are no *a priori* restrictions on the evolution of r_* before the PBH is formed. However, since an expanding Schwarzschild sphere describes white hole solutions $r'_+(v_S) < 0$. For $v > v_S$, the maximum of $C(v, r)$ does not coincide with $r_+(v)$ since the trapped region is of finite size. As a result, $w_1(v) < 1$ for $v > v_S$.

This means that at its formation a PBH is described by a $k = 1$ solution, which can be seen from Eq. (30), as $w_1 = 1$ implies $\Upsilon = 0$. It then immediately switches to the $k = 0$ solution, with matching decrease in $w_1(v)$ and increase in $\Upsilon\big(t(v, r_+)\big)$, and $w_1 < 1$ at all subsequent stages. The transition from f^1 to f^0 behavior is continuous as $\Upsilon(t_S) \equiv 0$ for the $k = 1$ solution and it increases thereafter.[30] A detailed discussion can be found in Ref. 10.

3.2. *Surface gravity*

The surface gravity κ plays an important role in GR and semiclassical gravity.[7–9] However, it is unambiguously defined only in stationary spacetimes (for a Schwarzschild black hole $\kappa = (2r_g)^{-1}$), where it is proportional to the Hawking temperature.

Generalizations of surface gravity to dynamical spacetimes are related to two (equivalent in stationary spacetimes) definitions of κ that are based on the peeling off properties and the inaffinity of null geodesics at the horizon, respectively.[9, 42] For sufficiently slowly evolving horizons with properties sufficiently close to their classical counterparts, these different generalizations of surface gravity are practically indistinguishable.[42] This agreement is important. Emission of Hawking-like radiation does not require the formation of an event or even an apparent horizon.[43–46] The role of the Hawking temperature is captured in various derivations either by the peeling[47] or the Kodama[48] surface gravity.

For PBHs, however, these quantities are very different. Here we consider only one version of the peeling surface gravity.[38] In Schwarzschild coordinates $\kappa_{\rm peel}$ is defined from the near-horizon behavior of null geodesics[9, 42] as the linear coefficient in the Taylor expansion of

$$\frac{dr}{dt} = \pm e^h f(t, r) \tag{44}$$

in powers of x as $x \to 0$ (i.e. $r \to r_g$). However, such an expansion is impossible for the metric functions of Eqs. (22)–(23). Alternatively, to be compatible with Eq. (28), $\kappa_{\rm peel}$ should be infinite, as we now demonstrate.

For differentiable C and h, the result is

$$\kappa_{\rm peel} = \frac{e^{h(t,r_g)}\,(1 - C'(t, r_g))}{2r_g}. \tag{45}$$

This quantity is undefined for $k = 0$ solutions as for a radial geodesic [Eq. (28)] it implies

$$\frac{dr}{dt} = \pm|r'_g| + \mathcal{O}(\sqrt{x}), \tag{46}$$

and $\kappa_{\rm peel}$ diverges (for both $k = 0$ and $k = 1$ solutions).[30]

The Kodama vector field has many useful properties of the Killing field to which, modulo possible rescaling, it reduces in the static case.[9,22,42] Similar to the Killing vector, it is most conveniently expressed in (v, r) coordinates,

$$K^\mu = (e^{-h_+}, 0, 0, 0). \tag{47}$$

It is covariantly conserved, and generates the conserved current

$$\nabla_\mu K^\mu = 0, \tag{48}$$

$$\nabla_\mu J^\mu = 0, \qquad J^\mu := G^{\mu\nu} K_\nu, \tag{49}$$

thereby giving a natural geometric meaning to the Schwarzschild coordinate time t. The MS mass is its Noether charge.

Since $K_{(\mu;\nu)} \neq 0$, the generalized Hayward–Kodama surface gravity is defined via[49]

$$\frac{1}{2} K^\mu (\nabla_\mu K_\nu - \nabla_\nu K_\mu) := \kappa_{\rm K} K_\nu, \tag{50}$$

evaluated on the apparent horizon. Hence

$$\kappa_{\rm K} = \frac{1}{2} \left(\frac{C_+(v,r)}{r^2} - \frac{\partial_r C_+(v,r)}{r} \right) \Bigg|_{r=r_+} = \frac{(1-w_1)}{2r_+}, \tag{51}$$

where Eq. (22) was used to obtain the final result. Thus at the formation of a black hole (i.e. of the first trapped surface) this version of surface gravity is zero. At the subsequent evolution stages that correspond to a $k = 0$ solution, $\kappa_{\rm K}$ is nonzero. However, it approaches the static value $\kappa = 1/(4M)$ only if the metric is close to the pure Vaidya metric with $w_1 \equiv 0$. This in turn contradicts the semiclassical results.[38]

4. Discussion

The solutions we have described follow from commonly obtained or assumed, but not always sufficiently articulated requirements: the formation of a minimally regular horizon in finite time of a distant observer. The two classes of spherically symmetric solutions that satisfy these requirements must violate the NEC in the vicinity of the outer apparent horizon, and the matter content is dominated by a null fluid. Unless we accept that semiclassical physics breaks down at the horizon scale, accretion is no longer possible after the horizon has formed: the solutions describe either evaporating black holes or expanding white holes.

It is still not clear how the collapsing matter actually behaves, and how the continuous transition from f^1 to f^0 behavior immediately after PBH formation (Sec. 3.1) can be realized in nature. A mechanism that converts the original matter into the exotic matter present in the vicinity of the forming apparent horizon is required to violate the NEC. However, the emission of collapse-induced radiation[43–45] is a nonviolent process that approaches at latter times the standard Hawking radiation and Page's evaporation law[8,50] $r_g' = -\alpha/r_g^2$, $\alpha \sim 10^{-3} - 10^{-4}$.

In addition, there is no obvious way to reconcile the two standard definitions of surface gravity that underpin different derivations of Hawking radiation to dynamical spacetimes (Sec. 3.2): the peeling surface gravity $\kappa_{\rm peel}$ diverges, whereas the Kodama surface gravity $\kappa_{\rm K}$ is zero at the instant of PBH formation and in contradiction with established semiclassical results thereafter. This has interesting repercussions for the formulation of the information loss paradox[38] and indicates that the Hawking radiation that is obtained on the Schwarzschild background is not an asymptotic form of the radiation that is emitted by a PBH.

Our results indicate that the observed ABHs may be horizonless UCOs rather than genuine PBHs with a horizon — not due to some exotic supporting matter or dramatic variation in the laws of gravity, but simply because the conditions for the formation of a horizon have not been met at the present moment of t. Even if no new physics is required to produce the mandatory NEC violation, the process may be too slow to transform the UCOs that we observe into PBHs. Eq. (28) of Sec. 2.1 sets the timescale of the last stages of infall according to Bob. Assuming that it is applicable through the radial interval of the order of r_g, we find $t_{\rm in} \sim r_g/r_g'$. For an evaporating macroscopic PBH, this is of the same order of magnitude as the Hawking process decay time $t_{\rm evp} \sim 10^3 r_g^3$. Such behavior was found in thin shell collapse models, where the exterior geometry is modeled by a pure outgoing Vaidya metric.[34] For a solar mass black hole, this time is about 10^{67}yr, indicating that it is simply too early for the horizon to form. It is also conceivable that the conditions are not met before evaporation is complete or before effects of quantum gravity become dominant.[8] Horizon avoidance may therefore occur due to the absence of new physics, and not because of it.

A more detailed understanding of the near-horizon geometry as well as the behavior of matter during gravitational collapse and PBH formation is needed to resolve all of the remaining questions. Coming of age of multimessenger astronomy and controversies surrounding the direct observation of ABHs make it a particularly timely project.

In classical gravity, nothing can escape from a black hole, not even light. In particular, this happens for stationary black holes because their horizons are null. We show, on the other hand, that the apparent horizon and the region near $r = 0$ of an *evaporating* charged, rotating black hole are both timelike. This implies that there exists a channel, via which classical or quantum information can escape to the outside, as the black hole evaporates. Since astrophysical black holes have at least some rotation, our results apply to all black holes in nature. We discuss implications of our result.

Keywords: Black hole information loss; Hawking radiation; evaporating black holes; rotating black holes; Vaidya metric.

1. Introduction

In classical general relativity, a black hole is a region of spacetime from which nothing escapes. This result underwent a change with the discovery of Hawking radiation.[1,2] Studying the evolution of a vacuum quantum state in curved spacetime with a horizon, Hawking showed that the ingoing vacuum state has a probability to yield a non-vacuum outgoing state when the former enters the horizon of a black hole. This means that a black hole can radiate energy to infinity via this quantum mechanism.

Now, both classical and quantum information can enter the horizon of a black hole. However, as Hawking's work showed, only thermal Hawking radiation carrying very little information emerges from it.[3] Therefore, when the black hole evaporates completely, all information carried by the matter that was used to create the black hole is apparently lost forever. This violates unitarity in quantum theory which

*Author for correspondence (saurya.das@uleth.ca)

requires the information of a quantum system be conserved during its evolution. Further study of this apparent information loss paradox led to the idea of black hole complementarity,[4–6] the firewall paradox[7,8] etc.

When discussing the above problem, people often overlook an implicit hypothesis that the causal structure of a black hole is not disturbed by Hawking radiation itself. Parikh and Wilczek were the first to examine this assumption and show that the singularity of an evaporating charged black [white] hole may be accessible for an observer outside when the metric is time-dependent.[9] However, the metric used in their paper in fact seems to represent a white hole, contrary to their claim that it is a black hole (see Appendix A for a detailed analysis). Recently, numerical simulation also shows that the horizon of a charged black hole may be timelike.[10] We know on the other hand, that much like other astronomical objects, all black holes in nature are rotating and uncharged, and the probability of finding a black hole with zero rotation is practically nil.

Motivated by the above, in this work,[11] we show that for a rotating and charged black hole which is Hawking radiating, there is a classical channel through which information can escape, and following the above reasoning, it provides an extended window of information recovery from its interior. In the process, the black hole shrinks of course, but presumably at a faster rate than predicted by Hawking radiation, because of the additional outflow of information and associated matter.

We demonstrate the above rigorously by constructing the Penrose diagram for the above process. In particular, we prove that the region immediately surrounding $r = 0$ is timelike, and the apparent horizon is timelike as well. These two results and the Penrose diagram all together imply null geodesics originating from anywhere near the centre of the black hole to the apparent horizon may emerge to the outside Universe. This in turn provides a route for classical or quantum information to escape from the black hole. This escape of potentially a large amount of information must be taken into account in any attempt to resolve the information loss problem. What is most significant is perhaps the fact that the escaping information need not be thermal.

2. Coordinates for an evaporating rotating charged black hole

Since we are interested in evaporating black holes, we will start with the following time-dependent metric, which represents a rotating and charged Vaidya-type black hole,[12,13] as shown in Appendix B

$$\begin{aligned} ds^2 = &-\left(1-\frac{2Mr-Q^2}{\sigma^2}\right)du^2 + 2du\,dr + \sigma^2 d\theta^2 - 2a\sin^2\theta\,dr\,d\phi \\ &-\frac{2(2Mr-Q^2)a}{\sigma^2}\sin^2\theta\,du\,d\phi + \left(\frac{2Mr-Q^2}{\sigma^2}\,a^2\sin^2\theta + r^2 + a^2\right)\sin^2\theta\,d\phi^2, \end{aligned} \tag{1}$$

where $\sigma^2 \equiv r^2 + a^2 \cos^2\theta$, and $M = M(u)$, $Q = Q(u)$ and $a = a(u)$ denote smooth decreasing functions of the retarded time u.

Next, to construct a two-dimensional Penrose diagram for the above metric, we restrict ourselves to the symmetry axis along $\theta = 0$.[14] Then one gets, from Eq. (1):

$$ds^2 = -\left(1 - \frac{2Mr - Q^2}{r^2 + a^2}\right)du^2 + 2\,du\,dr = -\left[\frac{r^2 - 2Mr + a^2 + Q^2}{r^2 + a^2}\,du - 2\,dr\right]du. \tag{2}$$

We also assume without loss of generality that M, a and Q are proportional to each other and linear functions of u

$$\begin{aligned} M(u) &= M_0 \text{ (constant)}, && u < u_0 && (3)\\ &= \mu u + b \equiv \tilde{u}, && u_0 < u \leq -b/\mu, \mu < 0 && (4)\\ &= 0, && -b/\mu < u && (5)\\ a(u) &= \lambda_1 M(u), && 0 \leq \lambda_1 \leq 1 && (6)\\ Q(u) &= \lambda_2 M(u), && 0 \leq \lambda_2 \leq 1. && (7) \end{aligned}$$

This means that the black hole starts its process of evaporation at time $u = u_0$, and undergoes a mass decrease at a constant rate μ. Contrary to Ref. [13], where the angular momentum was held fixed, in this work we make it time-dependent. This is because on the one hand, the form of the metric continues to hold with that generalization and moreover, the condition $\lambda_1, \lambda_2 \leq 1$ ensures that there are no naked singularities.

The following points may be noted here. First, continuity of the functions $M(u), a(u), Q(u)$ in Eqs. (3-7) guarantees that the various patches of the Penrose diagram that will smoothly join to each other.[9] Second, considering arbitrary decay rates (i.e. not constant over time) is also straightforward. In this case, one can simply break down the non-linear decay function such as $M(u)$ into a series of linear functions of the form $M(u) = \sum_{i=1}^{N}(\mu_i u + b_i)\left[\Theta(u_i + \frac{1}{2}) - \Theta(u_i + \frac{1}{2})\right]$ $(u_0 \leq u_i)$, and similarly for $a(u)$ and $Q(u)$, for $N \gg 1$.

Now, following Ref. [9] and details presented in Ref. [11], we find a set of coordinates which are smooth across the horizon. To this end, we first write metric (2) in the so-called 'double null' form:

$$ds^2 = -\frac{g(\tilde{u}, r)}{\mu} d\tilde{u} dv\ , \tag{8}$$

where,

$$dv \equiv \frac{1}{g(\tilde{u}, r)}\left[\left(\frac{r^2 - 2Mr + (\lambda_1^2 + \lambda_2^2)M^2}{r^2 + {\lambda_1}^2 M^2}\right)\frac{d\tilde{u}}{\mu} - 2dr\right]. \tag{9}$$

with the integrating factor

$$g(\tilde{u}, r) = \left(\frac{r^2 - 2Mr + (\lambda_1^2 + \lambda_2^2)M^2}{r^2 + {\lambda_1}^2 M^2}\right)\frac{\tilde{u}}{\mu} - 2r\ . \tag{10}$$

We may then read off

$$\frac{\partial v}{\partial r} = \frac{r^2 + \lambda_1^2 \tilde{u}^2}{-r[r^2 + \lambda_1^2 \tilde{u}^2] + \frac{\tilde{u}}{2\mu}\left[r^2 - 2\tilde{u}r + (\lambda_1^2 + \lambda_2^2)\tilde{u}^2\right]} \tag{11}$$

$$\frac{\partial v}{\partial \tilde{u}} = \frac{\frac{1}{2a}(r^2 - 2Mr + (\lambda_1^2 + \lambda_2^2)\tilde{u}^2)}{-r[r^2 + \lambda_1^2 \tilde{u}^2] + \frac{\tilde{u}}{2\mu}\left[r^2 - 2\tilde{u}r + (\lambda_1^2 + \lambda_2^2)\tilde{u}^2\right]} \ . \tag{12}$$

As one can see, the common denominators $D(r)$ of the above expressions are cubic in r, which may be rewritten as

$$\begin{aligned} D(r) &= -r[r^2 + \lambda_1^2 \tilde{u}^2] + \frac{\tilde{u}}{2\mu}\left[r^2 - 2\tilde{u}r + (\lambda_1^2 + \lambda_2^2)\tilde{u}^2\right] \\ &= -r^3 - \lambda_1^2 \tilde{u}^2 r + \frac{\tilde{u}}{2\mu} r^2 - \frac{\tilde{u}^2}{\mu} r + \frac{\tilde{u}^3}{2\mu}(\lambda_1^2 + \lambda_2^2) \\ &= -r^3 + \frac{\tilde{u}}{2\mu} r^2 - (\lambda_1^2 \tilde{u}^2 + \frac{\tilde{u}^2}{\mu}) r + \frac{\tilde{u}^3}{2\mu}(\lambda_1^2 + \lambda_2^2). \end{aligned} \tag{13}$$

Since $D(-\infty) > 0$, $D(+\infty) < 0$, and $D(0) = \frac{\tilde{u}^3}{2\mu}(\lambda_1^2 + \lambda_2^2) < 0$ because of $\mu < 0$ and $\tilde{u} > 0$ ($\tilde{u} = 0$ represents a flat spacetime and hence is ignored here), the scenarios with positive roots for the cubic equation $D(r) = 0$ are well described by Fig. 1. No other scenario has a positive root.

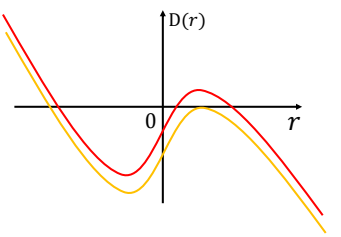

Fig. 1. Scenarios caused singularities for Eqs. (11) and (12).

For the case represented by the red line in Fig. 1, the denominators have three roots r_1, r_2, r_3, (with $r_1 > r_2 > 0 > r_3$) where v has coordinate singularities, and

$$v = \sum_{i=1}^{3} A_i \ln(r - r_i) \ , \tag{14}$$

with

$$\begin{aligned} A_1 &= \frac{r_1^2}{(r_1 - r^2)(r_1 - r_3)} + \lambda_1 \tilde{u}^2, \qquad A_2 = \frac{-r_2^2}{(r_1 - r^2)(r_2 - r_3)} + \lambda_1 \tilde{u}^2, \\ A_3 &= \frac{r_3^2}{(r_1 - r_3)(r_2 - r_3)} + \lambda_1 \tilde{u}^2 \ . \end{aligned} \tag{15}$$

Then the complete set of singularity free coordinates for the two patches may be defined as:

$$\begin{aligned} V_2(v) &\equiv e^{v/A_1} \\ &= (r-r_1)(r-r_2)^{A_2/A_1}(r-r_3)^{A_3/A_1} \ , \qquad r_2 \le r < \infty \qquad (16) \\ V_1(v) &\equiv k_1 - (-V_2)^{A_1/A_2} \\ &= k_2 + (r_1-r)^{A_1/A_2}(r_2-r)(r-r_3)^{A_3/A_2} \ , \qquad 0 \le r < r_2 \qquad (17) \end{aligned}$$

The constants k_i are determined by matching V_2 with V_1 in $r_2 < r < r_1$. If the denominator $D(r)$ of Eq. (11) is described by the gold line in Fig. 1, it has a negative root r_3 and a positive double root r_1 such that it can be factored as $(r-r_3)(r-r_1)^2$. This is nothing but a special case that $r_1 = r_2$ in the red-line scenario in Fig. 1.

3. Timelike regions

With the results in last section, it is easy to show that $r = 0$ and its immediate neighbourhood is *timelike*. For example, in the case of Eqs. (14-17) above,

$$\begin{aligned} ds^2 &= -\frac{g(\tilde{u},r)A}{V(\tilde{u},r)\mu}\, d\tilde{u}\, dV \qquad (18) \\ &\xrightarrow{r\to 0} -\left(\frac{\lambda_1^2+\lambda_2^2}{\lambda_1^2}\right) du^2 < 0 \ . \qquad (19) \end{aligned}$$

It may be noted that the 'ring singularity' of the metric is at $r = 0$ *and* $\theta = \pi/2$. It follows that except for that singular point, the region in the neighbourhood of $r = 0$ is regular and of finite curvature, except perhaps at the end of the evaporation process.

We now consider the apparent horizon and show that it is timelike as well. We follow the procedure of Ref. [15], and define the function:

$$f(u,r) = r - R_\pm \ , \qquad (20)$$

where $R_\pm$ represents the outer and inner apparent horizons of the evaporating rotating charged black hole. A rigorous calculations for $R_\pm$ yields

$$R_\pm = r_\pm + \frac{a\lambda_1(r_\pm^2+a^2)}{r_\pm^2 - (M+2a\mu\lambda_1)r_\pm}\mu + O(\mu^2), \qquad (21)$$

where

$$r_\pm = M \pm (M^2 - Q^2 - a^2)^{1/2} \qquad (22)$$

(see Appendix B for more details).

We assume that the evaporating process is sufficiently slow and that $|\mu|$ is sufficiently small. Therefore, we focus on the leading term in Eq. (21) for our future calculations. Thus, Eq. (20) reduces to

$$f(u,r) = r - M \mp (M^2 - Q^2 - a^2)^{1/2} \ , \qquad (23)$$

such that the apparent horizons are at

$$f(u,r) = 0, \ r_\pm = M \pm (M^2 - Q^2 - a^2)^{1/2} \ . \qquad (24)$$

Now since M, Q and a are functions of u the vector n_a, normal to the surface $f(u,r)=0$, will have components given by

$$n_u = f_{,u} = -\mu \mp \frac{\mu\ (M - \lambda_1 a - \lambda_2 Q)}{(M^2 - Q^2 - a^2)^{1/2}}\ , \qquad n_r = f_{,r} = 1\ , \tag{25}$$

and norm

$$n^2 = g^{ab} n_a n_b = 2\mu[-1 \mp (1 - \lambda_1^2 - \lambda_2^2)^{1/2}] > 0\ , \tag{26}$$

where we have used $\mu < 0$ from Eq. (4). Therefore, n_a is spacelike and the apparent horizon is timelike.

4. Penrose diagram

The information loss problem may be easily described using Penrose diagrams. The Penrose diagram in Fig. 2 depicts a static Schwarzschild (non-rotating, uncharged) black hole. In this case, the singularity is spacelike, and it is clear that information, from within the horizon, propagating along null or timelike geodesics cannot reach the outside Universe. The Penrose diagram in Fig. 3 describes an evaporating

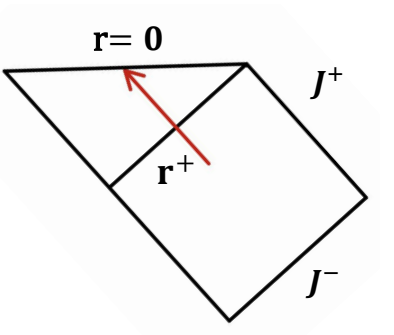

Fig. 2. Penrose diagram of a static Schwarzschild black hole.

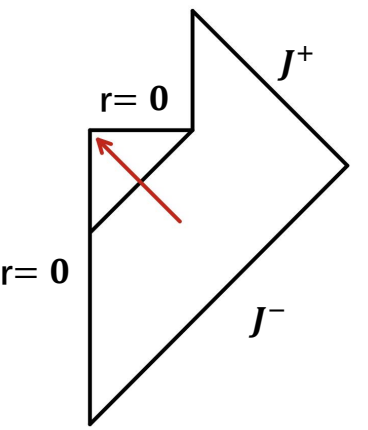

Fig. 3. Penrose diagram of an evaporating Schwarzschild black hole.

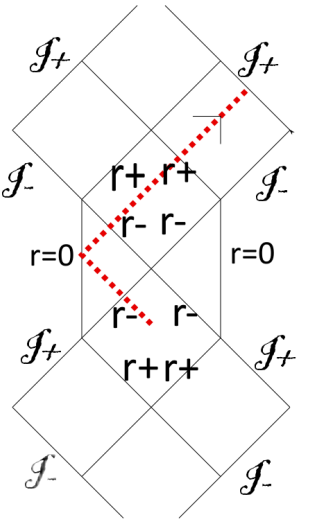

Fig. 4. Penrose diagram for stationary Kerr black hole.

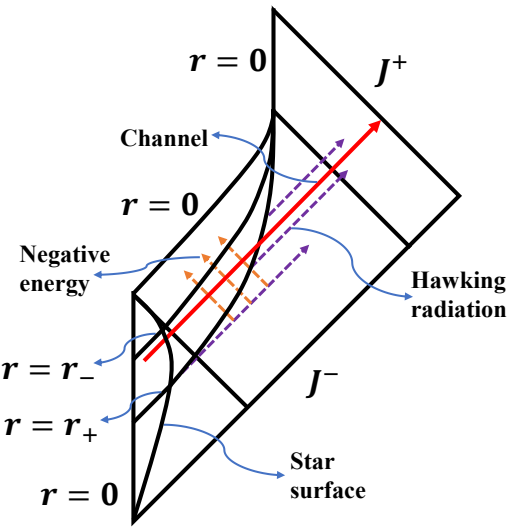

Fig. 5. Penrose diagram for an evaporating rotating (charged) black hole. This Penrose diagram describes a rotating (charged) star first collapsing into a rotating (charged) black hole. Then the black hole begins to evaporate, and both its inner and outer horizons at $\theta = 0$ follow timelike trajectories. After the black hole completely evaporates away, the spacetime is connected with a flat spacetime.

Schwarzschild black hole. The evaporating procedure of a Schwarzschild black hole does not change the fact that the horizon is along a null direction and hence does not improve the situation.

Similarly, Fig. 4 is the Penrose diagram of a maximally extended rotating black hole whose singularity is timelike. Although information propagating along null rays in such a Penrose diagram can exit a future horizon, it does so only by entering another Universe. Therefore, the information loss problem is not resolved in the present Universe.

Based on the results of Eqs. (19), (21), and (26), we can draw the Penrose diagram for the evaporating charged, rotating black hole (Fig. 5). As one can see, there is a channel (outgoing null rays in red) which can carry classical as well as quantum information all the way from the interior to infinity, crossing the timelike horizon along the way.

We assume $\theta = 0$ in Eq. (2) to simplify our calculations, it does not restrict our conclusion that there exists at least one such outgoing information channel. Even if future work shows that this channel is unique because its special azimuth, there is no limit in principle to the amount of information that can exit through this channel. Since our major calculations are carried out for a specific azimuth $\theta = 0$, its generalization to black holes in higher-dimensional spacetimes should be straightforward.

5. Discussion

We have shown in this article that the apparent horizon and the region close to $r = 0$ of an evaporating charged rotating black hole follow timelike trajectories. This implies that there exists a channel through which classical or quantum information can escape. Since proposals such as the fuzzball and firewall deal purely with quantum information, and in the context of Hawking radiation, there is no contradiction between those and our results here.[7,8,19] On the contrary, our approach complements the others.

It is known that matter flowing into the dynamic charged and rotating black hole may cause instability due to mass-inflation, resulting in the nature of the singularity changing.[20,21] However, we do not anticipate such a problem in our case since (a) our results pertain to the region of low curvature (not singularity), and (b) we have outgoing as opposed to infalling matter. That said a careful study of the effect for the spacetime under consideration is warranted and we hope to report on this in the future.

Since the horizon of a stationary black hole is null and the evaporating procedure is a quantum effect, emergence of such a classical channel is not a pure classical phenomenon. If the evaporation process stops for any reason before the black hole evaporates completely, our Fig. 5 would change and revert back to Fig. 4. However, since the Hawking temperature remains non-zero throughout, we do not consider this possibility.

Although our work does not completely resolve the problem of information loss, it complements other approaches in opening up a new information recovery channel. More work needs to be done to determine the extent of information that can be

extracted via this channel, and its interplay with the quantum resolution of the singularity.

Appendix A. The metric in Parikh and Wilczek's paper represents a white hole

To our knowledge, such an analysis was first done by in[9] for non-rotating black holes. However, contrary to their assuming the metric that they used to be that of an evaporating black hole, it is in fact that of a charged white hole. They study the metric[9]

$$ds^2 = -\left(1 - \frac{2Mr - Q^2}{r^2}\right)du^2 - 2du\,dr + r^2(d\theta^2 + \sin^2\theta\, d\phi^2), \tag{A.1}$$

where $M = M(u)$ and $Q = Q(u)$ denote smooth decreasing functions of the retarded time u. It is easy to see that Eq. (A.1) represents a white hole by taking $Q = 0$.[22] To show that Eq. (A.1) is the metric of a white hole, we now calculate the expansion of the null normal vector of this metric.

Since this metric is spherically symmetric, it is easy to figure out that the outward null normal vector l^μ and the inward null normal vector n^μ for this metric are

$$l^\mu = (0, 1, 0, 0) \quad \text{and} \quad n^\mu = \left(1, -\frac{r^2 - 2Mr + Q^2}{2r^2}, 0, 0\right). \tag{A.2}$$

It is easy to check that

$$l^\mu l_\mu = 0, \quad n^\mu n_\mu = 0 \quad \text{and} \quad l^\mu n_\mu = -1. \tag{A.3}$$

Finally, we calculate the expansion for both l^μ and n^μ by $\theta^{(A)} = A_{\mu;\nu}\sigma^{\mu\nu}$, where $\sigma^{\mu\nu} = g^{\mu\nu} + l^\mu n^\nu + n^\mu l^\nu$, to obtain

$$\theta^{(l)} = \frac{2}{r} \quad \text{and} \quad \theta^{(n)} = -\frac{r^2 - 2Mr + Q^2}{r^3}. \tag{A.4}$$

From Eq. (A.4) we know that $\theta^{(l)} > 0$ and $\theta^{(n)} < 0$ when r is larger than the apparent horizon. However, it is the vanishing of $\theta^{(n)}$ that defines an apparent horizon. Thus, the Vaidya-type metric in Parikh and Wilczek's paper represents a white hole.

Appendix B. The metric in our manuscript represents a black hole

To show that our metric represents an evaporating black hole, we calculate the expansion of the null normal vectors for the rotating charged Vaidya-type black hole, see Eq. (1) in the manuscript.

Suggested by the rotating charged stationary black hole,[23] we may conjecture that the outward null vector l^μ and the inward null vector n^μ for the rotating charged Vaidya-type black hole are

$$l^\mu = \left(\frac{r^2 + a^2}{\sigma^2}, \frac{\triangle}{2\sigma^2}, 0, \frac{a}{\sigma^2}\right) \quad \text{and} \quad n^\mu = (0, -1, 0, 0). \tag{B.1}$$

where $\sigma^2 = r^2 + a^2\cos^2\theta$ and $\triangle = r^2 + a^2 - 2Mr + Q^2$. It is easy to check that

$$l^\mu l_\mu = 0, \quad n^\mu n_\mu = 0 \quad \text{and} \quad l^\mu n_\mu = -1 \tag{B.2}$$

for the Vaidya-type metric in our manuscript. Then we calculate the expansion for both l^μ and n^μ by $\theta^{(A)} = A_{\mu;\nu}\sigma^{\mu\nu}$, where $\sigma^{\mu\nu} = g^{\mu\nu} + l^\mu n^\nu + n^\mu l^\nu$. Finally, we obtain

$$\theta^{(l)} = \frac{r\triangle + 2\,a\,a'(u)(r^2 + a^2\cos^2(\theta))}{(r^2 + a^2\cos^2(\theta))^2} \quad \text{and} \quad \theta^{(n)} = -\frac{2r}{r^2 + a^2\cos^2(\theta)}. \tag{B.3}$$

From Eq. (B.3) we see that $\theta^{(l)} > 0$ and $\theta^{(n)} < 0$ when r is larger than the apparent horizon and $\theta^{(l)} = 0$ defines the apparent horizon. Thus, the Vaidya-type metric in our manuscript represents a black hole.

The apparent horizon for a stationary rotating charged black hole is defined by $\triangle = 0$. Here, our calculations show that the time dependence of the angular momentum $a(u)$ makes the apparent horizon shift slightly from the stationary case with the size of the shift depending on the rate of change of $a(u)$ with respect to u.

If we insert our linear functions for M, Q and a, Eqs. (3-6) in the manuscript, into the expansion of the outward null normal vector and suppose the rate of change is very slow (μ is very small), we can obtain the corrected apparent horizon for $\theta = 0$ as

$$R_\pm = r_\pm + \frac{a\lambda_1(r_\pm^2 + a^2)}{r_\pm^2 - (M + 2a\mu\lambda_1)r_\pm}\mu + O(\mu^2). \tag{B.4}$$

Since we have proved $r_\pm$ is timelike, the apparent horizon of a slowly evaporating rotating charged black hole should also be timelike.

Black hole thermodynamics from entanglement mechanics

S. Mahesh Chandran* and S. Shankaranarayanan†

Since its inception, the Bekenstein-Hawking area relation for black-hole entropy has been the primary testing ground for various theories of quantum gravity. However, a key challenge to such theories is identifying the microscopic structures and explaining the exponential growth of microstates, providing a fundamental understanding of thermodynamic quantities. Since entropy is a single number, we explore other quantities to provide complete information about the black-hole microstates. We establish a one-to-one correspondence between entanglement energy, entropy, and temperature (quantum entanglement mechanics) and the Komar energy, Bekenstein-Hawking entropy, and Hawking temperature of the horizon (black-hole thermodynamics), respectively. We also show that this correspondence leads to the Komar relation and Smarr formula for generic 4-D spherically symmetric space-times. While offering an independent derivation of black-hole thermodynamics from field observables, the universality of results suggests that quantum entanglement is a *fundamental building block of space-time*.

Keywords: Entanglement Entropy; Black Hole Thermodynamics; Field Theory in Curved Space-times.

1. Introduction

Black holes are fascinating entities that typically arise from gravitationally collapsing bodies, such as stars at the end of their life cycle or star collisions. Despite their violent origin, black holes relax to a stationary state, which can then be fully described by a mere handful of variables such as their mass, charge and angular momentum. This makes it easier to probe various quantum and gravitational phenomena that come with it, further making it an ideal testing ground for ongoing research on quantum gravity.

Interestingly, like ordinary matter systems such as ideal gases, black holes also obey an equation of state. The physical parameters describing stationary black-holes satisfy what is known as the Komar relation[1–3]:

$$E_{\rm Komar} = 2\,T_{\rm H}\,S_{\rm BH}, \tag{1}$$

where $E_{\rm Komar}$ is related to the Hamiltonian of the Einstein-Hilbert action,[4] $T_{\rm H}$ is the Hawking temperature[5] and $S_{\rm BH}$ is the Bekenstein-Hawking entropy.[6] The above relation is a by-product of the Smarr formula[7,8]:

$$M = 2T_H\,S_{\rm BH} + 2\Omega_H J + \Phi_H Q \tag{2}$$

that relates the mass (M), angular momentum (J), entropy ($S_{\rm BH}$), electric charge (Q) of black-holes, angular velocity Ω_H, and Φ_H which is the potential difference between the horizon and infinity. It was shown that the Smarr formula, in its differential form and subject to certain assumptions, gives rise to the first law of black hole thermodynamics.[9] At the heart of this law is the analogy that connects thermodynamic entropy to surface area, and temperature to surface gravity.

Most of the effort in literature has been to understand the microscopic statistical origin of black-hole entropy,[10–13] and in extension, black hole thermodynamics. However, black-hole entropy has the problem of Universality[14]— wherein up to the leading order, several approaches using completely different microscopic degrees of freedom lead to Bekenstein-Hawking entropy.[10,13,14] The inability to conclusively distinguish such approaches, along with the fact that entropy is a single number, suggests that it may be impossible to identify the true degrees of freedom that give rise to black hole entropy. Therefore, it requires us to also identify other physical quantities corresponding to black hole thermodynamics, if we were to attempt resolving the universality problem.

Over the last decade or so, one such approach that has grown increasingly crucial to understanding black-hole physics, and quantum gravity in general, is quantum entanglement.[15–19] A fundamental feature of entanglement is the *Area law* — the entanglement entropy of blocks of low energy states of local Hamiltonian is often proportional to the measure of the boundary separating the block from its setting.[13,20–22] The area law has not only established a direct link between entanglement entropy and black hole entropy, but also led to the conjecture that space-time fabric might itself be built upon entanglement.[17] If entanglement is a necessity for the existence of space-time, then the *litmus-test* is to derive all the quantities of black-hole thermodynamics from entanglement.

In this talk, we show that the quantum scalar fields in a $(3+1)$-dimensional black-hole space-times with one or more horizons, provide a way to obtain the physical quantities from entanglement *aka entanglement mechanics*. We relate these quantities to black-hole thermodynamics, and further show that these quantities satisfy Smarr formula (2).[23]

2. Modeling scalar field in a background space-time

In this section, we recapitulate the procedure for probing entanglement mechanics of a minimally coupled scalar field against a static, spherically symmetric background space-time with one or more horizons. The line-element for such a space-time can in general be written as follows:

$$ds^2 = -f(r)dt^2 + \frac{1}{f(r)}dr^2 + r^2 d\Omega^2. \tag{3}$$

Depending on the form of $f(r)$, there is usually a handful of coordinate settings that help us understand the system better. Suppose the space-time in question has

a horizon (r_h), such as in the Schwarzschild case, it is useful to rewrite the metric in terms of proper-length coordinates[24]:

$$ds^2 = -f(r)dt^2 + d\rho^2 + r^2 d\Omega^2\,; \qquad \rho = \int_{r_h}^{r} \frac{dr}{\sqrt{f(r)}}. \tag{4}$$

Before modeling the scalar field in this setting, we have to address two fundamental aspects — i) Since entanglement entropy diverges in the continuum limit, the field has to be *regularized*. The regularisation provided by the more rigorous definition of quantum fields in terms of operator-valued distributions is difficult to calculate even for simple free theories.[25] We therefore resort to regularisation by discretization,[21,22] i.e., we treat quantum fields on a lattice, with the lattice spacing a fixed in units of proper length as depicted in Fig 1. (ii) To capture entanglement of the field across a space-time horizon, the field must be treated as a *bipartite* system made up of subsystems on either sides of the horizon. However, the proper length co-ordinates only capture the region on that side of the horizon where $f(r) > 0$. The physics in the region $f(r) < 0$ will hence remain inaccessible. The bipartition will then have to be performed as close to the horizon as possible, i.e., by tracing out a single degree of freedom along proper length co-ordinate. This is in fact a valid approximation for large horizon radius and/or small lattice spacing of discretized field.[23]

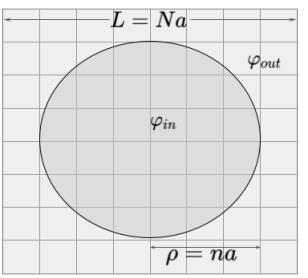

Fig. 1. Discretization scheme for a scalar field in proper length co-ordinates. The field essentially is replaced by a network of coupled harmonic oscillators placed at every grid point.

To set the model up, we begin with the action for a massive scalar field in an arbitrary space-time[26,27]:

$$S = \frac{1}{2}\int d^4x\sqrt{-g}\left[g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi - m_f^2\varphi^2\right]. \tag{5}$$

For the proper-length coordinate (4), we use the following spherical decomposition of the scalar field with appropriate scaling:

$$\dot{\varphi}(\rho,\theta,\phi) = \frac{f^{1/4}(r)}{r}\sum_{lm}\dot{\varphi}_{lm}(\rho)Z_{lm}(\theta,\phi) \tag{6}$$

$$\varphi(\rho,\theta,\phi)=\frac{f^{1/4}(r)}{r}\sum_{lm}\varphi_{lm}(\rho)Z_{lm}(\theta,\phi). \tag{7}$$

Substituting these in the action (5), leads to the following effective (1 + 1)-D Lagrangian:

$$L=\frac{1}{2}\sum_{lm}\int d\rho\left[\dot{\varphi}_{lm}^2-r^2\sqrt{f(r)}\left\{\partial_\rho\left(f^{1/4}(r)\frac{\varphi_{lm}}{r}\right)\right\}^2-f(r)\left\{m_f^2+\frac{l(l+1)}{r^2}\right\}\varphi_{lm}^2\right] \tag{8}$$

With the help of canonical conjugate momenta defined as $\pi_{lm}=\dot{\varphi}_{lm}$, we can now write down the Hamiltonian of the system. To regularize this Hamiltonian, we introduce lattice spacing a in the proper length co-ordinate as $\rho=ja$. The IR cut-off here is on the proper length, which is fixed to be $\rho_L=(N+1)a$. For each lattice point j, we obtain the corresponding lattice point in rescaled radial co-ordinate $r'=r/a$, by inverting the following expression for r_j:

$$j=\int_{\Delta_h}^{r_j}\frac{dr'}{\sqrt{f(r')}}. \tag{9}$$

where we have introduced the dimensionless parameters $\Delta_h=r_h/a$ and $r_j=r/a|_{\rho=ja}$. For convenience, we further define $f_j=f(r)|_{\rho=ja}$. It should be noted that the lattice points in radial co-ordinate $\{r_j\}$ are not equally spaced. On employing the midpoint discretization scheme,[13] we obtain a fully regularized Hamiltonian:

$$H=\frac{1}{2a}\sum_{lmj}\left[\pi_{lm,j}^2+r_{j+\frac{1}{2}}^2f_{j+\frac{1}{2}}^{1/2}\left\{f_j^{1/4}\frac{\varphi_{lm,j}}{r_j}-f_{j+1}^{1/4}\frac{\varphi_{lm,j+1}}{r_{j+1}}\right\}^2+f_j\left\{\Lambda^2+\frac{l(l+1)}{r_j^2}\right\}\varphi_{lm,j}^2\right], \tag{10}$$

where $\Lambda=a^2m_f^2$. Let us now factorize the Hamiltonian as $H=\tilde{H}/a$ and consider the following scaling transformations:

$$a\to\eta a;\quad m_f\to\eta^{-1}m_f;\quad r_h\to\eta r_h \tag{11}$$

Under these transformations, the parameters Λ and Δ_h remain invariant. The Hamiltonian H has therefore been factorized into a scale-dependent part $1/a$ and a scale-independent part $\tilde{H}$. Since the relations between entanglement measures of H and $\tilde{H}$ are well established,[23] it is sufficient to work with the scale-invariant part $\tilde{H}$. It can be seen that $\tilde{H}=\sum_{lm}\tilde{H}_{lm}$ exactly resembles a network of coupled harmonic oscillators:

$$\tilde{H}_{lm}=\frac{1}{2}\left[\sum_i\pi_{lm,i}^2+\sum_{ij}\varphi_{lm,i}K_{ij}\varphi_{lm,j}\right] \tag{12}$$

Here, K_{ij} is the coupling matrix, which contains all the relevant information about the interactions, and in which all information about entanglement entropy is encoded. To simplify further, we will focus on the massless case ($\Lambda = 0$), and also impose the Dirichlet boundary condition $\varphi_{lm,N+1} = 0$ to obtain a non-divergent scaling behavior. The coupling matrix will therefore have the following non-zero elements:

$$\begin{aligned} K_{11} =& f_1 \frac{l(l+1)}{r_1^2} + \frac{r_{3/2}^2}{r_1^2}\sqrt{f_1 f_{3/2}} \\ K_{jj\neq 1} =& f_j \frac{l(l+1)}{r_j^2} + \frac{\sqrt{f_j}}{r_j^2}\left\{ r_{j+\frac{1}{2}}^2 \sqrt{f_{j+\frac{1}{2}}} + r_{j-\frac{1}{2}}^2 \sqrt{f_{j-\frac{1}{2}}} \right\} \\ K_{j,j+1} =& K_{j+1,j} = -\frac{r_{j+\frac{1}{2}}^2}{r_j r_{j+1}} \left\{ f_{j+\frac{1}{2}}^2 f_j f_{j+1} \right\}^{1/4} \end{aligned} \tag{13}$$

Having fully described the model, we now introduce quantities associated with entanglement mechanics, namely, the entanglement entropy and entanglement energy, of a quantum field in a 4-D spherically symmetric space-time with at least one horizon[23,28]:

$$S_{\text{ent}} = -\operatorname{Tr} \rho_{red} \log \rho_{red} \quad ; \quad E_{\text{ent}} = \epsilon \operatorname{Tr} \left[\rho : H_{in} : \right], \tag{14}$$

where $: H_{in} :$ is the normal-ordered Hamiltonian corresponding to the reduced subsystem, ρ is the density matrix, and ρ_{red} is the reduced density matrix obtained by tracing over the field outside the horizon. The constant prefactor ϵ in the definition of entanglement energy accounts for the fact that it is not a unique measure;[23] it may be obtained *uniquely* by comparing with physical quantities of black-holes. While entanglement entropy (S_{ent}) essentially captures change in information content in the presence of the horizon, we may define entanglement energy (E_{ent}) as the disturbed vacuum energy or the *correlation energy* in the presence of the horizon. We further invoke the Komar relation(1) to define entanglement temperature as $T_{ent} = E_{ent}/2S_{ent}$.[23] Having formulated the quantities that describe entanglement mechanics for a given field, we proceed to simulate them in various space-times to infer its fundamental structure.

3. Entanglement mechanics of the field near space-time horizon

In this section, we discuss results from numerical simulations of entanglement mechanics in a variety of static, spherically symmetric space-times with one or more horizon(s).

3.1. *Schwarzschild Black Hole*

In the Schwarzschild space-time, $f(r) = 1 - r_h/r$, and the proper length (4) takes the form:

$$\rho = r\sqrt{1 - \frac{r_h}{r}} + \frac{r_h}{2} \ln \left[\frac{r}{r_h} \left\{ 1 + \sqrt{1 - \frac{r_h}{r}} \right\}^2 \right]. \tag{15}$$

where the horizon radius is $r_h = 2M$. On discretizing $\rho = ja$, we get a scale-invariant expression that connects lattice-points in the proper length and radial co-ordinates as follows:

$$j = r_j\sqrt{1-\frac{\Delta_h}{r_j}} + \frac{\Delta_h}{2}\ln\left[\frac{r_j}{\Delta_h}\left\{1+\sqrt{1-\frac{\Delta_h}{r_j}}\right\}^2\right], \tag{16}$$

where $\Delta_h = 2M/a$ and $r_j = r/a$ are dimensionless. We also see that $f_j = 1 - \Delta_h/r_j$. This confirms that the Hamiltonian in (10) is characterized by dimensionless parameters Λ and Δ_h, and is therefore invariant under the transformations:

$$a \to \eta a; \quad m_f \to \eta^{-1} m_f; \quad M \to \eta M \tag{17}$$

Now we focus on the scale-invariant Hamiltonian $\tilde{H}$, wherein we vary the rescaled horizon Δ_h, and assume that the entanglement mechanics of the field at the horizon can be approximated by tracing out the closest oscillator near the horizon. This approximation is reasonable for large values of Δ_h, wherein the radial distance of the closest oscillator from horizon is negligible ($r_1 \sim \Delta_h$).

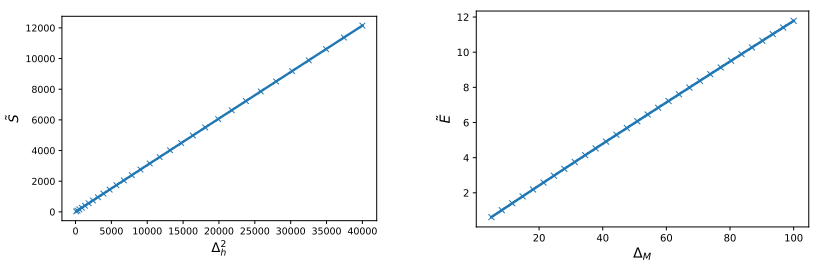
From Fig 2, we observe the following scaling relations:

$$\tilde{S} = c_s \Delta_h^2; \quad \tilde{E} = c_e \Delta_M, \tag{18}$$

where a linear fit fixes the values $c_s \sim 0.3$ and $c_e \sim 0.06$. For the original Hamiltonian H, we then have:

$$S = c_s \frac{r_h^2}{a^2}; \quad E = c_e \frac{M}{a^2}; \quad T = \frac{c_e}{4c_s r_h} = \frac{\pi c_e}{c_s} T_H \tag{19}$$

where T_H is the Hawking temperature. From the above relations, we see that (i) entanglement entropy exhibits an area law whereas entanglement energy scales linearly with horizon radius—the latter is fundamentally different from an area-law scaling observed in Minkowski space-time, (ii) entanglement temperature is independent of the UV cut-off a, and (iii) The entanglement mechanics follows the same laws of black-hole mechanics.[10] In the following sections, we will see if these observations extend for other space-times as well.



(a) (b)

Fig. 2. Entanglement Mechanics for Schwarzschild Black Hole.

3.2. *Reissner-Nordström*

We will now probe entanglement mechanics of the field in an asymptotically flat space-time with multiple horizons. The line-element for Reissner-Nordström black hole is given by (4), where

$$f(r) = 1 - \frac{2M}{r} + \frac{Q^2}{r^2}\,.$$

For $Q < M$, the roots are given by $r_\pm = M \pm \sqrt{M^2 - Q^2}$ where r_+ corresponds to the event-horizon and r_- refers to the internal Cauchy horizon. Thus, $f(r)$ is positive in two regions: 1. $0 < r < r_-$ and 2. $r_+ < r < \infty$.

3.2.1. *Cauchy horizon*

In terms of the dimensionless variable (χ), the Cauchy horizon is

$$r_- = Q\{\chi - \sqrt{\chi^2 - 1}\} \quad \text{where} \quad \chi = M/Q \in (1, \infty)\,.$$

To ensure that the proper length is positive definite quantity, we reverse the limits of integration in Eq. (4), i.e.,

$$\rho = \int_r^{r_h} \frac{dr}{\sqrt{f(r)}} = -\sqrt{Q^2 + r(r - 2\chi Q)} + \chi Q \ln\left[\frac{Q\sqrt{\chi^2 - 1}}{\chi Q - 2\left\{r + \sqrt{Q^2 + r(r - 2\chi Q)}\right\}}\right] \tag{20}$$

On discretizing $\rho = ja$, we convert the above expression into a dimensionless form:

$$j = -\sqrt{\Delta_Q^2 + r_j(r_j - 2\chi\Delta_Q)} + \chi\Delta_Q \ln\left[\frac{\Delta_Q\sqrt{\chi^2 - 1}}{\chi\Delta_Q - 2\left\{r_j + \sqrt{\Delta_Q^2 + r_j(r_j - 2\chi\Delta_Q)}\right\}}\right], \tag{21}$$

where $\Delta_Q \equiv Q/a$ and $r_j \equiv r/a$ are both dimensionless. We also see that

$$f_j = 1 - \frac{2\chi\Delta_Q}{r_j} + \frac{\Delta_Q^2}{r_j^2}. \tag{22}$$

The resulting Hamiltonian H is factorized into a scale-dependent part $1/a$ and a scale-independent part $\tilde{H}$. The latter is completely characterized by dimensionless parameters Λ, Δ_Q and χ, all of which are invariant under the scaling transformations:

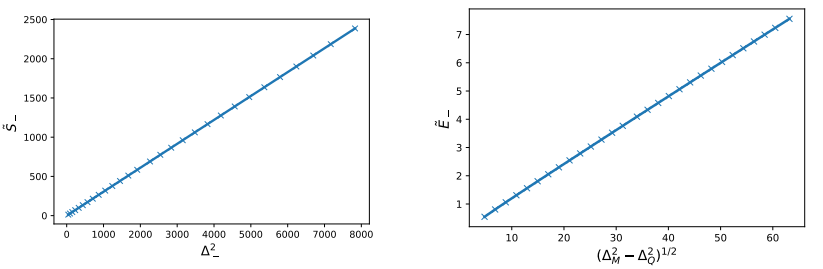
$$a \to \eta a; \quad m_f \to \eta^{-1} m_f; \quad M \to \eta M; \quad Q \to \eta Q \tag{23}$$

The IR cut-off on proper length is fixed at $r = 0$, leading to a certain discretization relation:

$$\Delta_Q \left[\chi \ln\sqrt{\frac{\chi + 1}{\chi - 1}} - 1\right] = N + 1 \tag{24}$$

The above relation tells us that if we fix Δ_q, then χ is discretized and vice versa. Here, we will consider the scenario where horizon changes on account of varying Δ_Q while keeping χ fixed. Physically, this corresponds to varying both mass and charge of the black hole proportionately to account for particles with a fixed mass-charge ratio (χ) that are entering the event horizon. As a result, both mass and charge have equally spaced discrete spectra:

$$Q_N = \frac{(N+1)a}{\left(\chi \ln \sqrt{\frac{\chi+1}{\chi-1}} - 1\right)}; \quad M_N = \chi Q_N; \tag{25}$$



(a) (b)

Fig. 3. Entanglement Mechanics at RN Cauchy horizon, when $\chi = 1.1$.

3.2.2. *Event horizon*

In terms of the dimensionless variable (χ), the event horizon is

$$r_+ = Q(\chi + \sqrt{\chi^2 - 1})\,.$$

From Eq. (4), we obtain:

$$\rho = \sqrt{Q^2 + r(r - 2\chi Q)} + \chi Q \ln \left[\frac{r - \chi Q + \sqrt{Q^2 + r(r - 2\chi Q)}}{Q\sqrt{\chi^2 - 1}} \right]. \tag{26}$$

On discretizing $\rho = ja$, we convert the above expression into a dimensionless form:

$$j = \sqrt{\Delta_Q^2 + r_j(r_j - 2\chi\Delta_Q)} + \chi\Delta_Q \ln \left[\frac{r_j - \chi\Delta_Q + \sqrt{\Delta_Q^2 + r_j(r_j - 2\chi\Delta_Q)}}{\Delta_Q\sqrt{\chi^2 - 1}} \right] \tag{27}$$

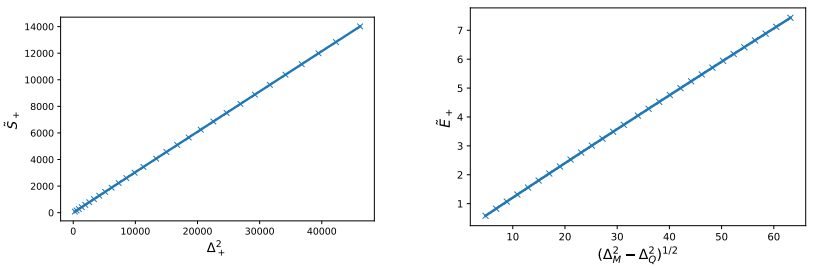
where $\Delta_Q \equiv Q/a$ and $r_j \equiv r/a$ are both dimensionless. From Figs 3 and 4, we obtain the following scaling relations for scale-invariant system $\tilde{H}$:

$$\tilde{S}_\pm = c_s \Delta_\pm^2; \quad \tilde{E}_\pm = c_e \sqrt{\Delta_M^2 - \Delta_Q^2}, \tag{28}$$

where a linear fit fixes the values $c_s \sim 0.3$ and $c_e \sim 0.12$ for both horizons. It can also be seen from here that in the limit $\Delta_Q \to 0$, we recover the values of c_e and c_s for Schwarzschild (18). As discussed above, $\tilde{S}_-$ and $\tilde{E}_-$ have discrete spectra. Since the entanglement energy is identical for both the horizons, we may therefore write for the total Hamiltonian (H):

$$S_\pm = c_s \frac{r_\pm^2}{a^2}; \quad E_+ = c_e \frac{\sqrt{M^2 - Q^2}}{a^2}; \quad T^{(\pm)} = \frac{\pi c_e}{c_s} T_H^{(\pm)} \tag{29}$$

where $T_H^{(-)}$ and $T_H^{(+)}$ are the Hawking temperatures of Cauchy and event horizon, respectively.



(a) (b)

Fig. 4. Entanglement Mechanics at RN event horizon, when $\chi = 1.1$.

3.3. *Schwarzschild de-Sitter*

We now move on to a space-time with multiple horizons that is asymptotically non-flat. A Schwarzschild black hole (of mass M) in a de-Sitter space-time (of radius l) is described by:

$$f(r) = 1 - \frac{2M}{r} - \frac{r^2}{l^2},$$

This space-time also has two horizons — r_b (event horizon) and r_c (cosmological horizon)[29]:

$$r_- = -\frac{2l}{\sqrt{3}} \cos\frac{\theta}{3}; \quad r_b = \frac{2l}{\sqrt{3}} \cos\frac{\pi + \theta}{3}; \quad r_c = \frac{2l}{\sqrt{3}} \cos\frac{\pi - \theta}{3} \tag{30}$$

where r_- is the third negative root, $\theta = \cos^{-1}(3\sqrt{3}\chi)$ and $\chi = M/l \in \left[0, 1/(3\sqrt{3})\right]$. $f(r)$ is positive in the region between the two horizons. Hence, in this region, we have two definitions for proper length — one w.r.t. the event horizon r_b which we refer to as ρ_b and the second w.r.t. the cosmological horizon r_c which we refer to as ρ_c.

3.3.1. *Event horizon*

The proper length with respect to the event horizon r_b is obtained as follows[23]:

$$\rho_b = \frac{2r_b l}{\sqrt{r_c(r_b - r_-)}} \Pi\left(\vartheta, \alpha^2, k\right), \tag{31}$$

where,

$$\vartheta = \sin^{-1}\sqrt{\frac{r_c(r-r_b)}{r(r_c-r_b)}}; \quad \alpha^2 = 1 - \frac{r_b}{r_c}; \quad k^2 = \frac{r_-(r_b-r_c)}{r_c(r_b-r_-)}. \tag{32}$$

On discretizing proper length $\rho_b = ja$, we convert the above expression into a dimensionless form:

$$j = \frac{2\Delta_b \Delta_l}{\sqrt{\Delta_c(\Delta_b - \Delta_-)}} \Pi\left(\vartheta, \alpha^2, k\right). \tag{33}$$

In terms of the dimensionless variables $\Delta_l = l/a$ and $r_j = r/a$, we have

$$f_j = 1 - \frac{2\Delta_M}{r_j} - \frac{r_j^2}{\Delta_l^2}, \tag{34}$$

and,

$$\begin{aligned} \Delta_- &= -\frac{2\Delta_l}{\sqrt{3}} \cos\frac{\theta}{3}; \quad \Delta_b = \frac{2\Delta_l}{\sqrt{3}} \cos\frac{\pi+\theta}{3}; \quad \Delta_c = \frac{2\Delta_l}{\sqrt{3}} \cos\frac{\pi-\theta}{3}; \\ \vartheta &= \sin^{-1}\sqrt{\frac{\Delta_c(r_j-\Delta_b)}{r_j(\Delta_c-\Delta_b)}}; \quad \alpha^2 = 1 - \frac{\Delta_b}{\Delta_c}; \quad k^2 = \frac{\Delta_-(\Delta_b-\Delta_c)}{\Delta_c(\Delta_b-\Delta_-)}. \end{aligned} \tag{35}$$

As a result, the Hamiltonian $\tilde{H}$ is fully characterized by dimensionless parameters Δ_l and Δ_M, both of which are invariant under the scaling transformations:

$$a \to \eta a; \quad m_f \to \eta^{-1} m_f; \quad M \to \eta M; \quad l \to \eta l \tag{36}$$

In the case of SdS, the IR cut-off on proper length is automatically fixed as we restrict ourselves to the region $\tilde{r}_b \le r_j \le \tilde{r}_c$:

$$N + 1 = \frac{2\tilde{r}_b \Delta_l}{\sqrt{\tilde{r}_c(\tilde{r}_b - \tilde{r}_-)}} \Pi\left(\frac{\pi}{2}, \alpha^2, k\right) \tag{37}$$

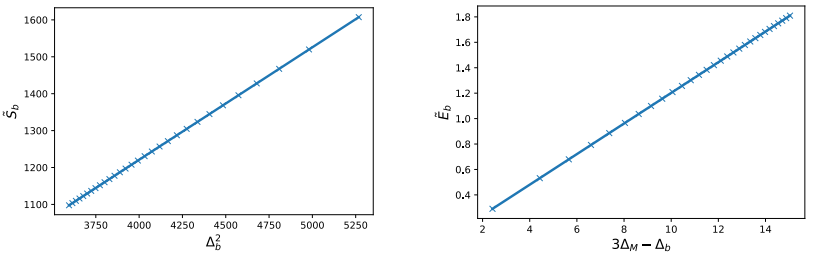
This is a discretization relation similar to what was obtained for RNBH. We will consider the case where we fix Δ_M and vary Δ_l by varying N. This is to ensure that χ is always between $[0, 1/(3\sqrt{3}]$. From Fig 5, we obtain the following scaling relations for the scale-invariant Hamiltonian ($\tilde{H}$):

$$\tilde{S}_b \sim c_s \Delta_b^2; \qquad \tilde{E}_b \sim c_e(3\Delta_M - \Delta_b) \tag{38}$$

where, $c_s \sim 0.3$ and $c_e \sim 0.12$ are the best-fit numerical values. In the limit $\Delta_l \to \infty$, we recover the prefactors of the Schwarzschild black hole (18). For the total Hamiltonian (H), the scaling relations become:

$$S_{b,N} \sim c_s \frac{r_{b,N}^2}{a^2}; \qquad E_{b,N} \sim c_e \frac{3M - r_{b,N}}{a^2}; \qquad T^{(b)} = \frac{\pi c_e}{c_s} T_H^{(b)} \tag{39}$$

where $T_H^{(b)}$ is the Hawking temperature of the event horizon in SdS.[29,30]



(a) (b)

Fig. 5. Entanglement Mechanics at SdS event horizon, when $\Delta_M = 25$.

3.3.2. *Cosmological horizon*

To explore the scaling properties of cosmological horizon, we define proper distance r_c as follows[31]:

$$\rho_c = \frac{2l}{\sqrt{r_c(r_b - r_-)}} \left[r_- F(\vartheta, k) - (r_c - r_-)\, \Pi\left(\vartheta, \alpha^2, k\right) \right], \tag{40}$$

where,

$$\sin\vartheta = \sqrt{\frac{(r_b - r_-)(r_c - r)}{(r_c - r_b)(r - r_-)}}; \quad \alpha^2 = \frac{r_b - r_c}{r_b - r_-}, \tag{41}$$

and the definition of k is the same as Eq. (32). On discretizing proper length $\rho_c = ja$, we convert the above expression into a dimensionless form:

$$j = \frac{2\Delta_l}{\sqrt{\Delta_c(\Delta_b - \Delta_-)}} \left[\Delta_- F(\vartheta, k) - (\Delta_c - \Delta_-)\, \Pi\left(\vartheta, \alpha^2, k\right) \right], \tag{42}$$

where in terms of dimensionless variables $\Delta_l = l/a$ and $r_j = r/a$, we can also rewrite:

$$\sin\vartheta = \sqrt{\frac{(\Delta_b - \Delta_-)(\Delta_c - r_j)}{(\Delta_c - \Delta_b)(r_j - \Delta_-)}}; \quad \alpha^2 = \frac{\Delta_b - \Delta_c}{\Delta_b - \Delta_-}, \tag{43}$$

Except for ϑ and α given above, the parameters used here follow the same definition as in (35). Now we impose an IR cut-off on proper length to restrict ourselves in the region $\tilde{r}_b \leq r_j \leq \tilde{r}_c$:

$$N + 1 = \frac{2\Delta_l}{\sqrt{\Delta_c(\Delta_b - \Delta_-)}} \left[\Delta_- K(k) - (\Delta_c - \Delta_-)\, \Pi\left(\frac{\pi}{2}, \alpha^2, k\right) \right] \tag{44}$$

This expression relates the number of oscillators N, Δ_l and χ, and we only need to fix two of these to fix the third. We will fix Δ_M here as we did for the event horizon, which leaves Δ_l with a discrete spectrum. From Fig 6, we see that the spectra for Δ_l obtained from ρ_b and ρ_c coincide exactly, and therefore the two discretization relations (37) and (44) are identical.

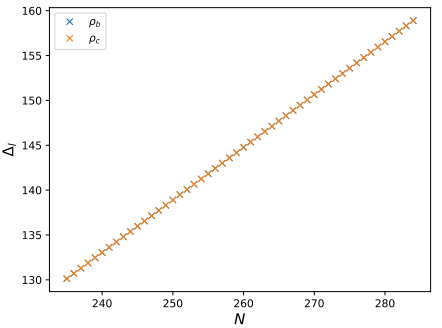


Fig. 6. Discretization of Δ_l from the cutoffs on proper lengths ρ_b and ρ_c, for $\Delta_M = 25$.

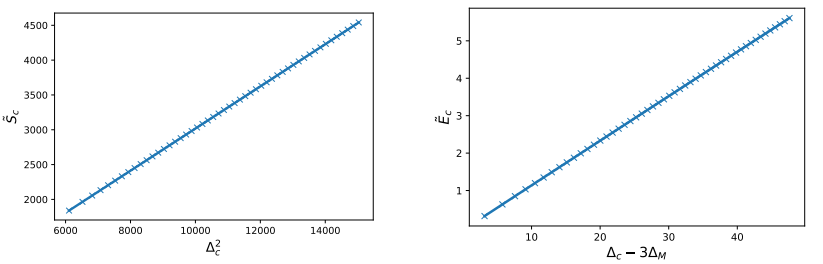
From Fig. 7, we obtain the following scaling relations for the scale-invariant system $\tilde{H}$:

$$\tilde{S}_c \sim c_s \Delta_c^2; \qquad \tilde{E}_c \sim c_e \left[\Delta_c - 3\Delta_M\right] \tag{45}$$

where $c_s \sim 0.3$ and $c_e \sim 0.12$ are the best-fit numerical values. For the total Hamiltonian H, the scaling relations become:

$$S_{c,N} \sim c_s \frac{r_{c,N}^2}{a^2}; \quad E_{c,N} \sim c_e \frac{r_{c,N} - 3M}{a^2}; \quad T^{(c)} \sim \frac{\pi c_e}{c_s} T_H^{(c)}, \tag{46}$$

where $T_H^{(c)}$ is the Hawking temperature of the cosmological horizon in SdS.



(a) (b)

Fig. 7. Entanglement Mechanics at SdS cosmological horizon, when $\Delta_M = 25$.

4. Black hole thermodynamics from entanglement mechanics

On numerically simulating the quantum entanglement mechanics near the horizon r_h for a variety of such space-times, we observe some universal properties associated with their scaling relations. Before we proceed, we first invoke the definition of entanglement energy wherein the pre-factor ϵ was introduced. Here, we may fix

this pre-factor as $\epsilon \sim 1.26$ upon imposing the condition that the entanglement temperature is identical to Hawking temperature ($T_{ent} = T_H$). While this rescales the proportionality constant c_e obtained numerically, the simulations nevertheless capture a universal one-to-one correspondence[23] between entanglement mechanics and black hole thermodynamics:

$$E_{\rm ent} = \frac{c_e}{a^2} E_{\rm Komar}; \quad S_{\rm ent} = \frac{c_s}{\pi a^2} S_{\rm BH}; \quad T_{\rm ent} = T_H \,. \tag{47}$$

Note that $E_{\rm ent}$ and $S_{\rm ent}$ depend on the UV cut-off (a), where as the temperature does not. Moreover, even with the pre-factor ϵ being assigned a new value, the constants of proportionality are found to be universal across all black-hole space-times, irrespective of whether they are asymptotically flat or non-flat:

$$c_e \sim 0.0955; \quad c_s \sim 0.3 \,. \tag{48}$$

Let us put these results in perspective: We have related quantum scalar fields near the horizon with the thermodynamic observables that describe any black-hole space-time (cf. Table 1). The fact that this is true for all 4-D spherically symmetric space-time suggests that entanglement of the quantum fields near the horizon carries crucial information about the black-hole thermodynamics. The above relations (47) go further and lead to the following universal and cut-off independent (a) result:

$$E_{\rm ent} = 2T_{\rm ent}\, S_{\rm ent} \qquad \Longleftrightarrow \qquad E_{\rm Komar} = 2T_H\, S_{\rm BH} \tag{49}$$

It is important to note that the above relation does not imply equality of their respective counterparts. On rearranging this relation further, we obtain the generalized Smarr formula of black hole thermodynamics, as summarized in Table 1.

Table 1. Generalized Smarr formula.

Space-time	**Entanglement Structure**	**Thermodynamic Structure**	**Smarr formula**	**Pressure**	**Potential**
Schwarzschild	$S_{\rm ent} = (c_s/a^2) r_h^2$ $E_{\rm ent} = (c_e/a^2) M$	$S_{BH} = \pi r_h^2$ $E_{\rm Komar} = M$	$M = 2T_{\rm H}\, S_{BH}$	—	—
Reissner-Nordström	$S_+ = (c_s/a^2) r_+^2$ $E_+ = (c_e/a^2)\sqrt{M^2 - Q^2}$	$S_{BH} = \pi r_+^2$ $E_{Komar} = \sqrt{M^2 - Q^2}$	$M = 2T_{\rm H}\, S_{BH} + Q^2/r_+$	—	Q/r_+
Schwarzschild-AdS	$S_{\rm ent} = (c_s/a^2) r_h^2$ $E_{\rm ent} = (c_e/a^2)[3M - r_h^2]$	$S_{BH} = \pi r_h^2$ $E_{Komar} = 3M - r_h^2$	$M = 2T_{\rm H}\, S_{BH} - r_h^3/l^2$	$3/8\pi l^2$	—
Schwarzschild-dS	$S_b = (c_s/a^2) r_b^2$ $E_b = (c_e/a^2)[3M - r_b^2]$	$S_{BH} = \pi r_b^2$ $E_{Komar} = 3M - r_b^2$	$M = 2T_{\rm H}\, S_{BH} + r_b^3/l^2$	$-3/8\pi l^2$	—

5. Conclusion

The Smarr formula for asymptotically flat and non-flat space-times is generally derived using Komar integral relations[32] or via the first law of thermodynamics with the help of scaling relations,[33] both of which makes use of Killing potential. In this talk, we developed an independent approach towards the derivation of the generalized Smarr formula, which essentially describes the equation of state for

black holes. The intrinsically quantum phenomenon of entanglement pertaining to the field near a horizon, gives rise to not just the thermodynamic quantities associated with the space-time, but also the exact relation connecting the same. This in turn gives entanglement mechanics an upper hand in addressing the universality problem of black hole entropy. While a wealth of other approaches may explain black-hole entropy, entanglement mechanics *alone* expands the analogy to include other thermodynamic quantities as well.

The results further complements two earlier results: First, Jacobson argued that entanglement provides a link between the presence of matter and the space-time geometry.[34] Second, in quantum gravity, Perez conjectured that degrees of freedom hidden from the classical space-time description but correlated to matter fields are necessary to maintain unitarity in the global evolution and prevent the information loss.[35] Our analysis here provides a crucial link to these results, placing entanglement at the center of a fundamental connection between space-time and matter, thereby holding the key to understanding black-hole horizons.

This paper investigates thermodynamics as well as thermal stability of the Reissner-Nordström black hole with the effects of non-linear electrodynamics. We first calculate the expressions for Hawking temperature, Helmholtz free energy, internal energy, enthalpy and Gibbs free energy of this black hole and then study their graphical behavior in the presence of non-linear electrodynamic effects. We also investigate thermal stability of the considered system with two different methods, i.e., through heat capacity and through Hessian matrix. It is found from both the methods that the considered system is thermodynamically stable in the presence of non-linear electrodynamic parameter (α). Finally, we analyze the phase transitions of Hawking temperature as well as heat capacity in terms of entropy for different values of charge (q), horizon radius (r_+) and coupling parameter. We obtain that Hawking temperature changes its phase from positive to negative for increasing values of q and r_+ while it shows opposite trend for higher values of α. The heat capacity changes its phase from negative to positive for large values of charge, horizon radius and coupling parameter.

Keywords: Thermodynamics; Stability; Phase transitions.

1. Introduction

The study of final outcomes of self-gravitating objects is one of the most important subjects in general relativity. Black hole (BH) is a completely collapsed structure of massive stars which is defined as a thermodynamical object with very strong gravitational field such that anything even light cannot escape from it. Black hole thermodynamics has resemblance with classical thermodynamics in which mass is related to energy, surface area to entropy and surface gravity to temperature. This resemblance motivated Bekenstein[1] to find out the relation between entropy and area of the event horizon of BH. In this regard, he found that entropy is proportional to the area of event horizon of BH. Hawking's discovery[2] of black body radiations further confirmed the validity of this relation. Consequently, it is impossible to obtain thermal equilibrium between BH and thermal radiations leading to the concept of holographic principle.[3]

Hawking[4] evaluated the expressions of surface gravity, angular frequency and electric potential for any BH having mass, angular momentum and charge. He also discussed generalized second law of BH thermodynamics as well as thermal equilibrium condition for BHs. Motivated by the work of Hawking, Davies[5] discussed about the entropy, thermal stability, phase transition and third law of BH thermodynamics. He also discussed quantum effects of BHs as well as nature and origin of

BH thermal radiations. Wald[6] reviewed the laws of BH thermodynamics, physical correspondence among laws of BH as well as classical thermodynamics, derivation of Hawking radiations, formula for entropy of BH and validity of generalized second law of thermodynamics.

In literature, there is a wide discussion about thermodynamics of different BH geometries. Balart and Vagenas[7] proposed the exact solutions of various regular charged BHs in the presence of non-linear electrodynamic effects and observed that the behavior of some BHs asymptotically coincide to RN BH. Tharanath et al.[8] studied thermal quantities of four regular BHs and observed second order phase transition. Faizal and Khalil[9] found leading order corrections to the thermodynamic quantities of RN, Kerr as well as charged-AdS BHs and concluded that in all three cases, these BHs create remnants. Pradhan[10] investigated local thermal stability as well as logarithmic corrections for entropy of charged accelerating BHs and observed that these BHs undergo second order phase transitions. Sharif and Zunaira[11] investigated the effects of thermal fluctuations on thermodynamics of charged BH with Weyl corrections and concluded that in the presence of logarithmic corrections small BHs are unstable. Sinha[12] discussed thermodynamics as well as stability of asymptotically flat RN BH and observed that this BH exhibits phase transition which is different from the phase transition of Schwarzschild BH.

Davies[13] developed thermodynamical theory of BHs and found that phase transition occurs in the Kerr-Newman BH. Hawking and Page[14] determined the presence of phase transition in the Schwarzschild-AdS BH. Biswas and Chakraborty[15] investigated that whether phase transition is possible in Horava-Lifshitz gravity under the consideration of classical and topological choices of BH thermodynamics. They concluded that phase transition occurs in Horava-Lifshitz gravity from stable to unstable phase for increasing values of radius. Kubiznak and Mann[16] analyzed the first order small-large BHs phase transition in charged AdS BH which is analogous to liquid-gas phase transitions of fluids.

Chaturvedi et al.[17] investigated phase transition in the framework of thermodynamic geometry for charged AdS BH and found first order phase transition for fixed electric charge. Wei et al.[18] studied thermodynamics and found first order phase transition for charged AdS BHs in five-dimensions. Ovgun[19] studied thermodynamics as well as phase transition of a specific charged AdS type BH in $f(R)$ gravity coupled with Yang-Mills field by considering cosmological constant as thermal pressure. Wei and Liu[20] discussed a relation between phase transition and null geodesics of charged AdS BH. Saleh et al.[21] examined thermodynamics as well as phase transition of Bardeen BH surrounded by quintessence and found that the presence of quintessence induces phase transition in the considered BH. Kuang et al.[22] evaluated thermal quantities of AdS non-linear electrodynamic BH. Bhatacharya et al.[23] provided a general criteria to get information and other various results with an extremal limit of BH spacetime. They also evaluated critical values of second order phase transition without considering any specific BH and showed that these values are in agreement with those of any specific BH cases.

Gonzalez et al.[24] studied thermodynamics and stability of charged BHs with non-linear electrodynamics and found that small BHs are stable locally. Dayyani[25] explored thermodynamical properties and phase transition of dilaton BH with non-linear electrodynamics and observed zeroth order phase transition. Yu and Gao[26] derived the exact solutions of RN BH with non-linear electrodynamics. Javed et al.[27] observed the effect of non-linear electrodynamics on weak field deflection angle of RN BH. Recently, Fauzi and Ramadhan[28] discussed thermodynamics of charged BHs with non-linear electrodynamics and verified the first law of BH thermodynamics.

In this paper, we study thermodynamical quantities, thermal stability and phase transition for RN BH with non-linear electrodynamic effects. The paper is outlined as follows. In section **2**, we discuss thermodynamic quantities and their graphical behavior for this BH. Section **3** is devoted to investigate thermal stable configuration and section **4** analyzes phase transitions in terms of entropy. In the last section, we conclude all the results.

2. Thermodynamics

In this section, we discuss thermodynamic quantities such as Hawking temperature, entropy, Helmholtz-Gibbs free energy, internal energy and enthalpy of RN BH with non-linear electrodynamic effects. The line element of this BH is given as[26]

$$ds^2 = f(r)dt^2 - \frac{dr^2}{f(r)} - r^2\left(d\theta^2 + \sin^2\theta d\phi^2\right), \tag{1}$$

with

$$f(r) = 1 + \frac{q^2}{r^2} - \left(\frac{2M}{r} + \frac{\alpha^2 r^2}{3}\right) + 2\alpha q, \tag{2}$$

where q, M and α represent charge, mass of BH and coupling constant, respectively. The line element (1) reduces to the RN BH when $\alpha = 0,\ q \neq 0$, Schwarzschild metric for $\alpha = 0,\ q = 0$ and it becomes Schwarzschild BH with the effects of non-linear electrodynamics for $\alpha \neq 0,\ q = 0$. Figure 1 shows the graphical analysis of the metric function (2) indicating the appearance of naked singularities for the increasing values of the coupling parameter. Setting $f(r_+) = 0$, the mass of BH in terms of r_+ can be obtained as

$$M = \frac{1}{6r_+}\left(3q^2 + r_+^2(6\alpha q - \alpha^2 r_+^2 + 3)\right), \tag{3}$$

where r_+ represents horizon radius of BH. To obtain the expression for Hawking temperature, we first evaluate surface gravity of the BH

$$\kappa = -\frac{\left(q + r_+ - \alpha r_+^2\right)\left(q - \alpha r_+^2 - r_+\right)}{2r_+^3}.$$

Consequently, the Hawking temperature ($T = \frac{\kappa}{2\pi}$) is

$$T = -\frac{\left(q + r_+ - \alpha r_+^2\right)\left(q - \alpha r_+^2 - r_+\right)}{4\pi r_+^3}. \tag{4}$$

The graphical sketch of Hawking temperature versus α is shown in Figure 2. It is found that Hawking temperature increases with the increasing values of coupling parameter throughout the considered domain.

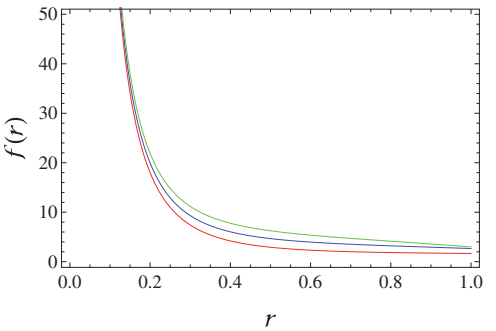

Fig. 1. Plot of the metric function versus r for $M = 1 = q$ with $\alpha = 1$(red), 2(blue) and 3(green).

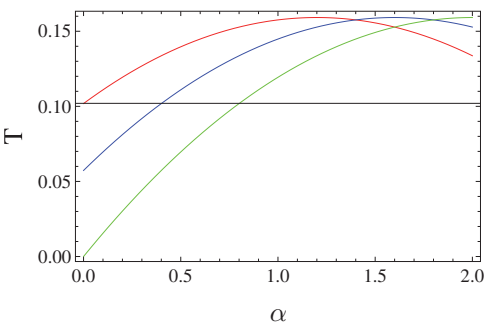

Fig. 2. Plot of Hawking temperature versus α for $r_+ = 0.5$ with $q = 0.3$(red), 0.4(blue) and 0.5(green).

According to Bekenstein area-entropy relation, the entropy of BH can be evaluated as[29]

$$S = \int_0^{2\pi}\int_0^{\pi} \sqrt{g_{\theta\theta}g_{\phi\phi}}d\theta d\phi = \pi r_+^2. \tag{5}$$

Now we calculate other thermal quantities by using the expressions of entropy and Hawking temperature. The expression of Helmholtz free energy can be

calculated as

$$F = \frac{1}{16}\left(4q^2\log(r_+) + r_+^2\left(-4\alpha q + \alpha^2 r_+^2 - 2\right)\right).$$

Figure 3 shows the graphical representation of Helmholtz free energy for different values of the coupling parameter. It is noted that Helmholtz free energy is an increasing function of r_+ and for increasing values of the coupling constant, it increases more rapidly. The increasing trend of Helmholtz free energy depicts that the reactions occurring inside the considered system are non-spontaneous and work done is required to make the system thermodynamically stable. The internal energy ($U = F + ST$) of the considered system can be obtained as

$$U = \frac{4q^2 r_+\log(r_+) - 4q^2 - 4\alpha q(r_+ - 2)r_+^2 + \alpha^2(r_+ - 4)r_+^4 - 2(r_+ - 2)r_+^2}{16r_+}.$$

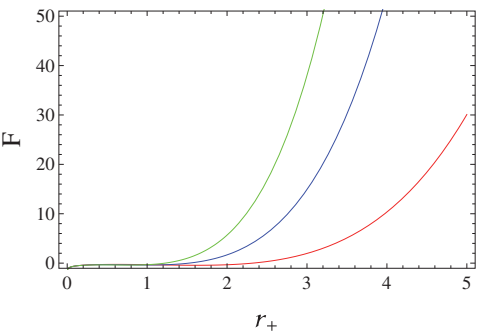

Fig. 3. Plot of Helmholtz free energy versus r_+ for $q = 1$ with $\alpha = 1$(red), 2(blue) and 3(green).

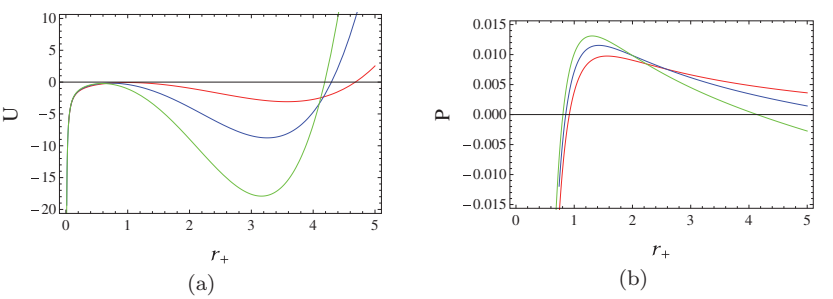

Fig. 4. (a) Plots of internal energy versus r_+ for $q = 1$ with $\alpha = 1$(red), 2(blue), 3(green). (b) Plot of pressure versus r_+ for $q = 1$ with $\alpha = 0.1$(red), 0.2(blue), 0.3(green).

The graphical representation of internal energy in terms of horizon radius is shown in Figure 4(a). It is observed that internal energy of the system fluctuates

for increasing values of r_+ and becomes positive towards the boundary of event horizon. The negative behavior of internal energy shows that the considered system is releasing heat for small values of r_+. The corresponding volume is given as[24]

$$V = \frac{4\pi r_+^3}{3}.$$

The pressure for the above calculated volume can be obtained by the relation

$$P = -\frac{dF}{dV} = -\frac{dF}{dr_+}\frac{dr_+}{dV},$$

which gives

$$P = -\frac{\left(q - \alpha r_+^2 + r_+\right)\left(q - r_+(\alpha r_+ + 1)\right)}{16\pi r_+^3}.$$

Figure 4(b) shows the graphical structure of pressure versus r_+ for different values of the coupling parameter. It is noted that pressure of the considered system firstly increases for certain values of horizon radius and then decreases monotonically for large radii. However, for increasing values of the coupling constant, the pressure of BHs with small radii increases slightly while shows opposite trend for large radii.

The expression of enthalpy ($H = VP + U$) can be calculated as follows

$$H = -\left(4q^2(r_+ + 3) - 12q^2 r_+ \log(r_+) + 4\alpha q(r_+ - 6)r_+^2 + \alpha^2(r_+ + 12)r_+^4 + 2(r_+ - 6)r_+^2\right)(48r_+)^{-1}.$$

The graphical analysis of enthalpy in terms of horizon radius is represented in Figure 5(a). It is observed that enthalpy of the considered system is an increasing function of horizon radius. The increasing values of the coupling parameter do not affect the enthalpy for BHs of both small as well as large radii. It is concluded that the considered system is absorbing heat from its surroundings. The Gibbs free energy ($G = H - ST$) of the considered system is obtained as

$$G = \frac{1}{48}\left(12q^2\log(r_+) - \left(2q + \alpha r_+^2\right)^2 - 2r_+^2\right).$$

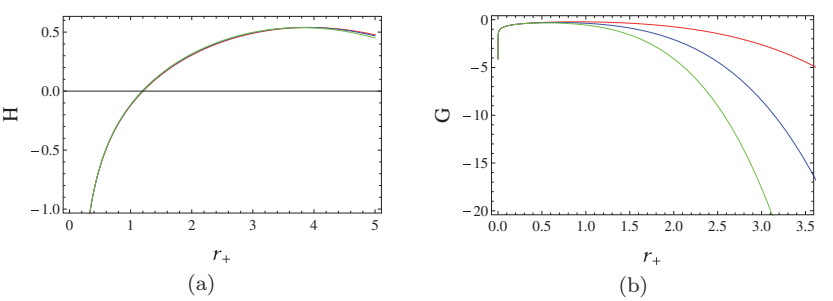

Fig. 5. (a) Plot of enthalpy (left) versus r_+ for $q = 1$ with $\alpha = 0.01$(red), 0.02(blue), 0.03(green). (b) Plot of Gibbs free energy (right) versus r_+ for $q = 1$ with $\alpha = 1$(red), 2(blue), 3(green).

Figure 5(b) represents the graphical structure of Gibbs free energy in terms of r_+ for different values of the coupling constant. It is noted that the Gibbs free energy of the system is inversely proportional to the horizon radius. The increasing values of the coupling parameter do not affect the Gibbs free energy of BHs with $r_+ < 1$ while for $r_+ \geq 1$, the Gibbs free energy is affected significantly and decreases more rapidly.

3. Thermal Stability

In this section, we discuss thermal stable configuration of RN BH with non-linear electrodynamic effects through the following two different methods:

- Heat Capacity;
- Hessian Matrix.

3.1. *Through Heat Capacity*

In order to analyze thermal stability of the considered system, the expression of heat capacity $(T\frac{\partial S}{\partial T})$ can be calculated as follows

$$C = \frac{\pi r_+^2 \left(q + r_+ - \alpha r_+^2\right)\left(q - \alpha r_+^2 - r_+\right)}{r_+^2 - 2\left(q^2 - \alpha q r_+^2\right)}. \tag{6}$$

The graphical analysis of heat capacity represents that it diverges at $r_+ = 0.56$ and this divergent point is known as Davies point (Figure 6). It is also noted that heat capacity changes its phase from negative to positive for increasing values of horizon radius which shows that the considered system is stable in the presence of non-linear electrodynamic effects.

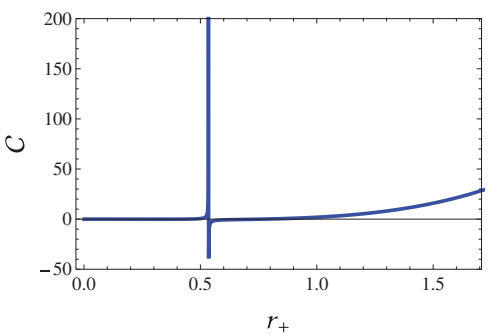

Fig. 6. Plot of heat capacity versus r_+ for $q = 1$ and $\alpha = 3$.

3.2. *Through Hessian Matrix*

We can also use Hessian matrix to investigate thermal stability of the considered system which contains second order partial derivatives of Helmholtz free energy and is defined as[30]

$$H = \begin{pmatrix} H_{mm} & H_{mn} \\ H_{nm} & H_{nn} \end{pmatrix} = \begin{pmatrix} \frac{\partial^2 F}{\partial T^2} & \frac{\partial^2 F}{\partial T \partial \upsilon} \\ \frac{\partial^2 F}{\partial \upsilon \partial T} & \frac{\partial^2 F}{\partial \upsilon^2} \end{pmatrix},$$

with $m \neq n$, and

$$H_{mm} = \frac{\partial^2 F}{\partial T^2}, \quad H_{mn} = \frac{\partial^2 F}{\partial T \partial \upsilon}, \quad H_{nm} = \frac{\partial^2 F}{\partial \upsilon \partial T}, \quad H_{nn} = \frac{\partial^2 F}{\partial \upsilon^2}.$$

It is noted that $H_{mm}H_{nn} = H_{mn}H_{nm}$, which implies that one of the eigenvalues of the Hessian matrix is zero. Therefore, to determine the stability of the considered geometry, we use trace of the Hessian matrix as

$$Tr(H) = H_{mm} + H_{nn},$$

where

$$\begin{aligned} H_{mm} = &- \left(4\pi^2 r_+^6 \left(9q^4 - 32\alpha q^3 r_+^2 + 2q^2 r_+^2 \left(17\alpha^2 r_+^2 - 8\right) + 4\alpha q r_+^4 (3\right.\right. \\ &\left.\left. - 2\alpha^2 r_+^2\right) - 3\alpha^4 r_+^8 - 4\alpha^2 r_+^6 + 3r_+^4)\right) \left(\left(-3q^2 + 2\alpha q r_+^2 + \alpha^2 r_+^4 + r_+^2\right)^3\right)^{-1}, \\ H_{nn} = &\left(r_+^2 \left(3\alpha + \left(q - \alpha r_+^2\right)^{-1}\right) + q\left(2r_+^2 \left(q - \alpha r_+^2\right)^{-2} - 1\right)\right) \\ &\times \left(4\left(\alpha - q r_+^{-2}\right)\right)^{-1}, \end{aligned}$$

hence

$$\begin{aligned} Tr(H) = &\left(r_+^2 \left(3\alpha + \left(q - \alpha r_+^2\right)^{-1}\right) + q\left(2r_+^2 \left(q - \alpha r_+^2\right)^{-2} - 1\right)\right) \\ &\times \left(4\left(\alpha - q r_+^{-2}\right)\right)^{-1} - \left(4\pi^2 r_+^6 \left(9q^4 - 32\alpha q^3 r_+^2 + 2q^2 r_+^2 \left(17\alpha^2 r_+^2 - 8\right)\right.\right. \\ &\left.\left. + 4\alpha q r_+^4 \left(3 - 2\alpha^2 r_+^2\right) - 3\alpha^4 r_+^8 - 4\alpha^2 r_+^6 + 3r_+^4)\right) \right. \\ &\left. \times \left(\left(-3q^2 + 2\alpha q r_+^2 + \alpha^2 r_+^4 + r_+^2\right)^3\right)^{-1}. \end{aligned}$$

A thermodynamical system is said to be stable if $Tr(H) \geq 0$.[31] Figure 7 shows the graphical analysis of the Hessian trace in terms of r_+ for different values of the coupling parameter. It is observed that the trace of Hessian matrix is not defined in the interval $0.5 < r_+ < 0.59$. It is also observed that the Hessian trace shows similar behavior to heat capacity and hence shows that the considered system is stable in the presence of non-linear electrodynamic effects.

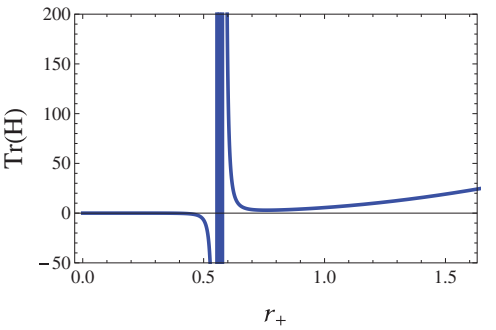

Fig. 7. Plot of Hessian trace versus r_+ for $q = 1$ and $\alpha = 3$.

4. Phase Transitions

Here we examine the phase transitions of Hawking temperature as well as heat capacity of RN BH with non-linear electrodynamic effects in terms of entropy. The Hawking temperature evaluated in Eq. (4) can be written in the form of entropy as

$$T = -\frac{\left(q - \alpha r_+^2 + r_+\right)\left(q - r_+(\alpha r_+ + 1)\right)}{4 r_+ S}.$$

Figure 8(a),(c),(e) represents the phase transitions of Hawking temperature in terms of S for different values of q, r_+ and α. It is noted that the Hawking temperature changes its phase from positive to negative for increasing values of q and r_+, respectively (Plot (a) and (c)). However, for increasing values of non-linear electrodynamic parameter, the Hawking temperature changes its phase from negative to positive (plot (c)). The expression of heat capacity for RN BH with non-linear electrodynamic effects in terms of entropy can be obtained from Eq. (6) as

$$C = \frac{S\left(q - \alpha r_+^2 + r_+\right)\left(q - r_+(\alpha r_+ + 1)\right)}{-2q^2 + 2\alpha q r_+^2 + r_+^2}.$$

The phase transitions of heat capacity versus entropy for different values of q, r_+ and α is shown in Figure 8(b),(d),(f). It is noted that heat capacity of the considered BH changes its phase from negative to positive for the increasing values of q, r_+ and α. It is also observed that the considered system is unstable for small values of the considered parameters while it shows stable behavior for large values of q, r_+ and α.

5. Concluding Remarks

In this paper, we have derived thermodynamical quantities for RN BH with non-linear electrodynamic effects and observed their behavior graphically. We have also discussed thermal stable configuration of this BH using both heat capacity as well as Hessian matrix and compared the results graphically. Firstly, we have calculated

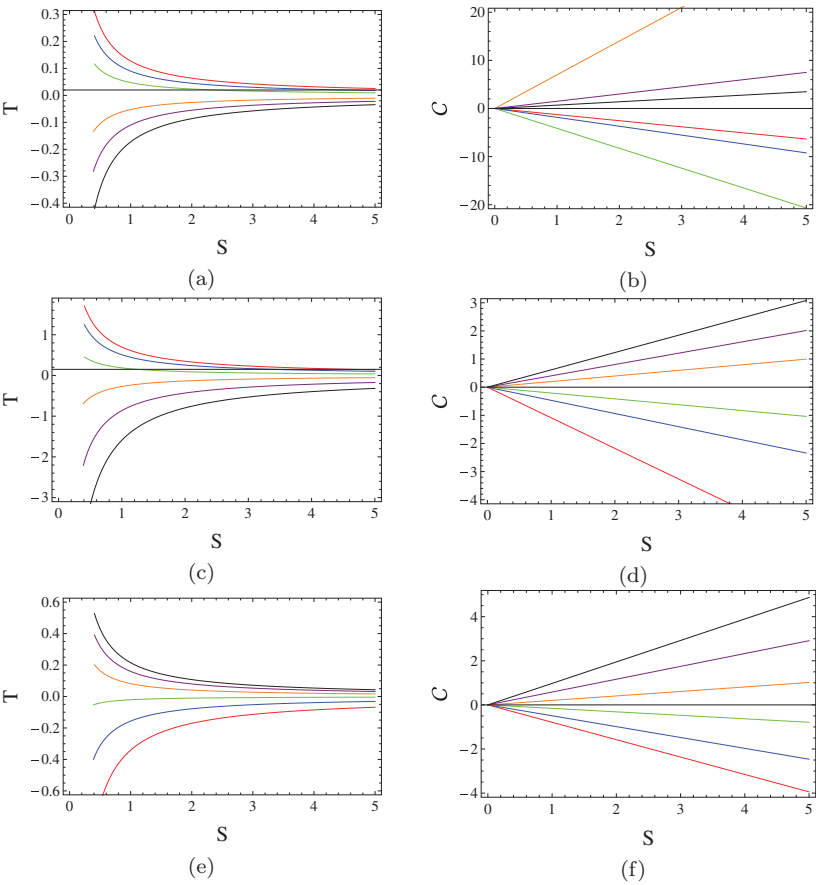

Fig. 8. Hawking temperature ((a), (c), (e)) versus S for $\alpha = 1$, $r_+ = 1$. We take $q = 1.7$(red), 1.8(blue), 1.9(green), 2.1(orange), 2.2(purple), 2.3(black) for plot (a), $\alpha = 1$, $q = 1$ with $r_+ = 0.4$(red), 0.5(blue), 0.6(green), 0.7(orange), 0.8(purple), 0.9(black) for plot (e) and $r_+ = 3$, $q = 1$ with $\alpha = 0.2$(red), 0.3(blue), 0.4(green), 0.5(orange), 0.6(purple), 0.7(black) plot (e). Heat capacity ((b), (d), (f)) versus S with $r_+ = 1$, $\alpha = 1$. We take $q = 1.1$(red), 1.2(blue), 1.3(green), 1.4(orange), 1.5(purple), 1.6(black) for plot (b), $\alpha = 2$, $q = 1$ with $r_+ = 0.7$(red), 0.8(blue), 0.9(green), 1.1(orange), 1.2(purple), 1.3(black) for plot (d) and $r_+ = 3$, $q = 1$, $\alpha = 0.2$(red), 0.3(blue), 0.4(green), 0.5(orange), 0.6(purple), 0.7(black) for plot (f).

the expressions of Hawking temperature with the help of surface gravity ($T = \frac{\kappa}{2\pi}$) and then Helmholtz free energy for the considered BH. The graphical representation of Helmholtz free energy shows that it is an increasing function of r_+ and the presence of non-linear electrodynamic effects only affect the Helmholtz free energy of BHs with large radii while BHs of small radii are unaffected. It is also noted that for increasing values of the coupling constant, it increases more rapidly. The increasing trend of Helmholtz free energy depicts that the reactions occurring inside the considered system are non-spontaneous. The internal energy of the system fluctuates and

has negative values for small values of r_+ which shows that the considered system is releasing heat. It is also observed that larger values of the coupling parameter induces large fluctuations in the internal energy of the system and vice-versa.

The enthalpy of the considered system is increasing continuously and showing that the considered system is absorbing heat while the increasing values of coupling parameter do not affect the enthalpy for BHs of both small as well as large radii (Figure 4(a)). Figure 5(a) shows that Gibbs free energy of the considered system is inversely proportional to the horizon radius. The increasing values of coupling parameter do not affect the Gibbs free energy of BHs with $r_+ < 1$ while for $r_+ \geq 1$, this free energy is affected significantly and decreases more rapidly.

Secondly, we have discussed thermal stability of the considered system with the help of heat capacity as well as Hessian matrix by observing their graphical behavior. It is noted that the heat capacity has Davies point at $r_+ = 0.56$ and changes its phase from negative to positive for increasing values of horizon radius which shows that the considered system is stable in the presence of coupling parameter (Figure 6). It is observed from Figure 7 that the trace of Hessian matrix is not defined in the interval $0.5 < r_+ < 0.59$ and shows similar behavior to heat capacity. It is concluded from both the methods that our system is thermodynamically stable in the presence of non-linear electrodynamic effects.

Finally, we have investigated the phase transitions of Hawking temperature as well as heat capacity in terms of entropy for the considered BH. It is found that Hawking temperature changes its phase from positive to negative for increasing values of both charge and horizon radius. This shows that BHs with small charge and radii are more hotter than the BHs with large charge and radii while it shows opposite behavior for increasing values of the coupling parameter. The heat capacity changes its phase from negative to positive for increasing values of the considered parameters which shows that BHs with small values of q, r_+ and α are unstable while BHs with large values are stable throughout the considered domain. We would like to mention here that all our results reduce to the RN BH for $\alpha = 0$.[9]

We investigate radial linear uniformly accelerated trajectories and their corresponding Rindler horizons in the black hole geometry. In a curved spacetime, a covariant definition for Rindler trajectories is provided in the context of the generalised Letaw-Frenet equations for trajectories with constant curvature scalar and vanishing torsion and hypertorsion. Interestingly, we arrive at a bound on magnitude of acceleration for Rindler trajectories such that, for acceleration greater than the bound value, the Rindler trajectory always falls into the black hole and the distance of closest approach for the trajectory to turn away is always greater than the Schwarzschild radius for all finite boundary data. We further investigate the past and future Rindler horizons using the analytical solution for the trajectories and discuss their features.

Keywords: Rindler trajectory, Schwarzschild spacetime, Letaw-Frenet equations.

1. Introduction

In a flat spacetime, Rindler trajectories are a special class of hyperbolic trajectories, moving along orbits of the boost Killing vector and lying in the right or left Rindler quadrant constrained by the future and past null Rindler horizons.[1] The investigation of quantum fields in this background leads to the Unruh effect, which states that the Minkowski vacuum appears as thermal to Rindler observer.[2] It has also been demonstrated that the Rindler observer in an inertial thermal bath with temperature T_B is unable to distinguish between the background thermal and quantum fluctuations as the corresponding reduced density matrix turns out to be symmetric in the two temperatures, the inertial bath temperature T_B and the acceleration temperature T_{unruh}.[3] An analogous case to be investigated would be in curved spacetime case of a black hole with Hawking radiation and an uniformly accelerated observer with arbitrary acceleration.

In this talk, we obtain a solution for radial Rindler trajectories in the Schwarzschild spacetime. In a curved spacetime, the flat spacetime hyperbolic trajectories are replaced by linearly uniformly accelerated (LUA) trajectories which are

locally hyperbolic at every point along the trajectory. We use the covariant definition in the context of the generalised Letaw-Frenet equations in curved spacetime for trajectories with constant curvature scalar and vanishing torsion and hyper-torsion. The accompanying Rindler horizons and the Rindler quadrant is expected to get modified in this case due to the presence of background curvature. We determine the causal past and future of the intercepts of the LUA trajectory at future and past null infinity respectively to analyse the corresponding Rindler horizons in the Schwarzschild background for such trajectories.

2. Rindler trajectories in Schwarzschild spacetime

In a curved spacetime, a generalisation of the Rindler trajectory involves, in addition to the constancy condition on the magnitude of acceleration, a further constraint on the trajectory that it must be *linear* with vanishing torsion and hyper-torsion. Such a construction is based on the generalised Letaw-Frenet equations in curved spacetime and the corresponding geometrical scalar invariants which lead to a covariant definition of the linear uniformly accelerated (LUA) trajectory.[4,5] For the LUA trajectory, the Letaw-Frenet equations take the following form of a constraint equation

$$w^i - |a|^2 u^i = 0 \tag{1}$$

where $w^i = u^j \nabla_j a^i$ with u^i and a^i being the velocity and acceleration vectors along the trajectory.

For the Schwarzschild spacetime,

$$ds^2 = \left(1 - \frac{r_s}{r}\right) dt^2 - \left(1 - \frac{r_s}{r}\right)^{-1} dr^2 - r^2\, d\theta^2 - r^2 \sin^2\theta\, d\phi^2 \tag{2}$$

we consider radial trajectories which start from the boundary $r \to \infty$, travel towards the black hole and then turn back to infinity. The equation for radial LUA trajectory consistent with the constraint equation is

$$\frac{dt}{dr} = \pm\Big(1 - \frac{r_s}{r}\Big)^{-1} \frac{(|a|\, r + h)\, \sqrt{r}}{|a|\, \sqrt{(r - r_{min})(r - r_{max})(r - r_n)}} \tag{3}$$

where $|a|$ is the constant magnitude of acceleration, h specifies the initial data at spatial infinity which accounts for the nonlinear shift in the trajectory along the radial direction, and r_{min}, r_{max} and r_n are the roots of the cubic polynomial, $r\,(|a|r + h)^2 - r + r_s$. The roots r_{min} and r_{max} are the turning points of the LUA trajectories initially moving towards and away from the black hole respectively. The root r_n being negative does not have any physical significance.

These turning points are positive real only when the magnitude of acceleration satisfies the following bound $|a|_b$

$$|a| \leq |a|_b = \frac{2\left(-9\,h + h^3 + \sqrt{(3 + h^2)^3}\right)}{27\, r_s}. \tag{4}$$

A LUA trajectory violating the acceleration bound always falls into the black hole. The turning point r_{min} corresponding to $|a|_b$ gives the lower bound on the distance of closest approach r_b for the return trajectory,

$$r_b = \frac{2}{3|a|_b}\left(\frac{\sqrt{3+h^2}}{2} - h\right). \tag{5}$$

The bound $|a|_b$ has a positive real value only when $h < 1$. Hence, altogether, in the Schwarzschild spacetime for a radial LUA trajectory to turn back at r_{min} it should have initial data $h < 1$ and magnitude of acceleration $|a| < |a|_b$. For all finite boundary data $h < 1$, the distance of closest approach r_b is found to be greater than the Schwarzschild radius r_s.

3. Rindler horizons in Schwarzschild spacetime

For a radially inward moving LUA trajectory satisfying all the conditions to escape back to infinity, the explicit solution $t(r)$ is obtained by integrating Eq. (3) in terms of the elliptic integrals (For details, see[6]). The constant of integration is fixed by choosing $t = 0$ when the trajectory is at its turning point $r = r_{min}$. The nature of trajectories is well explained by this solution in whole spacetime except at radial infinity where the elliptic integral of third kind, encountered in solution, is ill-defined.

This problem is circumvented by re-deriving the solution $t(r)$ as a series expansion. For a LUA trajectory starting from $r_i > r_{min}$, the relevant factors appearing in the denominator of Eq. (3) are expanded around r_{max} and r_s to get

$$\frac{dt}{dr} = \pm\frac{1}{|a|}\sum_{i=0}^{\infty}\sum_{j=0}^{\infty}\binom{-1}{i}\binom{-1/2}{j}\frac{(-r_s)^i(-r_{max})^j}{(r)^{i+j}}\frac{(|a|\,r+h)}{\sqrt{(r-r_{min})(r-r_n)}} \tag{6}$$

where the notation $\binom{x}{y}$ refers to binomial coefficients. Integrating this equation we get the solution $t(r)$ in terms of the Appell Hypergeometric functions $\mathbf{F_1}$ as,

$$\begin{aligned} t(r) = \pm\frac{2}{|a|}\sqrt{\frac{r_{min}\,(r-r_{min})}{r\,(r_{min}-r_n)}}\sum_{i=0}^{\infty}\sum_{j=0}^{\infty}G(i,j) \\ \left(|a|\,(r_{min}-r_n)\,\mathbf{F_1}\left[\frac{1}{2}, 2-i-j, \frac{-1}{2}, \frac{3}{2}; \frac{r-r_{min}}{r}, \frac{-r_n\,(r-r_{min})}{r\,(r_{min}-r_n)}\right]\right. \\ \left. + (h+|a|\,r_n)\,\mathbf{F_1}\left[\frac{1}{2}, 1-i-j, \frac{1}{2}, \frac{3}{2}; \frac{r-r_{min}}{r}, \frac{-r_n\,(r-r_{min})}{r\,(r_{min}-r_n)}\right]\right) \end{aligned} \tag{7}$$

where the coefficients $G(i,j)$ are defined to be

$$G(i,j) = \binom{-1}{i}\binom{-1/2}{j}\left(\frac{-r_s}{r_{min}}\right)^i\left(\frac{-r_{max}}{r_{min}}\right)^j. \tag{8}$$

This solution satisfies the boundary condition $t(r_{min}) = 0$ and has a well defined asymptotic value denoted by $\mathcal{C}$. Using the properties of Hypergeometric functions

the solution $t(r)$ for $r \to \infty$ is written in the form, $t(r) = \pm\,(r + r_s\,\log\,(r/r_s) + \mathcal{C})$, with $\mathcal{C}$ determined to be

$$\mathcal{C} = \frac{h}{|a|} + \frac{r_{max}}{2} + \frac{h\,(r_{max} + 2\,r_s)}{|a|\,\sqrt{-r_n\,r_{min}}}\,\sin^{-1}\left(\sqrt{\frac{-r_n}{r_{min} - r_n}}\right) + r_s\,\log\left(\frac{4\,r_s}{r_{min} - r_n}\right) + \frac{\sqrt{\pi}}{|a|}\,\sqrt{\frac{r_{min}}{r_{min} - r_n}}\,(S_d + S_s) \tag{9}$$

where S_d and S_s are double and single convergent summation series respectively expressed as,

$$S_d = \sum_{i=1}^{\infty}\sum_{j=1}^{\infty} G(i,j)\;\left[\,|a|\,(r_{min} - r_n)\,H_1(i+j) + (h + |a|\,r_n)\,H_2(i+j)\,\right] \tag{10}$$

$$S_s = \sum_{k=2}^{\infty}\,(\,G(k,0) + G(0,k)\,)\;\left[\,|a|\,(r_{min} - r_n)\,H_1(k) + (h + |a|\,r_n)\,H_2(k)\,\right] \tag{11}$$

with the functions being defined as

$$H_1(k) = \frac{\Gamma(k-1)}{\Gamma\left(k - \frac{1}{2}\right)}\;\mathbf{F}\left[\frac{1}{2}, \frac{-1}{2}, k - \frac{1}{2}; \frac{-r_n}{r_{min} - r_n}\right]$$

$$H_2(k) = \frac{\Gamma(k)}{\Gamma\left(k + \frac{1}{2}\right)}\;\mathbf{F}\left[\frac{1}{2}, \frac{1}{2}, k + \frac{1}{2}; \frac{-r_n}{r_{min} - r_n}\right]$$

The LUA trajectory asymptotes to null trajectories near radial infinity as expected, since away from the black hole the scenario becomes asymptotically flat. The asymptotic expansion of LUA trajectory $t(r)$ matches to the form of the null trajectories representing the future and past Rindler horizons,

$$r + r_s \log\left|\frac{r}{r_s} - 1\right| \mp t = \mathcal{C}^{\pm}$$

where we then have the intercepts at radial infinity, $\mathcal{C}^+ = \mathcal{C}^- = \mathcal{C}$ due to the symmetry about the $t = 0$ axis.

The Rindler quadrant for the radial LUA trajectories in the Schwarzschild spacetime is then the union of the past and future null infinity with the past and future horizons in the Penrose diagram. The intersection points of these are the spatial infinity i^0, the past and future intercepts $\mathcal{C}^-$ and $\mathcal{C}^+$ and the bifurcation point of the past and future horizons, which is found to be,

$$r_{null} = r_s\left(1 + W\left[e^{-1-\frac{\mathcal{C}}{r_s}}\right]\right) \tag{12}$$

where $W[x]$ is the productlog function. Thus, unlike in the case of the Rindler quadrant in the flat spacetime, for the Schwarzschild case, the bifurcation point r_{null} is dependent on the asymptotic initial data h as well as the acceleration magnitude $|a|$ and the Schwarzschild radius r_s.

4. Discussion

For the case of Schwarzschild black hole the following observations are made, in comparison with flat spacetime, regarding the Rindler trajectories: In the flat spacetime, all the Rindler trajectories with the magnitude of acceleration in range 0 to ∞ lie in the same Rindler quadrant. This is due to the reason that the corresponding intercept $\mathcal{C}$, the Rindler horizons and the bifurcation point are independent of $|a|$ and just depend on h. In fact, for the limiting case $|a| \to \infty$, the turning point r_{min} is the bifurcation point as the Rindler trajectory coincides with the past and future null horizons. However, in the Schwarzschild case, the intercepts $\mathcal{C}$, the corresponding Rindler horizons and the bifurcation points are all functions of $|a|$ as well. Hence, increasing $|a|$ decreases not just the turning point r_{min} but also the bifurcation point r_{null}. However, it turns out that the turning point does not catch up with the bifurcation point. These observations provide an alternate perspective to look at the acceleration bounds $|a|_b$. The lowest possible value for r_{null} is limited by the black hole horizon to being the Schwarzschild radius r_s, which in turn limits the lowest possible value of r_{min} to $r_{min} = r_b$ and hence a maximum value for the acceleration $|a|$.

E-mail: traschen@umass.edu

The symmetric two-point function for a massless, minimally coupled scalar field in the Unruh state is examined for Schwarzschild-de Sitter spacetime in two dimensions. This function grows linearly in terms of a time coordinate that is well-defined on the future black hole and cosmological horizons, when the points are split in the space direction. This type of behavior also occurs in two dimensions for other static black hole spacetimes when the field is in the Unruh state, and at late times it occurs in spacetimes where a black hole forms from the collapse of a null shell. The generalization to the case of the symmetric two-point function in two dimensions for a massive scalar field in Schwarzschild-de Sitter spacetime is discussed.

Keywords: Black hole, quantum field theory in curved space

1. Introduction

Hawking[1] predicted that black holes that form from collapse evaporate and at late times the particles are in a thermal distribution with a temperature that is proportional to the surface gravity of the black hole. In four dimensions (4D) it is very difficult to compute quantities such as the two-point function and the stress-energy tensor for a quantum field in the spacetime of a black hole that forms from collapse. Instead, it is significantly easier, although not easy, to do such computations in eternal black hole spacetimes which are either static or stationary. It is easier yet to work with a massless minimally coupled scalar field in spacetimes with two dimensions (2D) that have similar structures to the 4D black hole spacetimes.

Unruh[2] showed that, for an isolated eternal black hole in an asymptotically flat spacetime, there is a particular state for a quantum field that has the same properties as the *in* state for that field has at late times in a spacetime where the black hole forms from collapse. In particular, this state, called the Unruh state, has the same flux of particles at infinity for an eternal black hole as occurs at late times for a black hole that forms from collapse. Thus computations of various quantities for a quantum field in the Unruh state can give insight into the late time behaviors of these quantities in spacetimes where a black hole forms from collapse.

The simplest 4D black hole spacetimes to compute quantum effects in are those which are static and spherically symmetric outside of the event horizon where the metric has the general form

$$ds^2 = -f(r)dt^2 + f^{-1}(r)dr^2 + r^2 d\Omega^2 \ . \tag{1}$$

These are easily changed to 2D spacetimes by dropping the last term on the right. All 2D spacetimes are conformally flat and the massless, minimally coupled scalar field is conformally invariant in such spacetimes making it possible to analytically solve the mode equation in coordinates for which the metric is conformally flat.

In Ref. 3, the Hadamard Green's function, which is the symmetric two-point function, was computed and studied for a massless, minimally coupled scalar field in the Unruh state in 2D for Schwarzschild-de Sitter(SdS) spacetime, Schwarzschild spacetime, de Sitter space, a class of Bose-Einstein condensate analog black hole spacetimes, and a spacetime in which a null shell collapses to form a black hole. It was shown that in all of these cases there is linear growth in terms of a time coordinate T that is regular on the future horizon(s) when the points are split in the spatial direction.

In this proceeding we summarize some of the results of Ref. 3 for black holes. We also discuss the computation of the symmetric two-point function for a massive, minimally coupled scalar field in SdS. In this case, the mode functions and the two-point function must be computed numerically.

In Sec. 2, some properties of 2D SdS are reviewed along with the Unruh state for a massless, minimally coupled scalar field. The Hadamard Green's function for this field is displayed in Sec. 3 and its linear growth in time is discussed. Ongoing work related to the massive scalar field in 2D SdS is discussed in Sec. 4. In Sec. 5 the computation of the symmetric two-point function for a massless, minimally coupled scalar field in a 2D collapsing null shell spacetime is reviewed. Our results are summarized in Sec. 6. Throughout, our units are $\hbar = c = G = 1$.

2. Massless, Minimally Coupled Scalar Field in SdS

A Penrose diagram for SdS is given in Fig. 1. The 2D SdS metric is given by

$$ds^2 = -f(r)dt^2 + \frac{dr^2}{f(r)} \ , \tag{2a}$$

$$f(r) = 1 - \frac{2M}{r} - H^2 r^2 = \ -\frac{H^2}{r}(r - r_c)(r - r_b)(r + r_c + r_b) \ . \tag{2b}$$

Here $r_c > r_b$ are the locations of the cosmological and black hole horizons respectively, and $\frac{1}{3}\Lambda = H^2$. The two parameterizations are related by

$$M = \frac{r_b r_c (r_b + r_c)}{2(r_b^2 + r_c^2 + r_b r_c)}, \qquad H^2 = \frac{1}{r_b^2 + r_c^2 + r_b r_c} \tag{3}$$

It is useful to define the tortoise coordinate

$$r_*(r) = \int \frac{dr}{f} \ . \tag{4}$$

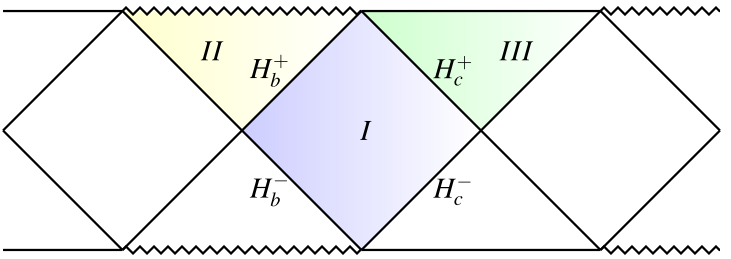

Fig. 1. Penrose diagram for SdS. Region I is the static patch between the black hole horizons and cosmological horizons, Region II is the interior of the black hole, and Region III is the cosmological region.

The ingoing and outgoing radial null coordinates are

$$u = t - r_* \ , \quad v = t + r_* \ . \tag{5}$$

One can define two sets of Kruskal coordinates, one for each horizon. The ones we are concerned with are

$$\begin{aligned} U_b &= \frac{1}{\kappa_b} e^{-\kappa_b u} \ , \quad r < r_b \ , \quad U_b = -\frac{1}{\kappa_b} e^{-\kappa_b u} \ , \quad r > r_b \\ V_c &= -\frac{1}{\kappa_c} e^{-\kappa_c v} \ , \quad r < r_c \ , \qquad V_c = \frac{1}{\kappa_c} e^{-\kappa_c v} \quad , \quad r > r_c \ . \end{aligned} \tag{6}$$

The surface gravities for the two horizons are

$$\begin{aligned} \kappa_b &= \frac{H^2}{2r_b}(r_c - r_b)(r_c + 2r_b) \ , \\ \kappa_c &= \frac{H^2}{2r_c}(r_c - r_b)(2r_c + r_b) \ , \end{aligned} \tag{7}$$

where for a horizon at $r = r_h$ we set $2\kappa_h = |f'(r_h)|$ so that each of the surface gravities is a positive quantity.

A set of coordinates that are good across $\mathcal{H}_b^+$ and $\mathcal{H}_c^+$ was found in Refs. 4, 5. Let

$$T = t + h(r) \ , \quad \text{where} \quad \frac{dh}{dr} = \frac{j}{f} \ , \qquad j(r) = -\gamma r + \frac{\beta}{r^2} \ , \tag{8}$$

and

$$\gamma = \frac{r_c^2 + r_b^2}{r_c^3 - r_b^3} \ , \quad \beta = \frac{r_c^2 r_b^2 (r_b + r_c)}{r_c^3 - r_b^3} \ . \tag{9}$$

Then the 2D SdS metric becomes

$$ds^2 = -f(r)dT^2 + 2j(r)drdT + \frac{1 - j^2}{f} dr^2 \ . \tag{10}$$

Note that for these choices of the constants γ and β, one finds that $j(r_b) = 1$ and $j(r_c) = -1$, which ensures that T interpolates between the ingoing null coordinate v at the future black hole horizon and the outgoing null coordinate u at the future cosmological horizon. These are ingoing and outgoing Eddington-Finklestein coordinates respectively. The metric (10) is well behaved in the static and cosmological regions and has the Eddington-Finklestein form on both the future black hole and future cosmological horizons. The coordinate T stays timelike and r stays spacelike beyond the cosmological horizon.

The definitions of r_* and T each contain an arbitrary constant which can be chosen such that

$$T = u \text{ on } \mathcal{H}_c^+ \ , \qquad \text{and} \quad T = v \text{ on } \mathcal{H}_b^+ \ . \tag{11}$$

The result is[3]

$$\begin{aligned} T &= t + h(r) \\ &= t + \frac{1}{2\kappa_b}\log\frac{|r-r_b|}{r_c-r_b} + \frac{1}{2\kappa_c}\log\frac{|r-r_c|}{r_c-r_b} + \frac{1}{2}\left(\frac{r_c}{r_b\kappa_b} - \frac{1}{\kappa_N}\right)\log\frac{r+r_c+r_b}{r_c+2r_b} \\ &\quad - \frac{r_b r_c}{2(r_c-r_b)}\log\frac{r^2}{r_c r_b} + \frac{r_c}{4r_b\kappa_b}\log\frac{r_c+2r_b}{2r_c+r_b} \ , \end{aligned} \tag{12}$$

and

$$\begin{aligned} r_*(r) &= \frac{1}{2\kappa_b}\log\frac{|r-r_b|}{r_c-r_b} - \frac{1}{2\kappa_c}\log\frac{|r-r_c|}{r_c-r_b} + \frac{1}{2\kappa_N}\log\frac{|r+r_c+r_b|}{r_c+2r_b} \\ &\quad - \frac{r_c}{4r_b\kappa_b}\log\frac{2r_c+r_b}{r_c+2r_b} - \frac{r_b r_c}{2(r_c-r_b)}\log\frac{r_b}{r_c} \ , \end{aligned} \tag{13}$$

where

$$\kappa_N = \frac{H^2}{2(r_c+r_b)}(2r_c+r_b)(r_c+2r_b) \ . \tag{14}$$

To relate the Kruskal coordinates to T and r, note that $u = T - (h(r) + r_*)$ and $v = T - h(r) + r_*$. Substitution gives

$$V_c = \frac{1}{\kappa_c}e^{-\kappa_c T}\tilde{V}_c \ , \quad \text{and} \quad U_b = \frac{1}{\kappa_b}e^{-\kappa_b T}\tilde{U}_b \ , \tag{15}$$

where $\tilde{V}_c$ and $\tilde{U}_b$ only depend on r and are given by

$$\begin{aligned} \tilde{V}_c &= e^{\kappa_c(h-r_*)} = \frac{r-r_c}{r_c-r_b}\left(\frac{r+r_c+r_b}{r_c+2r_b}\right)^{r_b/2r_c}\left(\frac{r_b}{r}\right)^{H^2 r_b(2r_c+r_b)/2} \ , \\ \tilde{U}_b &= -e^{\kappa_b(h+r_*)} = -\frac{(r-r_b)}{r_c-r_b}\left(\frac{r+r_b+r_c}{2r_c+r_b}\right)^{r_c/2r_b}\left(\frac{r_c}{r}\right)^{H^2 r_c(r_c+2r_b)/2} \ . \end{aligned} \tag{16}$$

Note that these expressions work both inside and outside the black hole and cosmological horizons.

The complete set of modes that comprise the Unruh state consist of modes that are positive frequency with respect to U_b on the past black hole horizon and modes that are positive frequency with respect to V_c on the past cosmological horizon.[6–8]

$$p^b_\omega = \frac{e^{-i\omega U_b(u)}}{\sqrt{4\pi\omega}} \text{ and } p^c_\omega = \frac{e^{-i\omega V_c(v)}}{\sqrt{4\pi\omega}} \tag{17}$$

Expanding the massless minimally coupled scalar field in terms of these gives

$$\phi = \int_0^\infty d\omega \left[a^b_\omega p^b_\omega + a^c_\omega p^c_\omega + a^{b\dagger}_\omega p^{b*}_\omega + a^{c\dagger}_\omega p^{c*}_\omega\right] , \tag{18}$$

where $a^{(b,c)}$ are the annihilation operators.

3. Symmetric Two-Point Function in SdS

For a massless, minimally coupled scalar field in 2D SdS in the Unruh state, the symmetric two-point function for an arbitrary splitting of the points is[3]

$$\begin{aligned} G^{(1)}(x,x') &= \langle U| \left(\phi(x)\phi(x') + \phi(x')\phi(x)\right) |U\rangle \\ &= \int_0^\infty d\omega [p^b_\omega(x) p^{b*}_\omega(x') + p^c_\omega(x) p^{c*}_\omega(x') + \text{c.c.}] \\ &= \frac{1}{2\pi}\int_{\omega_0}^\infty \frac{d\omega}{\omega}\left\{\cos[\omega(U_b - U_b^{'})] + \cos[\omega(V_c - V_c^{'})]\right\} \\ &= -\frac{1}{2\pi}\left\{ci[\omega_0|U_b - U_b^{'}|] + ci[\omega_0|V_c - V_c^{'}|]\right\} . \end{aligned} \tag{19}$$

Here ci is the cosine integral function which has the expansion $ci(z) = \gamma_E + \log z + O(z^2)$, and ω_0 is a small infrared cutoff.

Let x be on H^b_+ and x' on H^c_+ and take $T' = T$. Note that on H^+_b, $U_b = 0$, $v = T$ and on H^+_c, $V_c = 0$, $u = T$. Then

$$\begin{aligned} U_b - U_b^{'} &= -\kappa_b^{-1} e^{-\kappa_b T} , \qquad V_c - V_c^{'} = \kappa_c^{-1} e^{-\kappa_c T} , \\ 2\pi G^{(1)}(T,r;T,r') &= (\kappa_b + \kappa_c)T - \log\left[(\kappa_b\kappa_c)^{-1}\omega_0^2\right] - 2\gamma_E . \end{aligned} \tag{20}$$

Thus one sees an unexpected linear growth in the time coordinate T for this separation of the points. For a more general separation

$$2\pi G^{(1)}(T,r;T,r') = T(\kappa_b + \kappa_c) - \log\left(\frac{\omega_0^2}{\kappa_b\kappa_c}|\Delta\tilde{U}_b \Delta\tilde{V}_c|\right) - 2\gamma_E , \tag{21}$$

where $\Delta\tilde{U}_b$ and $\Delta\tilde{V}_c$ are functions of r and r', but not T.

In Ref. 3 a similar linear growth in a time coordinate for $G^{(1)}(x,x')$ in 2D for a massless minimally coupled scalar field was found in Schwarzschild spacetime for the Unruh state, de Sitter spacetime for the Bunch-Davies state, and a class of Bose-Einstein condensate analog black hole spacetimes for the Unruh state. A general argument was also given that linear growth should occur whenever there is a past horizon and no scattering for the Unruh state.

One may ask what these situations have in common. In each case the symmetric two-point function is computed for a massless minimally coupled scalar field in 2D in the Unruh state or its analog, the two-point function has an infrared divergence which requires an infrared cutoff, and each spacetime has a static patch and at least one past horizon. In the next two sections, two cases are discussed in which one or more of these conditions does not occur.

4. Massive Scalar Field in 2D SdS

One way to investigate the generality of the linear growth in time is to work with a massive scalar field. Work is in progress to compute the symmetric two-point function for this field. It is significantly more difficult than for the massless scalar field because the mode equation contains an effective potential term and does not have simple closed form solutions. Instead, when separation of variables is used, the radial part of the mode equation can be solved numerically.

The mode equation cannot be separated in Kruskal coordinates but it can be separated in terms of the coordinates t and r in (2b). The mode equation in this case is

$$-\frac{\partial^2 h}{\partial t^2}+\frac{\partial^2 h}{\partial r_*^2}-m^2 f=0\ . \tag{22}$$

The relevant solutions are of the form

$$h(t,r)=\frac{e^{-i\omega t}}{\sqrt{4\pi\omega}}\chi_\omega(r)\ , \tag{23}$$

with

$$\frac{d^2\chi}{dr_*^2}+(\omega^2-m^2 f)h=0\ . \tag{24}$$

A complete set of modes that specify the Boulware state can be obtained by combining modes which on the past black hole horizon have the form

$$h^b_\omega=\frac{e^{-i\omega u}}{\sqrt{4\pi\omega}}\ , \tag{25}$$

and those which on the past cosmological horizon have the form

$$h^c_\omega=\frac{e^{-i\omega v}}{\sqrt{4\pi\omega}}\ . \tag{26}$$

The modes that specify the Unruh state can be expanded in terms of these modes with the result

$$p^{(b,c)}_\omega=\int_0^\infty d\omega'\,[\alpha^{(b,c)}_{\omega\omega'}h^{(b,c)}_{\omega'}+\beta^{(b,c)}_{\omega\omega'}h^{(b,c)\,*}_{w'}]\ . \tag{27}$$

Since the mode equation reduces to its massless form on the past horizons, the initial conditions for the Unruh state are exactly the same as in the massless case (17).

Using the usual scalar product,[9] one finds[10]

$$\alpha^{(b,c)}_{\omega\omega'} = \frac{1}{2\pi}\sqrt{\frac{\omega'}{\omega}}\left(\kappa_{(b,c)}\right)^{-1-i\frac{\omega'}{\kappa_{(b,c)}}}\frac{\Gamma(-i\frac{\omega'}{\kappa_{(b,c)}})}{(-i\omega)^{-i\frac{\omega'}{\kappa_{(b,c)}}}} ,$$
$$\beta^{(b,c)}_{\omega\omega'} = \frac{1}{2\pi}\sqrt{\frac{\omega'}{\omega}}\left(\kappa_{(b,c)}\right)^{-1+i\frac{\omega'}{\kappa_{(b,c)}}}\frac{\Gamma(i\frac{\omega'}{\kappa_{(b,c)}})}{(-i\omega)^{i\frac{\omega'}{\kappa_{(b,c)}}}} . \tag{28}$$

Note that these are divergent in the limit $\omega' \to 0$ due to the poles in the Gamma functions. However, we have shown that because of scattering effects, these divergences are canceled in the integrand of Eq. (27). Also, it is important to note that the limit $\omega' \to 0$ needs to be taken before the limits $r \to r_b$ and $r \to r_c$. They cannot be interchanged.

At present, work is in progress to compute p^b_ω and p^c_ω numerically. It is not yet known whether the divergence that exists for the massless case for these mode functions continues to be present in the massive case.

5. Collapsing Null Shell Spacetime

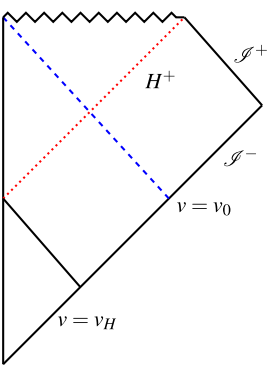

Fig. 2. Penrose diagram for a 2D spacetime in which a null shell collapses to form a black hole and there is a perfectly reflecting mirror at the origin. The trajectory of the shell is given by the dashed blue line and the event horizon is given by the dotted red line.

Another calculation that was done in Ref. 3 was to compute the two-point function for a massless scalar field in a 2D spacetime in which a null shell collapses to form a Schwarzschild black hole. Inside the shell the metric is the flat space metric

$$ds^2 = -dt^2 + dr^2 , \tag{29}$$

and outside it is Eq. (2b) with $H = 0$, which is the Schwarzschild metric. If one puts in a perfectly reflecting mirror and requires that the field vanish at the surface

of the mirror then one obtains the same conditions on the mode functions at $r = 0$ as in the 4D case. The Penrose diagram for this spacetime is shown in Fig. 2.

Inside the shell, the usual null coordinates are

$$u = t - r \ , \qquad v = t + r \ , \tag{30}$$

and outside the shell they are

$$u_s = t_s - r_* \ , \qquad v = t_s + t_* \ . \tag{31}$$

The coordinates r and v are continuous across the trajectory of the shell which is $v = v_0$, for some v_0. At the null shell surface one finds[11,12]

$$u(u_s) = v_H - 4MW\left[\exp\left(\frac{v_H - u_s}{4M}\right)\right] \ , \tag{32}$$

where $v_H = v_0 - 4M$ and W is the Lambert W function. On past null infinity both u_s and u are equal to $-\infty$. On the future horizon of the black hole $u_s = \infty$ and $u = v_H$.

Because of the mirror, the mode functions must vanish at $r = 0$. For the *in* state, at past null infinity they have the form

$$f_\omega^{\rm in} \to \frac{e^{-i\omega v}}{\sqrt{4\pi\omega}} \ . \tag{33}$$

The solution that satisfies these two conditions is

$$f_\omega^{\rm in} = \frac{1}{\sqrt{4\pi\omega}}(e^{-i\omega v} - e^{-i\omega u}) \ . \tag{34}$$

Since there is no scattering in 2D for the massless, minimally coupled scalar field, outside the shell the solution is

$$f_\omega^{\rm in} = \frac{1}{\sqrt{4\pi\omega}}(e^{-i\omega v} - e^{-i\omega u(u_s)}) \ . \tag{35}$$

Note that $f_\omega^{\rm in} = 0$ at $\omega = 0$. Thus there is no infrared divergence in the two-point function for this state and no infrared cutoff is necessary. One finds that[3]

$$2\pi G^{(1)}(x, x') = \log\left[\frac{|v - u(u_s')||v' - u(u_s)|}{|v - v'||u(u_s) - u(u_s')|}\right] \ . \tag{36}$$

Using $v = T - h(r) + r_*$ and $u = T - h(r) - r_*$, one finds for $T = T'$ and fixed values of r and r', that at late times

$$2\pi G(T, r; , T, r') \to \kappa T + \log(\kappa^2 T^2) + (r, r' \text{dependent terms}) \ . \tag{37}$$

Thus, there is not only a linear growth in T as there is for the Unruh state, but there is also a secondary logarithmic growth.

6. Conclusions

In Ref. 3, the behavior of the two point function was investigated for a massless, minimally coupled scalar field in the Unruh state in certain 2D spacetimes. It was found that linear growth in time of the form

$$2\pi G^{(1)}(T, r; T, r') = T \sum_J \kappa_J + (r, r' \text{dependent terms}) \tag{38}$$

occurs, where the sum is over the surface gravities of the past horizons and T is a time coordinate that is regular on the future horizons. Along with the existence of one or two past horizons, the Green's function for each spacetime is infrared divergent and thus requires an infrared cutoff to regularize this divergence.

The two-point function for this field in a 2D spacetime in which a null shell collapses to form a black hole was also computed. In this case there is no past horizon and thus no Unruh state. Instead, since the spacetime is asymptotically flat, the state for the massless, minimally coupled scalar field was chosen to be the initial vacuum state. By putting a perfectly reflecting mirror at the origin and requiring that the mode functions vanish there, the same type of condition that one finds in the 4D collapsing null shell spacetime if the shell is spherically symmetric was imposed. As a result of this condition, the two-point function has no infrared divergences.

It was found that at early times there is no linear growth in time of the form (38), however at late times there is growth of this form. There is also a subleading term that diverges logarithmically in time at late times. Thus, the linear growth in time found in the eternal black hole calculations also occurs, at least in 2D, for a black hole that forms from the collapse of a null shell. Perhaps this is not surprising since the Unruh state is supposed to give the leading order, late time behavior of quantities such as the two-point function and stress-energy tensor for the quantum field in the case of a black hole that forms from collapse. However, it does show that the linear growth in time does not depend on the existence of either a past horizon or an infrared divergence in the two-point function.

To see whether the linear growth in time only occurs for the massless scalar field, the case of a massive scalar field in the Unruh state in 2D SdS is being investigated. It has been shown that, when the mode functions for the Unruh state are expanded in terms of those for the Boulware state, an infrared diverge that occurs in the massless case is not present in the massive one. Work is in progress to determine whether the linear growth in time of the two-point function also occurs for a massive scalar field.

A method is presented which allows for the numerical computation of the stress-energy tensor for a quantized massless minimally coupled scalar field in the region outside the event horizon of a 4D Schwarzschild black hole that forms from the collapse of a null shell. This method involves taking the difference between the stress-energy tensor for the *in* state in the collapsing null shell spacetime and that for the Unruh state in Schwarzschild spacetime. The construction of the modes for the *in* vacuum state and the Unruh state is discussed. Applying the method, the renormalized stress-energy tensor in the 2D case has been computed numerically and shown to be in agreement with the known analytic solution. In 4D, the presence of an effective potential in the mode equation causes scattering effects that make the the construction of the in modes more complicated. The numerical computation of the *in* modes in this case is given.

Keywords: Black holes; Quantum field theory in curved space; Stress-energy tensor.

1. Introduction

The expectation value of the renormalized stress-energy tensor operator for a quantized field is a useful way to study quantum effects curved space. It can also be used in the context of semiclassical gravity to compute the backreaction of the quantum field on the background geometry. In the case of four-dimensional, 4D, black holes, this quantity has to date only been computed for static black holes[1–4,6–15] and Kerr black holes.[16,17] However, to our knowledge, a full numerical computation of this quantity has not been done for a quantized field in a 4D spacetime in which a black hole forms from the collapse of a null shell, which is probably the simplest model for the formation of a black hole.

In Ref. 18, we developed a method to numerically compute the full renormalized stress-energy tensor for a massless minimally coupled scalar field in the case of a spherically symmetric black hole in 4D that forms from the collapse of a null shell. This method can be used in the region outside the null shell and future horizon, where by Birkhoff's theorem, the geometry is described by the Schwarzschild metric.

In this proceeding, we review this method with a focus on the computation of a complete set of *in* modes that can be used to construct the quantum field in the region outside the null shell. We also present new numerical results for a low frequency *in* mode on the future horizon and for a mode with relatively high frequency on the part of the future horizon close to the null shell trajectory.

In Sec. 2, we review the null shell spacetime and the metrics describing the geometry inside and outside of the null shell. In Sec. 3, we discuss the quantization of the massless minimally coupled scalar field in the null shell spacetime. In Sec. 4, we present our method to expand the *in* modes in terms of a complete set of modes in pure Schwarzschild spacetime and present our numerical results for the high and low frequency modes on the future horizon. In Sec. 5, a proper method for the renormalization of the stress-energy tensor is given. In this section, we summarize the application of our method in Ref. 18 to the case of a collapsing null shell spacetime which has a perfectly reflecting mirror at the spatial origin.

2. Collapsing null shell

The model we consider is a spherically symmetric null shell whose collapse results in the formation of a black hole. The Penrose diagram of the spacetime is depicted in Fig. 1 The spacetime inside the null shell is described by the flat metric

$$ds^2 = -dt^2 + dr^2 + r^2 d\Omega^2 \,,$$

and from Birkhoff's theorem, the metric outside the shell is the Schwarzschild metric

$$ds^2 = -\left(1 - \frac{2M}{r}\right) dt_s^2 + \left(1 - \frac{2M}{r}\right)^{-1} dr^2 + r^2 d\Omega^2$$

with $d\Omega^2 = d\theta^2 + \sin^2\theta d\phi^2$. It is more convenient to use radial null coordinates to match the geometries inside and outside of the shell. In the interior,

$$u = t - r \,, \quad v = t + r \,.$$

and in the exterior region,

$$u_s = t_s - r_* \,, \quad v = t_s + r_* \,,$$

where $r_* = r + 2M \ln\left(\frac{r-2M}{2M}\right)$ is the tortoise coordinate in Schwarzschild spacetime. The null shell trajectory is $v = v_0$. We match the two spacetimes so that the v coordinate and the angular coordinates are continuous across the null shell trajectory. Applying this condition gives the following relation between the u an u_s coordinates[19,20]

$$u_s = u - 4M \log\left(\frac{v_H - u}{4M}\right),$$

where $v_H = v_0 - 4M$.

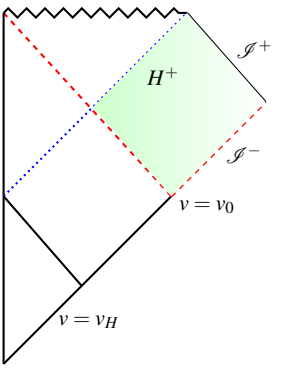

Fig. 1. Penrose diagram for a spacetime in which a null shell collapses to form a spherically symmetric black hole. The vertical line on the left corresponds to the surface $r = 0$ which is also the surface where $u = v$. The dashed red line on $v = v_0$ is the trajectory of the null shell. The horizon, H^+ is the dotted blue curve. Inside the shell trajectory H^+ corresponds to the surface $u = v_H$ and outside the shell trajectory it corresponds to $u_s = \infty$. A Cauchy surface is shown by the dashed line. It is the union of the surface $v = v_0$ with the part of $\mathscr{I}^-$ with $v > v_0$.

3. Massless minimally coupled scalar field

We consider a massless minimally coupled scalar field in the null shell spacetime. In a general static spherically symmetric spacetime, it can be expanded in the following way,

$$\phi = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} \int_0^{\infty} [a_{\omega\ell m} f_{\omega\ell m} + a^{\dagger}_{\omega\ell m} f^*_{\omega\ell m}]$$

with $\Box\, f_{\omega\ell m} = 0$. In the region inside the null shell, $v < v_0$, separation of variables gives

$$f_{\omega\ell m} = \frac{Y_{\ell m}(\theta,\phi)}{r\sqrt{4\pi\omega}} \psi_{\omega\ell}(t,r) = \frac{Y_{\ell m}(\theta,\phi)}{r\sqrt{4\pi\omega}} e^{-i\omega t} \chi_{\omega\ell}(r), \tag{1}$$

while in the region outside the null shell, $v > v_0$, it gives

$$f_{\omega\ell m} = \frac{Y_{\ell m}(\theta,\phi)}{r\sqrt{4\pi\omega}} \psi_{\omega\ell}(t_s,r) = \frac{Y_{\ell m}(\theta,\phi)}{r\sqrt{4\pi\omega}} e^{-i\omega t_s} \chi_{\omega\ell}(r). \tag{2}$$

In the regions $v < v_0$ and $v > v_0$ respectively, the radial parts of the mode functions satisfy the differential equations

$$\frac{d^2\chi_{\omega\ell}}{dr^2} = -\left[\omega^2 - \frac{\ell(\ell+1)}{r^2}\right] \chi_{\omega\ell}. \tag{3}$$

$$\frac{d^2\chi_{\omega\ell}}{dr_*^2} = -\left[\omega^2 - \left(1 - \frac{2M}{r}\right)\left(\frac{2M}{r^3} + \frac{\ell(\ell+1)}{r^2}\right)\right] \chi_{\omega\ell}\,. \tag{4}$$

The *in* state is fixed by requiring that $\psi_{\omega\ell} = e^{-i\omega v}$ on past null infinity and it vanishes at $r = 0$. The solution with these properties has the form

$$\psi^{in}_{\omega\ell}(r,t) = C_\ell e^{i\omega t}\omega r j_\ell(\omega r) \tag{5}$$

inside the null shell, where C_ℓ is fixed by the aforementioned condition on past null infinity. Here j_ℓ is a spherical bessel function of the first kind. It is not possible for this solution to have the form $e^{-i\omega t_s}\chi_{\omega\ell}(r)$ outside the null shell. The solution in this region is more complicated.

4. Computation of $f^{in}_{\omega\ell m}$

We can compute $f^{in}_{\omega\ell m}$ outside the null shell and the event horizon by expanding it in terms of a complete set of modes since the geometry here is the Schwarzschild geometry. This problem can be mapped to the shaded part of pure Schwarzschild spacetime shown in Fig. 2. We choose a complete sets of modes that consists of the union of the modes $f^{H^+}_{\omega\ell m}$ that are positive frequency on future horizon and zero on future null infinity, and the modes $f^{\mathscr{I}^+}_{\omega\ell m}$ that are positive frequency on the future null infinity and zero on the future horizon, *i.e.*,

$$\begin{aligned} f^{in}_{\omega\ell m} = \sum_{\ell'=0}^{\infty}\sum_{m'=-\ell'}^{\ell'}\int_0^\infty d\omega' \Big[& A^{\mathscr{I}^+}_{\omega\ell m\omega'\ell'm'}\, f^{\mathscr{I}^+}_{\omega'\ell'm'} + B^{\mathscr{I}^+}_{\omega\ell m\omega'\ell'm'}\, (f^{\mathscr{I}^+}_{\omega'\ell'm'})^* \\ & + A^{H^+}_{\omega\ell m\omega'\ell'm'}\, f^{H^+}_{\omega'\ell'm'} + B^{H^+}_{\omega\ell m\omega'\ell'm'}\, (f^{H^+}_{\omega'\ell'm'})^* \Big]. \end{aligned} \tag{6}$$

The matching coefficients $A^{\mathscr{I}^+}_{\omega\ell m\omega'\ell'm'}$, $B^{\mathscr{I}^+}_{\omega\ell m\omega'\ell'm'}$, $A^{H^+}_{\omega\ell m\omega'\ell'm'}$, and $B^{H^+}_{\omega\ell m\omega'\ell'm'}$ can be found using the following scalar products on the Cauchy surface shown in Fig. 2.

$$A^{(\mathscr{I}^+,H^+)}_{\omega\ell m\omega'\ell'm'} = (f^{\text{in}}_{\omega\ell m}, f^{(\mathscr{I}^+,H^+)}_{\omega'\ell'm'}), \tag{7}$$

$$B^{(\mathscr{I}^+,H^+)}_{\omega\ell m\omega'\ell'm'} = -(f^{\text{in}}_{\omega\ell m}, (f^{(\mathscr{I}^+,H^+)}_{\omega'\ell'm'})^*). \tag{8}$$

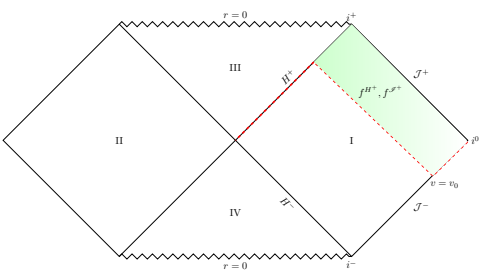

Fig. 2. Penrose diagram for Schwarzschild spacetime showing the Cauchy surface used for matching the in modes in the null shell spacetime to a complete set of modes in Schwarzschild spacetime in the region outside the past and future horizons. The Cauchy surface is denoted by the dashed red curve.

The reason one can expand the *in* modes in this way is that the same differential equations govern the evolution of the *in* modes in the shaded region in Fig. 1 and the shaded region in Fig. 2 because the metric is the same in both regions. However, one may notice that the union of the part of past null infinity with $v > v_0$ and the null shell surface does not form a Cauchy surface in pure Schwarzschild spacetime. We resolve this issue by adding the part of the future horizon with $-\infty < v < v_0$ to the union of $\mathscr{I}^-$ with $v > v_0$ and the null shell surface $v = v_0$, as shown in Fig. 2. We also need to specifity $\psi^{in}_{\omega\ell}$ on the Cauchy surface to evaluate the scalar products in Eqs. 7 and 8. On the part of the Cauchy surface with $v > v_0$ on past null infinity, $\psi^{in}_{\omega\ell} = e^{-i\omega v}$ and on the part where $v = v_0$, $\psi^{in}_{\omega\ell}$ is given by Eq. 5. For the part with $v < v_0$ on the future horizon, we can specify $\psi^{in}_{\omega\ell}$ any way we like so long as it is continuous at $v = v_0$.

Before computing the matching coefficients, we introduce a different complete set of modes that are defined by two linearly independent solutions to the radial mode equation in Schwarzschild spacetime with the following properties

$$\chi^{\infty}_{R} \to e^{i\omega r_*} , \qquad r_* \to \infty, \tag{9}$$

$$\chi^{\infty}_{L} \to e^{-i\omega r_*} , \qquad r_* \to \infty. \tag{10}$$

Near the horizon, they have the behaviors[21]

$$\chi^{\infty}_{R} \to E_R(\omega)e^{i\omega r_*} + F_R(\omega)e^{-i\omega r_*} , \qquad r_* \to -\infty, \tag{11}$$

$$\chi^{\infty}_{L} \to E_L(\omega)e^{i\omega r_*} + F_L(\omega)e^{-i\omega r_*} , \qquad r_* \to -\infty. \tag{12}$$

where E_R, E_L, F_R, and F_L are scattering parameters that can be determined numerically.

Evaluating the scalar products in Eqs. 7 and 8 gives the following results for the matching coefficients[18]

$$A^{H^+}_{\omega\omega' l} = -\frac{i}{2\pi}\sqrt{\frac{\omega'}{\omega}}\frac{e^{i\omega' v_0}}{\omega' - i\epsilon}\psi^{\rm in}_{\omega\ell}(v_H, v_0) + \frac{i}{2\pi}\sqrt{\frac{\omega'}{\omega}}\frac{1}{F^*_L(\omega', \ell)}\frac{e^{i(\omega'-\omega)v_0}}{\omega' - \omega + i\epsilon}$$
$$+ \frac{i}{2\pi\sqrt{\omega\omega'}}\int_{-\infty}^{v_H} du\ \left[\partial_u\psi^{\rm in}_{\omega\ell}(u, v_0)\right]\psi^{H^+}_{\omega'\ell}{}^*(u_s(u), v_0), \tag{13}$$

$$B^{H^+}_{\omega\omega' l} = \frac{i}{2\pi}\sqrt{\frac{\omega'}{\omega}}\frac{e^{-i\omega' v_0}}{\omega' + i\epsilon}\psi^{\rm in}_{\omega\ell}(v_H, v_0) - \frac{i}{2\pi}\sqrt{\frac{\omega'}{\omega}}\frac{1}{F_L(\omega', \ell)}\frac{e^{-i(\omega+\omega')v_0}}{\omega' + \omega - i\epsilon}$$
$$- \frac{i}{2\pi\sqrt{\omega\omega'}}\int_{-\infty}^{v_H} du\ \left[\partial_u\psi^{\rm in}_{\omega\ell}(u, v_0)\right]\psi^{H^+}_{\omega'\ell}(u_s(u), v_0). \tag{14}$$

$$A^{\mathscr{I}^+}_{\omega\omega' l} = -\frac{i}{2\pi}\sqrt{\frac{\omega'}{\omega}}\frac{F^*_R(\omega',\ell)}{F^*_L(\omega',\ell)}\frac{e^{-i(\omega-\omega')v_0}}{\omega'-\omega+i\epsilon}$$
$$-\frac{i}{2\pi\sqrt{\omega\omega'}}\int_{-\infty}^{v_H} du\,\left[\psi^{\rm in}_{\omega\ell}(u,v_0)-e^{-i\omega v_0}\right]\partial_u\psi^{\mathscr{I}^+}_{\omega'\ell}{}^*(u_s(u),v_0), \qquad (15)$$

$$B^{\mathscr{I}^+}_{\omega\omega' l} = \frac{i}{2\pi}\sqrt{\frac{\omega'}{\omega}}\frac{F_R(\omega',\ell)}{F_L(\omega',\ell)}\frac{e^{-i(\omega+\omega')v_0}}{\omega'+\omega-i\epsilon}$$
$$+\frac{i}{2\pi\sqrt{\omega\omega'}}\int_{-\infty}^{v_H} du\,\left[\psi^{\rm in}_{\omega\ell}(u,v_0)-e^{-i\omega v_0}\right]\partial_u\psi^{\mathscr{I}^+}_{\omega'\ell}(u_s(u),v_0). \qquad (16)$$

In the case $\ell = 0$, the *in* mode functions have the form $f^{in}_{\omega 00} = \frac{\psi^{in}_{\omega 00}}{r\sqrt{4\pi\omega}}$ where $\psi^{in}_{\omega 0} = e^{-i\omega v} - e^{-i\omega u}$ for $v \le v_0$. Note that the terms with closed form in Eqs. 13–16 (v-dependent terms) are the only terms that contribute to the v-dependent part of $f^{in}_{\omega 00}$ and the integral terms contribute to the u-dependent part of $f^{in}_{\omega 00}$. We used the v-dependent terms in the matching coefficients to construct $f^{in}_{\omega 00}$ on H^+. The numerical results are shown in Fig. 3 and Fig. 4. In Fig. 3, the real and imaginary parts of the v-dependent part of the *in* mode function have been numerically computed on H^+. The results show that *in* mode function is continuous across the null shell as expected. For large values of ω, the effective potential in the mode equation is always small compared to ω^2 and one can ignore the scattering effects. Hence, one should expect to see the same behaviour as in the 2D case where there are no scattering effects. This is shown to be correct in Fig. 4. where the real and imaginary parts of $f^{in}_{\omega 00}$ are plotted for $M\omega = 9$.

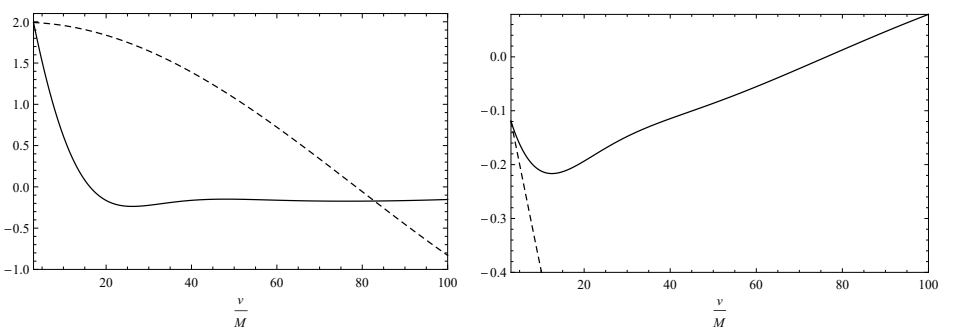

Fig. 3. Real part (left) and imaginary part (right) of $\psi^{in}_{\omega 00}(v)$ on H^+ for $v > v_0$. $\frac{v_0}{M} = 3$ and $M\omega = 0.02$. The dashed lines and solid lines correspond to the *in* modes in the 2D and the 4D cases respectively.

5. Stress-energy tensor and renormalization

One can renormalize the stress-energy tensor by subtracting from the unrenormalized expression for the stress-energy tensor for the in vacuum state, the unrenor-

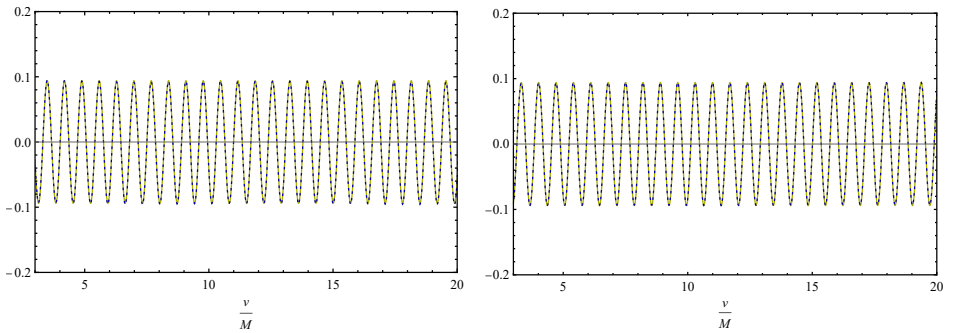

Fig. 4. Real part (left) and imaginary part (right) of $\psi^{in}_{\omega 00}(v)$ on H^+ for $v > v_0$. $\frac{v_0}{M} = 3$ and $M\omega = 9$. The dashed blue lines and solid yellow lines correspond to the *in* modes in the 2D and the 4D cases respectively.

malized stress-energy tensor for the Unruh state. Since the renormalization counterterms are local and thus do not depend on the state of the quantum field, this quantity will be finite. Then one can add back the unrenormalized stress-energy tensor for the Unruh state and subtract from it the renormalization counter terms. Schematically one can write

$$\langle \text{in}|T_{ab}|\text{in}\rangle_{\text{ren}} = \Delta\langle T_{ab}\rangle + \langle U|T_{ab}|U\rangle_{\text{ren}}, \tag{17}$$

where $\Delta\langle T_{ab}\rangle = \langle \text{in}|T_{ab}|\text{in}\rangle_{\text{unren}} - \langle U|T_{ab}|U\rangle_{\text{unren}}$. Note that the Unruh state is defined by a set of modes that are positive frequency on the past horizon with respect to the Kruskal time coordinate and the set of modes that have the form $\psi_{\omega\ell} = e^{-i\omega v}$ on past null infinity. The quantity $\langle U|T_{ab}|U\rangle_{\text{ren}}$ has been numerically computed for a massless minimally coupled scalar field in Schwarzschild spacetime. Thus what remains is to compute the difference between the unrenormalized expressions.

The unrenormalized stress-energy tensor can be computed by taking derivatives of the Hadamard Green's function as follows,[22]

$$\langle T_{ab}\rangle_{\text{unren}} = \frac{1}{4}\lim_{x'\to x}\left[\left(g_a^{c'}G^{(1)}_{;c';b}(x,x') + g_b^{c'}G^{(1)}_{;a;c'}(x,x')\right) - g_{ab}\,g^{cd'}G^{(1)}_{;c;d'}(x,x')\right], \tag{18}$$

where the quantity $g_a^{b'}$ parallel transports a vector from x' to x and is called the bivector of parallel transport.

5.1. *Stress-energy tensor in 2D*

In this section, we show how our method can be applied to the case of a 2D null shell spacetime which has a perfectly reflecting mirror at $r = 0$. There is no scattering

that means $E_R = F_L = 1$ and $E_L = F_R = 0$. The matching coefficients are,[18]

$$A^{\mathscr{I}^+}_{\omega\omega'} = -\frac{1}{2\pi}\sqrt{\frac{\omega}{\omega'}}(4M)^{i4M\omega'}e^{-i(\omega-\omega')v_H}\frac{\Gamma(1-i4M\omega')}{[-i(\omega-\omega')+\epsilon]^{1-i4M\omega'}}, \tag{19}$$

$$B^{\mathscr{I}^+}_{\omega\omega'} = \frac{1}{2\pi}\sqrt{\frac{\omega}{\omega'}}(4M)^{-i4M\omega'}e^{-i(\omega+\omega')v_H}\frac{\Gamma(1+i4M\omega')}{[-i(\omega+\omega')+\epsilon]^{1+i4M\omega'}}. \tag{20}$$

The expression for f^{in}_ω can be obtained by substituting Eqs. 19 and 20 into Eq. 6. Those for f^{Unruh}_ω can be obtained using similar expressions. See Ref. 18 for more details. Next, we construct the Hadamard form of the Green's function which in 2D is

$$G^{(1)}_{in}(x,x') = \int_0^\infty d\omega\ [f^{in}_\omega(x)f^{in\,*}_\omega(x') + f^{in\,*}_\omega(x)f^{in}_\omega(x')]\ . \tag{21}$$

We subtract off the corresponding expression for the Unruh state to obtain

$$\Delta G(x,x') = G^{(1)}_{in}(x,x') - G^{(1)}_{\text{Unruh}}(x,x'),$$

which gives

$$\Delta\langle T_{tt}\rangle = -(1-\frac{2M}{r})\lim_{x'\to x}\frac{1}{4}(\Delta G_{;t';r} + \Delta G_{;t;r'}). \tag{22}$$

Our method results in a complicated operation for $\Delta\langle T_{tt}\rangle$ which initially contains a triple integral. One of the integrals can be computed in closed form with the result[18]

$$\begin{aligned}\Delta\langle T_{tt}\rangle = \Re\Bigg\{ &\frac{i}{8\pi^3}\int_0^\infty d\omega_1\ \int_0^\infty d\omega_2\ e^{-2\pi M(\omega_1+\omega_2)} \\ &\times\Bigg\{ e^{i(\omega_2-\omega_1)u_s}\frac{(4M\omega_1 e^{\frac{v_H}{4M}})^{4iM\omega_1}}{(4M\omega_2 e^{\frac{v_H}{4M}})^{4iM\omega_2}}\frac{\Gamma(1-4iM\omega_1)\Gamma(1+4iM\omega_2)}{4M(\omega_1-\omega_2-i\epsilon)} \\ &+ e^{-i(\omega_2+\omega_1)u_s}(4M\omega_1 e^{\frac{v_H}{4M}})^{4iM\omega_1}(4M\omega_2 e^{\frac{v_H}{4M}})^{4iM\omega_2} \\ &\times\frac{\Gamma(1-4iM\omega_1)\Gamma(1-4iM\omega_2)}{4M(\omega_1+\omega_2)}\Bigg\}\Bigg\}\ .\end{aligned} \tag{23}$$

This quantity has been computed numerically and the results are shown in Fig. 5. The stress-energy tensor for a massless minimally coupled scalar field in the 2D collapsing null shell spacetime has been previously computed analytically using a different method[19,20,23–25] and the stress-energy tensor for the Unruh state has also been computed analytically.[19,20,23–30] Our results are shown with the dots in Fig. 5 and the result found by using previous methods is shown with a solid curve. They agree to more than ten digits. It is worth mentioning that in 2D, once $\Delta\langle T_{tt}\rangle$ is numerically computed, $\Delta\langle T_{rr}\rangle$ and $\Delta\langle T_{rt}\rangle$ can be easily determined.[18]

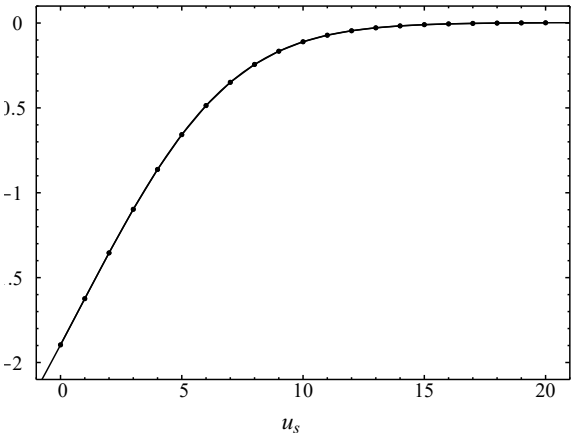

Fig. 5. The quantity $10^4 M^2 \langle T_{tt} \rangle$ is plotted for the massless minimally coupled scalar field in the region exterior to the null shell and to the event horizon. The dots correspond to the results of the numerical computations. The solid curve represents the analytic results in (reference).

6. Summary

We have reviewed a method of computing the stress-energy tensor for a massless minimally-coupled scalar field in a spacetime in which a spherically symmetric black hole is formed by the collapse of a null shell. This method primarily involves two parts. One part is the expansion of the *in* mode functions in terms of a complete set of modes in the part of a Schwarzschild black hole that is outside the event horizon. The matching coefficients of the expansion have been found in terms of the integrals of the mode functions and closed form terms. These matching coefficents have been used to numerically compute part of the *in* mode function on the future horizon of the black hoe.

The second part of the method is the renormalization of the stress-energy tensor which involves taking the difference between the stress-energy tensor for the "in" state in the collapsing null shell spacetime and that for the Unruh state in the Schwarzschild spacetime. Finally, we reviewed the computation of the stress-energy tensor in the corresponding 2D case using aformentioned method.

Acknowledgment

P. R. A. would like to thank Eric Carlson, Charles Evans, Adam Levi, and Amos Ori for helpful conversations and Adam Levi for sharing some of his numerical data. A.F. acknowledges partial financial support from the Spanish Ministerio de Ciencia e Innovación grant FIS2017-84440-C2-1-P and from the Generalitat Valenciana grant PROMETEO/2020/079. This work was supported in part by the National Science Foundation under Grants No. PHY-1308325, PHY-1505875, and PHY-1912584 to Wake Forest University. Some of the numerical work was done

using the WFU DEAC cluster; we thank the WFU Provost's Office and Information Systems Department for their generous support.

Einstein equations projected on black-hole horizons give rise to the equations of motion of a viscous fluid. This suggests a way to understand the microscopic degrees of freedom on the black-hole horizon by focusing on the physics of this fluid. In this talk, we shall approach this problem by building a crude microscopic model for the Horizon-fluid(HF) corresponding to asymptotically flat black-holes in 3+1 dimensions. The symmetry requirement for our model is that it should incorporate the S1 diffeo-symmetry on the black-hole horizon. The second constraint comes from the demand that the correct value of the Coefficient of the Bulk Viscosity of the HF can be deduced from the model. Both these requirements can be satisfied by an adoption of the eight vertex Baxter model on a S2 surface. We show that the adiabatic entropy quantisation proposed by Bekenstein also follows from this model. Finally, we argue the results obtained so far suggest that a perturbed black-hole can be described by a CFT perturbed by relevant operators and discuss the physical implications.

Keywords: Black Hole; Horizon-fluid; Bulk Viscosity; deformed CFT.

1. Introduction

Gravity, quantum theory, and thermodynamics[1–3] are related at some fundamental level. The laws of black-hole mechanics are formally similar to the Laws of Thermodynamics and suggest that black-holes have entropy and temperature.[4–8] A satisfactory explanation of black-hole thermodynamics requires a statistical mechanical origin of entropy. It has been argued that most of the black-hole degrees of freedom (DOF) reside on the horizon, as the black-hole entropy scales as area.[1,9] Also, black-hole thermodynamics deals only with equilibrium states.

Gravity causes the non-stationary black-hole horizon to interact with external fields (perturbations) continually. These interactions lead to the transfer of energy from the external fields to black-hole degrees of freedom. If we compute observables involving black-hole, we observe *dissipative* effects corresponding to interaction with fields. In macroscopic black-hole physics, this can be explicitly seen by projecting the equations of motion of external fields and gravity theory on the black-hole

event horizon leading to dissipative equations. In these scenarios, fluid dynamics description is useful as only average quantities resulting from the interactions at the microscopic level are observed on macroscopic scales.[10] Interestingly, it was shown black-hole horizon behaves like a viscous fluid and satisfies Damour-Navier-Stokes equation.[11–13]

Since we do not have a consistent model of quantum gravity, we explore here the viability of certain ideas in the context of a toy model for the non-stationary black-hole horizon that is slightly perturbed from stationarity. The toy model we construct takes into account *two different aspects of the black-hole horizon.* First, the model incorporates near-horizon symmetries of the stationary black-hole.[14–20] Second, the model accounts for the physics of transport phenomena of horizon-fluid.[21,22]

The first aspect is the constraint of symmetry on the microscopic theory. Thus, for example, we demand that the model must incorporate near-horizon symmetries. The second aspect can be viewed as the expectation that the transport phenomena exhibited by the horizon-fluid corresponding to a black-hole in the hydrodynamic limit should follow from this model.

A Conformal Field Theory (CFT) on the black-hole horizon can partly incorporate the near-horizon symmetries and is a natural candidate for the microscopic theory of stationary black-holes. We extend the analysis and show that a perturbed CFT can also incorporate this symmetry. Thus in our model, a non-stationary black-hole can be viewed as interacting with external fields. For the microscopic description, this means adding interaction terms to the stationary black-hole described by CFT. We can see this process as a perturbed black-hole relaxing to a stationary black-hole by emitting QNMs.[23] In practice, we shall deform the CFT by introducing only a mass term. However, it plays a vital role by determining the infra-red cutoff for the theory and, as a consequence, also determining the value of the coefficient of Bulk Viscosity, ζ.

We focus only on the Bulk Viscosity here, which means we only consider homogeneous processes, e.g., the increase of black-hole area in a spherically symmetric space-time due to infalling spherical mass shell. Modeling such processes is comparatively easier. Stationary, non-extremal black-holes in 4-dimensional general relativity exhibit an infinite-dimensional symmetry in the near-horizon region.[14–20,24,25] Thus, the near-horizon possess infinite-dimensional algebra such as $\mathcal{S}1$ diffeomorphism[19,20] or (near) BMS.[25–28] The CFT describing a stationary black-hole can incorporate the $\mathcal{S}1$ diffeosymmetry[19,20] as it possesses a representation of the Virasoro algebra.[20,29]

The perturbed CFT we choose possesses symmetries that lead to a representation of the Virasoro algebra.[30] These are *Integrable field theories* with an infinite number of conserved charges corresponding to an infinite number of symmetries.[31] The crucial point that allows us to model the black-hole horizon-fluid by such a perturbed CFT model is that one of the representations of the Virasoro algebra corresponding to the perturbed CFT is also a representation of the $\mathcal{S}1$

diffeomorphism symmetry. Throughout what follows, we use natural units setting $\hbar = c = G = k_B = 1$.

2. The microscopic model

We consider here the *Eight-vertex Baxter model*[32–37] for our purpose. We show that this model exhibits both the two aspects discussed above. The model has the following properties that form crucial ingredients for the microscopic model building of the horizon-fluid: First, it possesses *lattice* Virasoro algebra corresponding to $\mathcal{S}1$ diffeomorphism symmetry.[38,39] Second, it consists of two staggered 2D Ising lattices, and its free energy density is the same as that of the 2D Ising model. However, the two-sublattice symmetry is very different from that of the usual Ising model. Hence, the Baxter solution's critical indices are, in general, different from that of Ising.[38] Third, it exhibits a second-order phase transition. In the continuum limit, it is an Integrable Field Theory near the critical point and is a CFT at the critical point.[39–41]

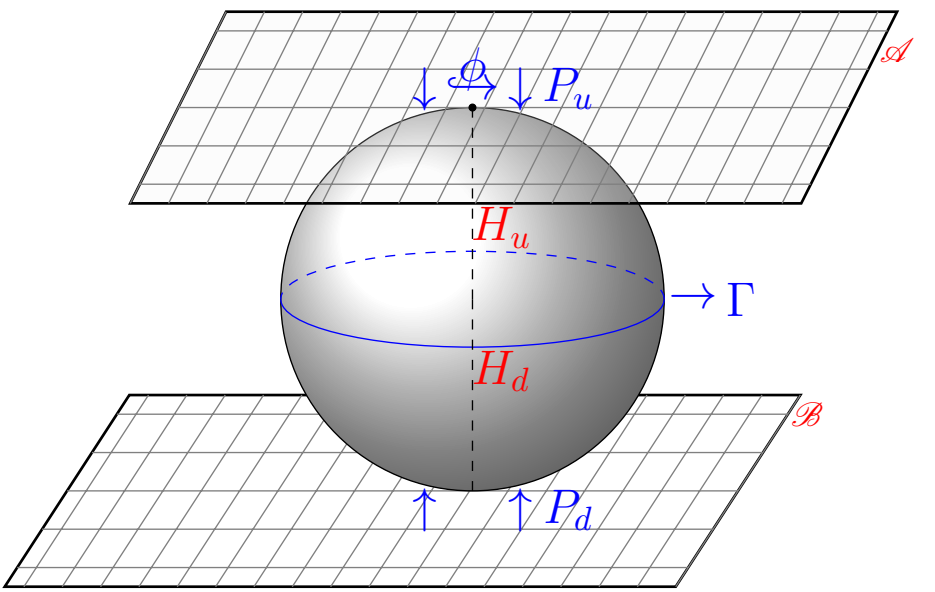

Fig. 1. The projection of the 8-vertex Baxter model from the two sub-lattices to S^2 surface of the horizon.

The Baxter model can be adapted to the cross-section of a black-hole event-horizon, a S^2 surface. As shown in 1, this model can be adopted on the two hemispheres of the S^2 surface through projection from two Baxter lattices. Let P_u (P_d) denote the map corresponding to the projection $\mathcal{A} \to H_u$ ($\mathcal{B} \to H_d$). For the

consistency of the model, we need to impose the condition $P_u^{-1} \circ \{\Gamma\} \equiv P_d^{-1} \circ \{\Gamma\}$, where, P^{-1} denotes the inverse map and Γ is equatorial plane of the S^2 surface.

The above condition retains the periodic boundary condition of the Baxter model. The projection allows relating the Euclidean boost parameter of the Baxter model[41] to the azimuthal angle in the spherical polar coordinate. We can then relate the Virasoro algebra (corresponding to the $\mathcal{S}1$ diffeomorphism) of the Euclidean boost parameter to the $\mathcal{S}1$ diffeomorphism of the azimuthal angle in the horizon-fluid model. Thus, the projection retains the model's main physical features[41] and *directly* incorporates a representation of the $S1$ diffeosymmetry in the model. *It is simply the diffeosymmetry of the azimuthal angle for the black-hole system.*

3. Eight-vertex model and deformed CFT

The Eight-vertex model has eight possible arrangements of arrows at a vertex with four distinct Boltzmann weights a, b, c, d. These satisfy two constraints:[37]

$$\frac{cd}{ab} = \frac{1-\Gamma}{1+\Gamma} \; ; \; \frac{a^2+b^2-c^2-d^2}{2(ab+cd)} = \Delta \tag{1}$$

For constant Γ and Δ, there exists a one-parameter family of Boltzmann weights (w) which satisfy the star–triangle relations and, hence, the eight-vertex model has a one-parameter family of commuting transfer matrices.[37] This allows one to parameterize the Boltzmann weights explicitly in terms of *spectral variable* (u):

$$\begin{aligned} a &= \mathrm{snh}(\lambda - u) \; b = \mathrm{snh}\, u \\ c &= k\,\mathrm{snh}\,\lambda, \qquad d = k\,\mathrm{snh}(\lambda - u) \end{aligned} \tag{2}$$

where, k is the elliptic modulus, and snh is the hyperbolic analogue of sn and is given by $\mathrm{snh}\;\; u = -i\;\; \mathrm{sn}(iu)$. It has been shown that the transfer matrix of the eight-vertex model commutes with the XYZ Hamiltonian:[43]

$$H_{\mathrm{XYZ}} = -\frac{1}{2}\sum_{j=1}^{N} J_\sigma \sigma_j^\sigma \sigma_{j+1}^\sigma \quad \text{where} \quad \sigma = x, y, z\,. \tag{3}$$

The coupling constants are related to the weights by the relation: $J_x : J_y : J_z = 1 : \Gamma : \Delta$. The spins σ_n's are related to the vertex weights by the vertex operator (V_n):

$$V_n = \frac{1}{2}\left[a + c + [a-c]\sigma_n^z \sigma_{n+1}^z + [b+d]\sigma_n^x \sigma_{n+1}^x + \sigma_n^y \sigma_{n+1}^y\right]$$

where,

$$\begin{aligned} a &= \exp\left[K_1 + K_2 + K''\right], \\ b &= \exp\left[-K_1 + K_2 + K''\right], \\ c &= \exp\left[-K_1 + K_2 - K''\right], \\ d &= \exp\left[K_1 - K_2 - K''\right]. \end{aligned} \tag{4}$$

The Hamiltonian of the Baxter model is:

$$H_{\text{Baxter}} = \sum_{\sigma} \left[K_1 \, \sigma_1 \sigma_3 + K_2 \, \sigma_2 \sigma_4 + K'' \, \sigma_1 \sigma_2 \sigma_3 \sigma_4 \right] \tag{5}$$

where σ_1, σ_3 (σ_2, σ_4) are the lattice spins in one (second) Ising sublattice with coupling constant K_1 (K_2) as shown in 2, and K'' refers to the four-spin coupling that connects the two sublattices.

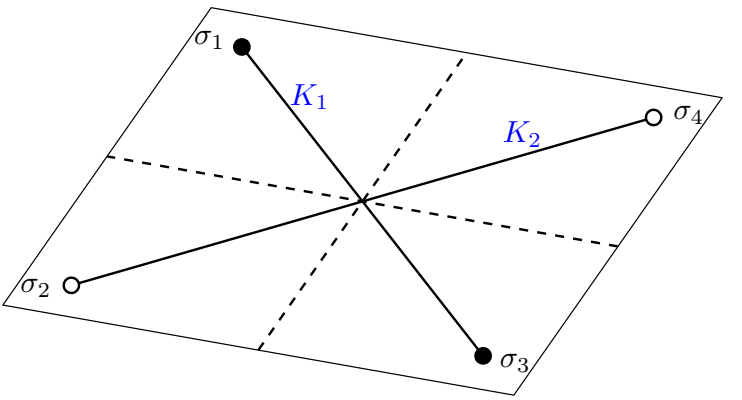

Fig. 2. A single face of the 8-Vertex Baxter model in the spin formulation. K_1 and K_2 are the horizontal and vertical spin-spin couplings of the two Ising sublattices.

It is possible to obtain the statistical weight (partition function) in the row-to-row transfer matrix and corner transfer matrix formulations.[37] In our case, it is convenient to use the corner transfer matrix (CTM) formulation as it directly connects the algebra with the conserved charges.

CTM can be expressed conveniently in terms of Fermions described by the following XYZ spin-chain Hamiltonian.[37,39–41] In this formulation, the partition function is evaluated by choosing a spin in the middle of the lattice and fixing the spins along the vertical and horizontal axes while summing over all spins in the interior of each quadrant.[37] The final sum over the spins along the axes may be interpreted as the trace of a product of four corner transfer matrices.

Thus we see that the eight vertex Baxter model is closely related to the XYZ spin chain. Now we can map it to a theory of Fermions by introducing the Corner Transfer Matrix(CTM).

The CTM operator can be viewed physically as connecting semi-infinite rows of arrows with a semi-infinite column of arrows of one quadrant of the lattice. In the thermodynamic limit, the following relation holds:[37]

$$\mathcal{A}(u) = \exp\left[-\frac{\pi u}{2K} \, \mathcal{L}_0 \right] , \tag{6}$$

where K is a complete elliptic integral associated with modulus k and

$$\mathcal{L}_0 = \frac{2K}{\pi} \sum_{j=-\infty}^{\infty} j\mathcal{H}_{XYZ}(j, j+1). \tag{7}$$

$\mathcal{H}_{XYZ}$ corresponds to the Hamiltonian of a spin chain with nearest neighbour (3) To keep the calculations transparent, we set $\Gamma = 0$, i.e., $cd = ab$ in (1). This corresponds to the condition $J_z = 0$ in the Hamiltonian (3) which is the well-known XY model.[37] $\mathcal{L}_0$ in Eq. (7) is diagonalized by the operators:

$$\Psi(l) = N_l \int d\alpha \, e^{-\imath\alpha l\pi/2K} \chi(\alpha) \tag{8}$$

where N_l is the normalization constant, and $\chi(\alpha) = \mathrm{sn}\,\alpha\, a^{\alpha}(\alpha) + \imath\sqrt{k}\,\mathrm{cn}\,\alpha\, a^{y}(\alpha)$. The integration over α is over one complete real period of the elliptic functions from $-2K + \imath K'/2$ to $2K + \imath K'/2$. Itoyama and Thacker showed that $\mathcal{L}_0$ could be expressed as

$$\mathcal{L}_0 = \sum_l l : \bar{\Psi}(l)\Psi(l) : + h\,, \tag{9}$$

where, h is a constant. $\mathcal{L}_0$ is embedded into a Virasoro algebra as a central element.[39–41] The normal ordering is defined by the relations, $\Psi(l)|h\rangle = 0(\forall\ l \geq 1), \overline{\Psi}(l)|h\rangle = 0, (\forall\ l \leq 1)$. Other Virasoro operators $\mathcal{L}_n$ can be constructed from these momentum space operators.[41] From (8), it follows that,

$$[\mathcal{L}_n, \mathcal{L}_m] = (n-m)\mathcal{L}_{n+m} + \frac{1}{12}c(n^3 - n)\delta_{n+m,0}. \tag{10}$$

As noted in Ref.,[41] the physical Hilbert space built from the state $|h\rangle$, forms the highest weight representation of the Virasoro algebra. Since the eigenvalues of $\mathcal{L}_0$ are doubled due to the zero modes of the operator $\Psi(0)$ and $\overline{\Psi}(0)$, the highest weight vector forms a two-dimensional representation under parity conjugation. At the critical point, the central charge $c = 1$ and $h = \frac{1}{8}$.

Using the following classical generators (l_n^{Diff}),

$$l_n^{Diff} = -\frac{1}{2}\zeta^{n+1}\frac{d}{d\zeta} - \frac{1}{2}\frac{d}{d\zeta}\zeta^{n+1}. \tag{11}$$

we can obtain other Virasoro algebra, different from the one described above. The difference is that l_n^{Diff} are generators of diffeo-transformation of the spectral rapidity parameter or the Euclidean boost parameter (α).[41,44] We can then construct the corresponding Virasoro algebra by defining the following $\mathcal{L}_n^{diff}$:

$$\begin{aligned}\mathcal{L}_n^{diff} &= : \int_{-K}^{3K} \frac{d\beta}{2\pi} B(\beta + 2K - \imath K')l_n B(\beta) : + h\delta_{n,0} \\ &= \sum_l \left(l + \frac{n-1}{2}\right) : \bar{\psi}(l)\psi(l+n) : + h\delta_{n,0}.\end{aligned} \tag{12}$$

This demonstrates that the eight-vertex model possesses the Virasoro algebra given by (12), which holds the key to incorporating near-horizon $S1$ diffeo-symmetry in the model of the horizon-fluid. The 2-D Euclideanized space-time (τ, q) can be identified with the 2-D Euclidean space (x_1, x_2) on which the horizon-fluid resides. The rapidity or the boost parameter in a Euclideanized space-time corresponds to an angle of rotation. A closer look reveals that in our case, the rapidity is the azimuthal angle (See (1)). Thus, l_n^{Diff} diffeomorphism algebra of the spectral rapidity corresponds to the l_n^{Diff} diffeomorphism symmetry on the black-hole horizon. Thus we see that the microscopic modelling of the horizon-fluid with a mass gap incorporates the l_n^{Diff} diffeomorphism symmetry on the black-hole horizon.

4. Continuum limit and modelling horizon-fluid

Long-range effects dominate the critical properties of this model; hence, a continuum approximation will suffice for our purpose. The eight-vertex model's continuum limit is a theory of massive Dirac Fermions (Ψ_1, Ψ_2)[41]

$$\mathcal{S}_{\text{Dirac}} = \int d\tau dq \left[\frac{1}{2} i\overline{\Psi}_1 \Big(\frac{\overleftrightarrow{\partial}}{\partial \tau} + \frac{\overleftrightarrow{\partial}}{\partial q} \Big) \Psi_1 + \frac{1}{2} i\overline{\Psi}_2 \Big(\frac{\overleftrightarrow{\partial}}{\partial \tau} - \frac{\overleftrightarrow{\partial}}{\partial q} \Big) \Psi_2 - m(\bar{\Psi}_1 \Psi_2 + \bar{\Psi}_2 \Psi_1) \right]. \tag{13}$$

The above action possesses an infinite sequence of conserved densities. Physically, this implies that besides the total angular momentum, the entire momentum distribution is conserved.[41] We can rewrite these operators as integrals of local densities in coordinate space:

$$\mathcal{L}_n = \int dq \, J_0^{(n)}(q) \,, \tag{14}$$

where J_0 is the zeroth component of a conserved current. $J_0^{(-1)}$ is the Hamiltonian plus the momentum operator, and $J_0^{(0)}$ (at $\tau = 0$) is the first moment of the Dirac Hamiltonian.[41] Integrability ensures the operators are related to the infinite sequence of conserved charges, with one for each new $\mathcal{L}_n$.[41]

The action (13) is useful to identify the infinite number of conserved charges. However, for our purpose here, starting from the action (13) it is cumbersome to look at the hydrodynamic or long-wavelength properties. Hence, to derive ζ, we will not make direct use of the action (13). Instead, to make contact with the macroscopic level, i.e., Damour's fluid description, we turn to the fact that the Free-energy density of the Baxter model is the same as that of a classical Ising model in 2-dimensions near the critical point.[37] On the other hand, the theory of the 2-dimensional Ising model can be described by a theory of a free massive scalar field φ in a two-dimensional Euclidean spacetime.[45] The key is to identify the microscopic field with the phenomenological order parameter.

The task of identifying the microscopic field with the phenomenological order parameter is non-trivial. For the transport theory, we need to describe the dynamics of the black-hole horizon, starting from a $(2+1)-$dimensional Hamiltonian.

However, the microscopic model we have constructed is characterized by the *2-D Euclidean space-time Hamiltonian*. This means that the microscopic model suffices to describe the quantum states for a system in thermal equilibrium with the desired accuracy but is inadequate if we consider how the system evolves with time. In other words, such Hamiltonians do not contain information about the dynamics of the black-hole horizon.

There are two ways to tackle this issue. Both approaches keep the thermal states the same but provide different inputs about the dynamics of the system. One way is to assume that a phenomenological Langevin equation gives the dynamics. From this, one can work out the transport theory and compute the correct coefficient of Bulk Viscosity for the Horizon-fluid. The other approach is to construct a $(2+1)-$dimensional Hamiltonian with the same symmetries as the mass gap possessed by the 2-D Euclidean space-time Hamiltonian. For a general process, this is a challenging problem. Fortunately, this difficulty is bypassed for the processes describing bulk viscosity of the fluid using the mean-field theory description. We should emphasize that in this case also, the thermal states remain the same. (The collection of the thermal states of the $(2+1)-$dimensional theory is equivalent to collecting the quantum states of the $1+1$ dimensional Euclideanized theory subject to appropriate boundary conditions.) We shall only discuss the second approach here as a Langevin-type equation can also be derived from the dynamical quantum theory under suitable approximation.

The mean-field description will not capture all the details of the symmetries of the quantum states of the model or can reproduce the correct scaling exponents; however, it works satisfactorily to describe horizon-fluid properties. Thus, the 2-D mean-field theory Hamiltonian of the microscopic model can be extended to the following $2+1$ dimensional space-time Hamiltonian:

$$H_{\text{eff}}(\varphi) = \int \left[\frac{1}{2}\big(\frac{\partial\varphi}{\partial t}\big)^2 + \frac{1}{2}\big(\nabla\varphi\big)^2 + \frac{m_{eff}^2}{2}\varphi^2\right] dA, \tag{15}$$

where the integral is over the area of the event horizon. The above Hamiltonian satisfies the essential requirement of possessing $Z2$ symmetry. Still, it suffers from the weakness that there is very little guidance otherwise in terms of symmetry requirements. One can view the above Hamiltonian as a Mean-Field description of the horizon-fluid near a critical point.

We are now in a position to identify the above Hamiltonian (15) with the horizon-fluid. As a first step, we write down the Landau-Ginzburg expression for the entropy functional corresponding to the horizon-fluid instead of using the Free Energy functional.[46] This is because the black-hole (of horizon area A) constantly interacts with the environment, leading to energy flow. Thus, we need a framework in which the energy density and the order parameter appear in the formalism on the same footing. As shown in Ref.,[46] the appropriate thermodynamic potential to consider in such a case, is the entropy functional and not free energy. The stationary state of the black-hole corresponds to the thermodynamic equilibrium state of the black-hole

with maximum entropy. The quasi-stationary state of a black-hole corresponds to the vacuum of the deformed CFT.

Following,[21] we assume that the entropy density of the horizon-fluid is homogeneous. We focus on a macroscopically small but finite element of the black-hole horizon area, denoted as $\mathcal{A}$. $\mathcal{A}$ satisfies the condition $\mathcal{A}/A \ll 1$. The order parameter (η) is taken to be:

$$\eta = C\sqrt{\mathcal{A}}\,.$$

We can fix the value of the constant C only by relating it to a macroscopic quantity. The entropy functional $(\mathcal{S})$ of the horizon-fluid of this finite element about $(T, \mathcal{A})$ is given by:[46]

$$\mathcal{S} = \mathcal{S}_0(T, \mathcal{A}) - a\,\eta^2 - b\,\eta^4, \tag{16}$$

where a, b are constants. Let the value of the entropy functional $\mathcal{S}$ in the quasi-stationary state by $\mathcal{S}_{QS}$ and the stationary state by $\mathcal{S}_S$, respectively. Note that $\mathcal{S}_S$ is the global maximum for entropy functional $\mathcal{S}$. We assume that the process of going from $\mathcal{S}_{QS}$ to $\mathcal{S}_S$ is a slow physical process so that we can use equilibrium thermodynamics to describe the quasi-stationary state. For the microscopic model of the horizon-fluid, this means that the ground state of the deformed CFT evolves slowly into a state of CFT. The slow evolution implies that the deformed CFT vacuum is likely to possess some of the symmetries of a CFT state. This is reminiscent of the adiabatic evolution of a quantum state.

Rewriting (16) in terms of the horizon-area at equilibrium, we get,

$$\begin{aligned} S_{\max} = \frac{\mathcal{A}_{\max}}{4} &= \mathcal{S}_0 - a\,C^2\mathcal{A}_{\max} - b\,C^4\mathcal{A}_{\max}^2\,, \\ \text{where}\quad a = -\frac{1}{4C^2};&\quad \mathcal{S}_0 - b\,C^4\,\mathcal{A}^2 = 0\,. \end{aligned} \tag{17}$$

Denote the deviation of any variable from its equilibrium value by a prefix δ. The change in the entropy functional is related to the change in the energy density of the horizon-fluid:

$$\delta\mathcal{H}(\delta\eta) = -T\,\delta\mathcal{S} = \frac{T}{2C^2}\delta\eta^2. \tag{18}$$

where we have $k_B = 1$. [Expansion around the maximum implies that the terms proportional to $\delta\eta$ cancel out as the expansion is being done around a maximum value of the entropy function. This leads to the condition $2b\eta_{max}^2 = -a$. Substituting this in the terms quadratic in $\delta\eta$, i.e. $(a{+}2b\eta_{max}^2)\delta\eta^2)$ leads to the above expression.]

Using the above expression, we can relate the order parameter (η) with the scalar field (φ) and the change in the energy density of the horizon fluid $(\delta\mathcal{H}(\delta\eta))$ with $H_{\text{eff}}(\varphi)$ (15), i.e.

$$\delta H = \int dA\,\delta\mathcal{H} = \delta H_{\text{eff}}\,. \tag{19}$$

For the homogeneous process, the spatial gradient terms in the Hamiltonian (15) can be ignored. Also, the field is taken to vary slowly so the kinetic term in the Hamiltonian (15) can be ignored. Using the universality near critical point, we have:[37,41]

$$\langle\varphi_*\rangle = \frac{\delta\eta}{\sqrt{\mathcal{A}}}, \tag{20}$$

where, $\langle\varphi_*\rangle$ is the average value of the field φ_* in the area $\mathcal{A}$. As seen from the above expression, φ_* is dimensionless, and is related to φ as follows: $\varphi = \sqrt{\Upsilon}\varphi_*$ where Υ has the dimensions of energy. The change in the energy of the horizon fluid is given by:

$$\delta H = \frac{\Upsilon}{2}\int dA\, m_*^2\,\varphi_*^2, \quad \text{where} \quad m_* = \frac{1}{C} \quad \text{and} \quad \Upsilon = T \tag{21}$$

Thus, we have made the connection between the microscopic model with black-hole thermodynamics. m_* has the dimensions of energy, i.e., $m_* = 1/(l_P^2\, C)$, l_P being the Planck length. C is dimensionless. Note that we have set $l_P = 1$. In the next section, we evaluate the correlations for this process (bulk viscosity). The thermal correlations considered here remain the same for Hamiltonian corresponding to action (13) and H_{eff}.

5. Bulk viscosity from the microscopic model

We use the above mean-field theory description to calculate the viscosity coefficient of the horizon-fluid from the correlations of the energy-momentum tensor of the scalar field given by the Hamiltonian (15). Jeon has developed such a description.[42] First, however, we need to make suitable changes to apply to the horizon-fluid.

According to Jeon, the coefficient of bulk-viscosity (ζ) of a viscous-fluid with stress-tensor is:[42]

$$\zeta = \frac{\beta}{2}\lim_{\omega\to 0}\lim_{\mathbf{q}\to 0}\sigma_{\bar{P}\bar{P}}, \tag{22}$$

where, $\sigma_{\bar{P}\bar{P}}$ is given by

$$\sigma_{\bar{P}\bar{P}}(\omega,\mathbf{q}) = \frac{1}{2\pi\mathcal{A}}\int d^2\mathbf{x}\int_{-\infty}^{\infty} dt e^{-i\mathbf{q}.\mathbf{x}+i\omega t}\langle\bar{P}(t,\mathbf{x})\bar{P}(0)\rangle, \tag{23}$$

where $\mathcal{A}$ is the area normalization of the spatial part,

$$\bar{P}(t,\mathbf{x}) = P(t,\mathbf{x}) - v_S^2\rho(t,\mathbf{x}) = \frac{1}{2}T_i^i(x^\mu) - v_S^2 T_{00}(x^\mu). \tag{24}$$

and v_S is the speed of sound of the field.

To apply this formalism to horizon-fluid, we need to make suitable changes in the formulation. As mentioned earlier, the stress-tensor of the horizon-fluid vanishes as the infalling matter-energy reaches the horizon and the horizon becomes quasi-stationary.[11–13] In other words, when the matter reaches an equilibrium at

a given temperature, the stress-tensor of the horizon-fluid is zero. Thus, the field-theoretic description of the horizon-fluid corresponds to the deviation of the energy-momentum tensor of the field ($T^H_{\mu\nu}$) from its thermal average at the thermal state ($\langle T^H_{\mu\nu}\rangle_{\rm equilibrium}$). In the case of normal-fluid, we use the stress-tensor (cf. 23). For the horizon-fluid on the other hand, the key quantity is the deviation of the energy-momentum tensor of the field, i.e.,

$$\delta T^H_{\mu\nu} = T^H_{\mu\nu} - \langle T^H_{\mu\nu}\rangle_{\rm equilibrium}\,.$$

Physically, this corresponds to the state when the expectation value of the stress-energy tensor of the perturbed CFT on the horizon is the thermal average. Thus, for the horizon-fluid, Eqs. (23) and (24) become:

$$\delta P(\bar{t},\mathbf{x}) = \frac{1}{2}\delta T^i_i(x^\mu) - \delta T_{00}(x^\mu) \tag{25}$$

$$\sigma_{\delta\bar{P},\delta\bar{P}}(\omega,\mathbf{q}) = \frac{1}{2\pi\mathcal{A}}\int d^2\mathbf{x}\int_{-\infty}^{\infty} dt e^{-i\mathbf{q}\cdot\mathbf{x}+i\omega t}\langle\delta\bar{P}(t,\mathbf{x})\delta\bar{P}(0)\rangle_0. \tag{26}$$

For the horizon-fluid, v_S is equal to the speed of light ($c=1$). For the Hamiltonian (15), we have:

$$\bar{P} = -\frac{1}{2}(\nabla\phi)^2 - m^2_{\rm eff}\phi^2. \tag{27}$$

We can ignore contributions from the $(\nabla\phi)$ term for the homogeneous perturbations responsible for the bulk viscosity. We can determine $\delta T_{\mu\nu}$ by systematically tracking the deviation of the field ϕ from its average value at equilibrium state, i.e.,

$$\phi = \langle\phi\rangle_0 + \delta\phi$$

where $\langle\rangle_0 \equiv \phi_0$ denotes the ensemble average of the density matrix.

For a field at a temperature T, the density matrix is the thermal density matrix at T. In the hydrodynamic limit, ϕ_0 is given by:

$$\phi_0^2 = \frac{\sum e^{-\beta H}\phi^2}{\sum e^{-\beta H}} = \frac{\int\mathcal{D}\phi\phi^2 e^{-\beta\int\frac{m^2_{\rm eff}}{2}\phi^2 d^2x}}{\int\mathcal{D}\phi e^{-\beta\int\frac{m^2_{\rm eff}}{2}\phi^2 d^2x}} = \frac{1}{2m^2_*}, \tag{28}$$

where star denotes that rescaled variables [see the discussion below Eq. (33)]. Writing $\phi = \phi_0 + \delta\phi$, (27) can be written as

$$\delta\bar{P} = -2m^2_*\phi_0\delta\phi = -2\frac{m_*}{\sqrt{2}}\delta\phi = \sqrt{2}m_*\delta\phi = \frac{\sqrt{2}}{C}\delta\phi. \tag{29}$$

The Coefficient of Bulk Viscosity is given by,

$$\zeta = 2\pi\,{\rm Im}\Big[\frac{1}{4\pi\mathcal{A}}\lim_{\mathbf{q}\to0}\lim_{\omega\to m_*}\int d^3x e^{-i\mathbf{q}.\mathbf{x}+i\omega t}\langle\big[\delta\bar{P}(t,\mathbf{x}),\delta\bar{P}(0)\big]\rangle\theta(-t)\Big]. \tag{30}$$

Substituting (29) in (30), and keeping in mind that the perturbations are homogeneous, one gets,

$$\zeta = {\rm Im}\Big[\lim_{\omega\to m_*}\frac{1}{C^2}\int_{-\infty}^{\infty} dt e^{i\omega t}\langle\big[\delta\hat{\phi}(t),\delta\hat{\phi}(0)\big]\rangle\theta(-t)\Big]. \tag{31}$$

$\langle\big[\delta\hat{\phi}(t,\mathbf{x}),\delta\hat{\phi}(0)\big]\rangle\theta(-t)$ corresponds to the advanced Green's function that appears because of the teleological nature of the event horizon [for detailed discussion, see[12,13,21]], and

$$\big[\delta\hat{\phi}(t),\delta\hat{\phi}(0)\big]=\big[\hat{\phi}(t),\hat{\phi}(0)\big] \tag{32}$$

To obtain the above commutation relation of the field operator, we write the Hamiltonian (15) as

$$H_{\rm HF}=\frac{T}{2}\int\left[\Big(\frac{\partial\varphi_*}{\partial t}\Big)^2+\big(\nabla\varphi_*\big)^2+m_*^2\varphi_*^2\right]dA\,. \tag{33}$$

where $\phi=\sqrt{T}\phi_*$, and ϕ_* is the rescaled (dimensionless) effective scalar field and T is taken to be a constant for convenience. Rewriting $\hat{\varphi}_*$ (also $\hat{\varphi}$) in terms of the creation and annihilation operators, i.e.,

$$\hat{\varphi_*}(t,\mathbf{x})=\sum_{\mathbf{k}_*}[\hat{a}_{\mathbf{k}_*}u_{\mathbf{k}_*}(t,\mathbf{x})+\hat{a}^\dagger_{\mathbf{k}_*}u^*_{\mathbf{k}_*}(t,\mathbf{x})], \tag{34}$$

where,

$$u_{\mathbf{k}_*}(t,\mathbf{x})=\frac{1}{\sqrt{2\pi}}\frac{1}{\sqrt{2\omega_*}}e^{i(\mathbf{k}_*.\mathbf{x}-\omega_* t)} \tag{35}$$

and $\mathbf{k}_*$, ω_*, $\mathbf{x}$ and t are dimensionless variables. Expressing the dimensionless part of the above Hamiltonian (33) in the frequency domain, we have:

$$H_{\rm eff}(\varphi)=T\sum_{\mathbf{k}_*}(\hat{a}^\dagger_{\mathbf{k}_*}\hat{a}_{\mathbf{k}_*}+\frac{1}{2})\omega_*, \tag{36}$$

where the dispersion relation is given by:

$$\omega_*^2={\mathbf{k}_*}^2+\frac{1}{C^2}\quad\text{and}\quad C=\frac{1}{m_*}\,. \tag{37}$$

In the hydrodynamic limit ($\mathbf{k}_*\to 0$), the above expression reduces to $\omega_{*H}=1/C$. Substituting Eq. (32) in Eq. (31) and after a little algebraic manipulation in terms of dimensionless variables, we have:[47]

$$\zeta[\omega_{*H}]=\mathrm{Im}\left[-\frac{i}{4C^2}\frac{T\omega_{*H}}{E_\beta(\omega_{*H})}\int_{-\infty}^{\infty}\langle\hat{\varphi}(0)\hat{\varphi}(t)+\hat{\varphi}(t)\hat{\varphi}(0)\rangle e^{-i\omega_{*H}t}\theta(-t)dt\right], \tag{38}$$

where $E_\beta(\omega_{*H})$ is the average energy of excitation in the mode with frequency ω_{*H} at temperature T. The above integral exhibits a pole at $\omega'_*=\omega_{*H}$, which is the well-known pole at the hydrodynamical limit. Using the fact that the process corresponding to bulk viscosity is homogeneous, we have

$$\langle\hat{\varphi}^2_{\omega_H}(0)\rangle=\frac{1}{(2\pi)^2}\frac{1}{4m_*^2}=\frac{1}{(2\pi)^2}\frac{C^2}{4} \tag{39}$$

In the hydrodynamic limit, we get:

$$\zeta[\omega_{*H}]=-\frac{1}{128\pi^2}\frac{T\omega_{*H}}{E_\beta(\omega_{*H})}=-\frac{1}{128\pi^2}2\tanh\frac{1}{2C}\,. \tag{40}$$

Demanding that the above expression matches with the expression derived by Damour[11]:

$$\zeta = -\frac{1}{16\pi}\,,$$

we have

$$\tanh\frac{1}{2C} = \frac{1}{4\pi}. \tag{41}$$

Solving this equation numerically, we get, $C = 6.2696$ and hence, $m_* = 0.1595$. The negative sign of a transport coefficient arises due to $\theta(-t)$ in the response function of the black-hole horizon.[21]

6. Discussion

The minimal microscopic model for the horizon-fluid discussed here incorporates three simple ideas. First, the model contains an infinite-dimensional symmetry algebra, namely the Virasaro algebra, corresponding to black-holes' near-horizon $S1$ diffeo-symmetry. Second, the model describes a perturbed CFT that possesses a representation of the Virasoro algebra. The deformation is characterized by a mass term and is supposed to address the perturbed nature of the non-stationary black-hole horizon. Finally, the mass gap provides a simple derivation of ζ and area quantization, thus demonstrating that in the long-wavelength limit, it can connect with the known semiclassical Physics of black-holes. Historically, Bekenstein was the first to derive the quantization of area using adiabatic quantization. We obtained quantization of entropy by slowly evolving the black-hole horizon. Adiabatic quantization of a system is applicable when some of the parameters characterizing the system evolve slowly.

In this talk, only the homogeneous perturbations of the stationary black-hole have been considered. We need to construct a microscopic model, including general perturbations, which can describe the horizon-fluid. This complete theory would, of course, be richer than the toy model we have put forward. So the Baxter model serves only as an illustration in this sense. Nonetheless, an improved model should also share the first three critical features of the current model mentioned above. Thus, we expect a more comprehensive microscopic future model of the horizon-fluid to describe a system close to the critical point. It should represent the near-horizon symmetry algebra and a mass gap with a fixed, known value.

Our results also lead to an interesting suggestion. The twin requirements of the theory incorporating near-horizon symmetries($S1$ diffeomorphism) and possessing length scales due to external perturbations can be naturally satisfied if the theory on the non-stationary black-hole horizon is a deformed CFT. Similar types of arguments also lead to the expectation that the theory on the stationary black-hole horizon is a CFT.[19] Since the non-stationary black-hole eventually becomes stationary, it is reasonable to assume that the deformed CFT flows into a CFT as the black-hole horizon dynamically evolves. Note that the above argument does not

depend on any specific model. This leads us to conjecture that *the low energy theory on the black-hole horizon flows towards a critical point as the perturbed black-hole ultimately becomes stationary.* We think that this conjecture may be a good starting point to construct quantum theory models of the black-hole horizon.

Mass formulas are obtained for stationary axisymmetric solutions of the Einstein-Maxwell dilaton-axion theory, which have a regular rod structure on the axis of symmetry. Asymptotic mass, angular momentum and charge are expressed as the sums of masses, angular momenta and charges of rods dressed with field contributions. The calculation is based on a three-dimensional sigma model representation of the stationary EMDA system and the Tomimatsu approach proposed for the Einstein-Maxwell system. Our results provide an alternative interpretation of mass formulas and thermodynamics for black holes with Dirac and Misner strings. It is also applicable to aligned multiple black holes with struts.

Keywords: Black hole mass formulas, Dirac string, Misner string, therodynamics of black holes with NUT

1. Introduction

Mass formulas for black holes and the concept of irreversible mass were proposed by Christodoulou,[1] Hawking,[2] Christodoulou and Ruffini,[3] and Smarr[4] in the early 1970s, shortly before Hawking discovered the evaporation of a black hole.[5] They have played an important role in understanding the energy extraction from rotating black holes and the energy balance of merging black holes, which was brilliantly confirmed in the recent experiments of Ligo. The thermodynamics of black holes[6–9] then gave them a deep quantum interpretation. The mathematical foundations and detailed derivation of mass formulas in the Einstein-Maxwell theory were given by Carter.[10]

The original integral Smarr's mass formula[4] relates the total values of mass, angular momentum and electric charge of black holes in Einstein-Maxwell theory with the horizon area. The area term in this formula was originally interpreted mechanically as the work of *stresses* of the horizon. Further, this interpretation was forgotten in favor of the thermodynamic one. When interest turned to solutions with NUT, it was immediately found,[11–14] that the Misner string also contributes to the Smarr mass formula, and this contribution was included in the entropy term. This interpretation was revived recently in slightly different terms in a series of papers,[15–19] based on the Bonnor interpretation of the Misner strings as mild physical singularities.[20]

In our opinion, the most natural description of solutions with Misner and Dirac strings as well as aligned multicenter solutions with struts can be given in terms of

the rod structure, introduced by Harmark,[21] developing earlier ideas of Emparan and Reall.[22] The main novelty of this approach is the derivation of separate formulas for the partial masses for each component of the entire system, represented by a set of rods. In this interpretation, Misner's strings appear as independent components on the same base and as black holes.

Using the representation of vacuum stationary axisymmetric solutions in Weyl coordinates, we consider the solutions as generated by data on the polar axis, which look like distributional matter objects that are sources of the Poisson equation for the gravitational potential.[23] Accordingly, the total gravitational field can be viewed as a nonlinear superposition of the components such as black holes, struts, Misner and Dirac strings. Despite the nonlinearity of Einstein's equations, the total mass, angular momentum (and electric charge in the case of an electrovacuum) can be represented as the sum of the individual contributions of the constituents. This simple additivity is associated with conservation laws for the Komar and Gauss integrals. The magnetic charge and magnetic mass (NUT) in this description are due to the Misner and Dirac strings, which correspond to the individual elements in the rod system, so these charges do not enter the black hole horizon mass. Their contribution enters the asymptotic Komar mass as the proper masses of the Dirac and Misner strings along with the black hole contribution.

The difference between the horizon and the string rods is that the directions of the former are timelike, and the directions of the latter are spacelike. Both rods are Killing horizons and have an associated surface gravity. But the entropic interpretation of the surface contribution of spacelike rods (often encountered) does not seem convincing. An alternative interpretation may be similar to Smarr's original point of view.

This programme was previously performed for the Einstein-Maxwell system,[24,25] and here it is extended to Einstein-Maxwell-dilaton-axion gravity (EMDA). We show that Tomimatsu's proposal within the context of electrovacuum[26,27] on calculating Komar integrals over rods in terms of the boundary values of Ernst's potentials can be generalized to the sigma model representation of stationary dilaton-axion gravity. Surprisingly, the obtained mass formulas are very similar to the formulas obtained in the case of Einstein-Maxwell.

2. Stationary EMDA gravity

The EMDA gravity can be viewed as a consistent truncation of a toroidal reduction of the heterotic string,[28] or as a truncation of $N = 4$ four-dimensional supergravity.[29,30] Rotating electrically charged black hole solution of EMDA theory was obtained by Sen[28] within the first approach and independently, with the inclusion of NUT and magnetic charge, by Gal'tsov and Kechkin[31] in the second context. Recently, these solutions have attracted attention as an alternative to the Kerr metric in an effort to find astrophysical evidence for new physics.[32–34]

The mass formulas and thermodynamics of EMDA black holes have been discussed frequently in the past, though not in full generality, see, for example[35,36] (a more complete list of references prior to 2008 can be found in[36]). Our discussion here, based on generalization of,[25] covers solutions with Misner and Dirac strings, and is also applicable to hitherto unknown solutions for double black holes with struts that are expected to exist.

The EMDA action in our conventions reads:

$$S=\frac{1}{16\pi}\int\left\{R-2\partial_\mu\phi\partial^\mu\phi-\frac{1}{2}\mathrm{e}^{4\phi}\partial_\mu\kappa\partial^\mu\kappa-\mathrm{e}^{-2\phi}F_{\mu\nu}F^{\mu\nu}-\kappa F_{\mu\nu}\tilde{F}^{\mu\nu}\right\}\sqrt{-g}d^4x, \tag{1}$$

where $\tilde{F}^{\mu\nu}=\frac{1}{2}E^{\mu\nu\lambda\tau}F_{\lambda\tau}$. Dilaton ϕ and axion κ parameterize a coset $SL(2,R)/SO(2)$, and the $SL(2,R)$ group is the symmetry of the full action. To see this, one can introduce the complex scalar

$$\zeta=\kappa+i\mathrm{e}^{-2\phi} \tag{2}$$

and the self-dual Maxwell field $\mathcal{F}=\left(F+i\tilde{F}\right)/2$. Then the action takes the form

$$S=\frac{1}{16\pi}\int\left\{R-2\left|\partial\zeta(\zeta-\bar{\zeta})^{-1}\right|^2+(i\zeta\mathcal{F}_{\mu\nu}\mathcal{F}^{\mu\nu}+c.c.)\right\}\sqrt{-g}d^4x, \tag{3}$$

which is invariant under the $SL(2,R)$ transformations

$$\begin{aligned}&\zeta\to\frac{\alpha\zeta+\beta}{\gamma\zeta+\delta},\qquad \alpha\beta-\gamma\delta=1,\\ &F\to(\gamma\kappa+\delta)F+\gamma\mathrm{e}^{-2\phi}\tilde{F},\end{aligned} \tag{4}$$

which interchange the modified Maxwell equations and the Bianchi identity

$$\nabla_\nu G^{\mu\nu}=0,\quad \nabla_\nu\tilde{F}^{\mu\nu}=0, \tag{5}$$

$$G^{\mu\nu}=e^{-2\phi}F^{\mu\nu}+\kappa\tilde{F}^{\mu\nu}. \tag{6}$$

The Einstein equations are

$$R_{\mu\nu}=2\phi_{,\mu}\phi_{,\nu}+\frac{1}{2}\mathrm{e}^{4\phi}\kappa_{,\mu}\kappa_{,\nu}-\mathrm{e}^{-2\phi}\left(2F_{\mu\lambda}F^{\lambda}{}_{\nu}+\frac{1}{2}F^2g_{\mu\nu}\right). \tag{7}$$

For stationary and axisymmetric configurations the axion and dilaton kinetic term disappear from the Einstein equations in the $t-\varphi$ sector, and the dilaton enters only through the scale factor $\mathrm{e}^{-2\phi}$ in front of the Maxwell energy-momentum tensor. This is crucial for our derivation.

Assuming the existence of the Killing vector $k=\partial_t$, the metric can be represented as

$$ds^2=g_{\mu\nu}dx^\mu dx^\nu=-f(dt-\omega_i dx^i)^2+\frac{1}{f}h_{ij}dx^i dx^j, \tag{8}$$

where three-dimensional metric h_{ij}, three-dimensional rotation vector ω_i, $(i,j=1,2,3)$ and the scale factor f depend only on the space coordinates x^i. The spatial

parts of the Bianchi identities and the modified Maxwell equations can be solved by introducing electric v and magnetic u potentials

$$F_{i0} = \frac{1}{\sqrt{2}}\partial_i v, \tag{9}$$

$$G^{ij} = -\frac{f}{\sqrt{2h}}\epsilon^{ijk}\partial_k u. \tag{10}$$

The mixed R_0^i Einstein equations are solved by introducing the twist potential χ obtained by dualizing the rotation two-form:

$$f^2 h_{il}\frac{\epsilon^{ljk}}{\sqrt{h}}\partial_j\omega_k = \partial_i\chi + v\partial_i u - u\partial_i v. \tag{11}$$

The remaining equations reduce to those of three-dimensional gravitating sigma-model equations for six scalars $X^A = f, \chi, v, u, \phi, \kappa,\ A = 1, \ldots, 6$, and the three-dimensional metric h_{ij}:

$$S = \int \left[\mathcal{R}(h) - \mathcal{G}_{AB}(X)\,\partial_i X^A\,\partial_j X^B\,h^{ij}\right]\sqrt{h}\,d^3x, \tag{12}$$

where the target space metric $\mathcal{G}_{AB}$ can be presented as

$$dl^2 = \frac{1}{2}f^{-2}[df^2 + (d\chi + vdu - udv)^2] - f^{-1}[e^{2\phi}(du - \kappa dv)^2 + e^{-2\phi}dv^2] + 2d\phi^2 + \frac{1}{2}e^{4\phi}d\kappa^2. \tag{13}$$

The isometry group of this metric is $SO(3,2)$, as was identified in.[37] Based on isomorphism $SO(3,2) \sim Sp(4,R)$, a convenient 4×4 matrix representation of the coset $Sp(4,R)/SO(1,2)$ was suggested,[38] suitable for the generation technique. In terms of complex coordinates, one of which is (2) and two other are the following generalization of the Ernst potentials[39]

$$\Psi = u - \zeta v, \quad \mathcal{E} = if - \chi + v\Psi, \tag{14}$$

the target space is a three-dimensional Kähler space.

3. Rod structure

Consider the spacetime metric, admitting two commuting Killing vectors k, m corresponding to stationarity and axial symmetry. Let t, φ be chosen so that $k = \partial_t$, $m = \partial_\phi$ with $t \in R$ and $\varphi \in [0, \pi]$. The remaining coordinates will be primarily assumed of the Boyer-Lindquist type, r, θ with $0 < r < \infty$ and $\theta \in [0, \pi]$. We assume that the spacetime manifold has no strong naked curvature singularities, but can have visible line singularities along (a part of) the polar axis in the sense of Israel.[23] These includes cosmic strings (conical singularities), struts in aligned multiple black hole solutions (conical singularities of both positive or negative tension) and Misner strings in spacetimes with NUTs, without time periodicity being imposed. We also assume that spacetime is asymtotically flat, or

asymptotically locally flat. To such a spacetime one can ascribe a *rod structure* following Harmark.[21]

Let $\gamma_{ab},\ x^a = t,\ \varphi$ is the two-dimensional Lorentzian metric of the subspace spanned by the Killing vectors. Introduce the Weyl cordinates ρ, z such that ρ is

$$\rho = \sqrt{|\det \gamma|}\,, \tag{15}$$

and z to ensure the metric form:

$$ds^2 = \gamma_{ab}(\rho, z)dx^a dx^b + e^{2\nu}(d\rho^2 + dz^2)\,, \tag{16}$$

where ν is a function of (ρ, z). To find the rod structure, one has to solve the equation

$$\rho(r, \theta) = 0. \tag{17}$$

Generically, the solution splits the polar axis into a certain number of finite or semi-infinite intervals $(-\infty, z_1], [z_1, z_2], \ldots, [z_N, +\infty)$ called rods (we will label two semi-infinite rods by $n = \pm$, and the remaining finite ones by an index n corresponding to the left bound of the interval). Each rod can be equipped with a two-dimensional vector, called *rod direction*, via the following reasoning. At $\rho = 0$ the matrix $\gamma_{ab}(0, z)$ is degenerate by virtue of the definition (15), so it must have zero eigenvalues. For quasiregular spacetimes, such that on the symmetry axis there are no strong curvature singularities these eigenvalues must be non-degenerate except, perhaps, for a discrete set of "turning" points z_n which mark the ends of rods. The eigenvector v^a_n, satisfying the equation

$$\gamma_{ab}(0, z)v^b_n = 0 \tag{18}$$

on any segment $z \in [z_n, z_{n+1}]$, is called the n-s rod direction. By continuity, this vector can be extended to small $\rho \neq 0$, and a more accurate analysis shows that, in the leading order in ρ, its 2D norm behaves as

$$v^2_n = \gamma_{ab}v^a_n v^b_n \sim \pm a(z)\rho^2, \qquad e^{2\nu} \sim c^2 a(z), \tag{19}$$

where c is some constant and the sign $\pm$ corresponds to *spacelike* and *timelike* rod respectively.

Normalization of directional vectors can be chosen in different ways. One possibility, *Killing* normalization, relates to preferred normalisation an associated Killing vector in spacetime: $V = v^0 k + v^1 m$, namely, $v_0 = 1$ in the timelike case, and $v_1 = 1$ in spacelike. In view of behavior near the axis (19), in both cases the rod itself (i.e. the submanifold $\rho = 0$) will be the Killing horizon for so defined Killing vector. Another possibility is to choose the scale factor in such a way as to ensure the finiteness of its norm at $\rho \to 0$:

$$l^a_n = \lim_{\rho \to 0} \rho^{-1} e^{-\nu} v^a_n, \tag{20}$$

again with an option of further constant rescaling. An important property of so defined rod direction is its constancy (in view of (19) along the rod, i.e.,

$$\partial_z l_n^a = 0. \tag{21}$$

Timelike rods of finite length correspond to black hole horizons, infinite timelike rods describe acceleration horizons. The constant components of such a horizon rod are connected with its angular velocity Ω_H and the surface gravity $\varkappa_H$ of the Killing vector

$$\xi = k + \Omega_H\, m\,. \tag{22}$$

The surface gravity

$$\varkappa_H = (-\xi_{\mu;\nu}\xi^{\mu;\nu}/2)^{1/2} \tag{23}$$

can be expressed in the Weyl coordinates as

$$\varkappa_H = \lim_{\rho\to 0}\left(-\rho^{-2}e^{-2\nu}\gamma_{ab}v^a v^b\right)^{1/2}, \tag{24}$$

with $v^0 = 1$, $v^1 = \Omega_H$. It may be convenient to choose a canonical normalization of the directional vectors that corresponds to the unit surface gravity:

$$l_H = (1/\varkappa_H,\ \Omega_H/\varkappa_H)\,. \tag{25}$$

Spacelike rods correspond to line defects, such as cosmic strings, struts, Misner strings, which can be also Dirac strings associated with the corresponding vector potentials. These rods are Killing horizons for some spacelike Killing vectors. For them one also has constant angular velocities Ω_n and *spacelike* surface gravities

$$\varkappa_n = \lim_{\rho\to 0}\left(\rho^{-2}e^{-2\nu}\gamma_{ab}v_n^a v_n^b\right)^{1/2}, \tag{26}$$

so that the normalized directional vectors will be

$$l_n = (1/\varkappa_n,\ \Omega_n/\varkappa_n)\,. \tag{27}$$

Here $v_n^1 = 1$. With the normalized spacelike directional vector, the period (28) will be 2π. If the coordinate η associated with the spacelike rod Killing vector $l = \partial_\eta$, conical singularity is absent with perdiocity of η with

$$\Delta\eta = 2\pi \lim_{\rho\to 0}\left(\rho^2 e^{2\nu}\left(\gamma_{ab}l_n^a l_n^b\right)^{-1}\right)^{1/2}. \tag{28}$$

This is important in the situation when two spacelike rods meet at the turning point, where potentially a mismatch of periodicities may lead to *orbifold* singularities. This may happen for instantons.[41]

4. Komar charges

Following,[25] we start with the Komar definition[40] of the asymptotic mass and angular momentum:

$$M_\infty = \frac{1}{4\pi}\oint_{\Sigma_\infty} D^\nu k^\mu d\Sigma_{\mu\nu}, \quad J_\infty = -\frac{1}{8\pi}\oint_{\Sigma_\infty} D^\nu m^\mu d\Sigma_{\mu\nu}. \tag{29}$$

We also need a conserved electric charge as the surface integral. The definition of a conserved electric charge in EMDA follows from the modified Maxwell equations:

$$Q_\infty = \frac{1}{4\pi}\oint_{\Sigma_\infty} G^{\mu\nu} d\Sigma_{\mu\nu}. \tag{30}$$

Consider some stationary axisymmetric solution with an arbitrary rod structure z_n, l_n. Each rod must be surrounded by a thin cylinder Σ_n. Using Ostrogradski formula one can transform the asymptotic total mass to the sum of the local Komar masses M_n^d of rods ("direct" masses) and the bulk contribution coming from the fields: $M = \sum_n M_n^d + M_F$, where

$$M_n^d = \frac{1}{4\pi}\oint_{\Sigma_n} D^\nu k^\mu d\Sigma_{\mu\nu}, \qquad M_F = \frac{1}{4\pi}\int D_\nu D^\nu k^\mu dS_\mu, \tag{31}$$

where Σ_n are the spacelike surfaces bounding the various sources[a], and the second integral is over the bulk. Similarly, the asymptotic angular momentum will read $J = \sum_n J_n^d + J_F$, where

$$J_n^d = -\frac{1}{8\pi}\oint_{\Sigma_n} D^\nu m^\mu d\Sigma_{\mu\nu}, \qquad J_F = -\frac{1}{8\pi}\int D_\nu D^\nu m^\mu dS_\mu, \tag{32}$$

Using the well-known Killing lemma for k,

$$D_\nu D^\nu k^\mu = -[D_\nu, D^\mu]k^\nu = -R^\mu{}_\nu k^\nu, \tag{33}$$

and similarly for m, and an explicit form for the Ricci tensor in EMDA theory (7), one can express the bulk integrals as

$$M_F = -\frac{1}{4\pi}\int \mathrm{e}^{-2\phi}\left(F_{it}F^{it} - F_{i\varphi}F^{i\varphi}\right)\sqrt{|g|}d^3x, \tag{34}$$

$$J_F = \frac{1}{4\pi}\int \mathrm{e}^{-2\phi}F_{i\varphi}F^{it}\sqrt{|g|}\,d^3x. \tag{35}$$

Using the identities

$$F_{it}\tilde{F}^{it} - F_{i\varphi}\tilde{F}^{i\varphi} = 0, \qquad F_{i\varphi}\tilde{F}^{it} = 0 \tag{36}$$

[a]We use the metric signature (-+++) and the convention $d\Sigma_{\mu\nu} = 1/2\sqrt{|g|}\,\epsilon_{\mu\nu\lambda\tau}dx^\lambda dx^\tau$ with $\epsilon_{t\rho z\varphi} = 1$ in Weyl coordinates. We will label t, φ by an index a, and the remaining coordinates ρ, z by i, j. The two-dimensional Levi-Civita symbol ϵ_{ij} is defined with $\epsilon_{\rho z} = 1$ and $\epsilon_{xy} = 1$ respectively.

one can rewrite (34) and (35) as

$$M_F = -\frac{1}{4\pi}\int \left(F_{it}G^{it} - F_{i\varphi}G^{i\varphi}\right)\sqrt{|g|}d^3x, \tag{37}$$

$$J_F = \frac{1}{4\pi}\int F_{i\varphi}G^{it}\sqrt{|g|}\,d^3x. \tag{38}$$

In view of the modified Maxwell equations, these expressions can be presented in the full divergence form

$$M_F = -\frac{1}{4\pi}\int \partial_i\left[\sqrt{-g}\left(A_tG^{it} - A_\varphi G^{i\varphi}\right)\right]d^3x, \tag{39}$$

$$J_F = \frac{1}{4\pi}\int \partial_i\left(\sqrt{|g|}A_\varphi G^{it}\right)\,d^3x, \tag{40}$$

suggesting the representation of the asymptotic mass and angular momentum as the surface integrals over the rods[b]:

$$M_\infty = \sum_n M_n, \qquad M_n = \frac{1}{8\pi}\oint_{\Sigma_n}\left(g^{ij}g^{ta}\partial_j g_{ta} + 2\left(A_tG^{it} - A_\varphi G^{i\varphi}\right)\right)d\Sigma_i \tag{41}$$

$$J_\infty = \sum_n J_n, \qquad J_n = -\frac{1}{16\pi}\oint_{\Sigma_n}\left(g^{ij}g^{ta}\partial_j g_{\varphi a} + 4A_\varphi G^{it}\right)d\Sigma_i, \tag{42}$$

where we have also rewritten the direct Komar integrals in an explicit form. Thus we have succeeded in presenting the EMDA bulk contributions in the form of the integrals over the rods in the same was as it was done in[25] for the Einstein-Maxwell system. This procedure can be regarded as rod's dressing by the bulk field. So the resulting Smarr formulas for the asymptotic mass and angular momentum were written as sums of the dressed rod's contributions. Note, that in the general case, this is the only representation for the global M, J that can be found, since different forms of rod's contribution do not allow one to write asymptotic quantities directly in terms of physical charges as was possible for a single black hole.

From now on we assume the standard Weyl-Papaperou parametrization of the metric

$$ds^2 = -f(dt - \omega d\varphi)^2 + f^{-1}[e^{2k}(d\rho^2 + dz^2) + \rho^2 d\varphi^2], \tag{43}$$

and represent the four-potential as

$$\sqrt{2}\,A_\mu dx^\mu = vdt + Ad\varphi, \tag{44}$$

(note that v, u, A in this paper differs from these in[25] by $\sqrt{2}$ to be consistent with the EMDA literature). Computation of the direct rod Komar integrals integrals was given in.[4] It amounts to dualizing the rotation three-form

$$\partial_i\chi = -f^2\rho^{-1}\epsilon_{ij}\partial_j\omega + \left(u\partial_i v - v\partial_i u\right), \tag{45}$$

[b]We assume that the integrals over in infinite sphere vanish, otherwise they must be added too. This happens if the North and South Misner and Dirac strings are arranged non-symmetrically, by adding suitable constants to the asymptotic values of the rotation function ω and the azimuthal component of the four-potential A_φ.

and leads to

$$M_n^d = \frac{1}{8\pi}\int_n \omega\left[\partial_z\chi + (v\partial_z u - u\partial_z v)\right] dzd\varphi \tag{46}$$

Similarly for the angular momentum

$$J_n^d = -\frac{1}{16\pi}\int_n \omega\left\{2 - \omega\left[\partial_z\chi + (v\partial_z u - u\partial_z v)\right]\right\} dzd\varphi \tag{47}$$

Note the appearance of the electromagnetic potentials in the expressions for direct rod mass and angular momentum due to use of dualized twist potential, i.e., implicit use of Einstein equations. These terms will be exactly canceled by the field contributions to the same quantities.

To continue, we show that, apart from constancy (i.e. z-independence) of the rod angular velocity $\Omega = 1/\omega$ and the generalized surface gravity $\varkappa$, one can prove for any rod the following relations:

$$\lim_{\rho\to 0}\left(G^{\rho t} - \omega G^{\rho\varphi}\right)\sqrt{|g|} = 0, \tag{48}$$

$$\lim_{\rho\to 0}\left(v + A/\omega\right) \equiv -\sqrt{2}\Phi = \text{const}, \tag{49}$$

where Φ can be interpreted as an electric potential of the rod. Together with constancy of ω, the last relation gives also

$$\partial_z A = -\omega\partial_z v, \tag{50}$$

as $\rho \to 0$.

Using (48-50), and the EMDA dualization equation (10) one can rewrite the field contribution to the dressed rod mass (34) as

$$M_n^F = -\frac{1}{8\pi}\oint_{\Sigma_n}\left[\omega\left(v\partial_z u - u\partial_z v\right) - \partial_z(uA)\right] dzd\varphi. \tag{51}$$

Combining this with the direct Komar mass (46) we obtain the dressed rod's mass

$$M_n = \frac{1}{8\pi}\int_{\Sigma_n}\left[\omega\partial_z\chi + \partial_z(A\,u)\right] dzd\varphi. \tag{52}$$

It may seem surprising that this formula does not differ from that for Einstein-Maxwell system. No explicit scalar terms are seen.

For the bulk contribution to the angular momentum, one also applies the Eq. (48) and then magnetic dualization equation (10). The subsequent transformations are the same as in[25] and lead to the same result

$$J_n^F = \frac{1}{8\pi}\int_H \left[\omega^2 u\partial_z v + \omega\partial_z(Au)\right] dzd\varphi. \tag{53}$$

Combining with the direct Komar momentum, we obtain for the dressed rod:

$$J_n = \frac{1}{16\pi}\int_H \omega\left[-2 + \omega\partial_z\chi + \partial_z(A\,u) - \sqrt{2}\omega\Phi_n\partial_z u\right] dzd\varphi, \tag{54}$$

this expression also does not contain the dilaton and axion. Now consider Komar electric charge of a rod (30). Explicitly, it is given by the flux

$$Q_n = \frac{1}{4\pi}\int_{\Sigma_n}\sqrt{|g|}G^{t\rho}dzd\varphi. \tag{55}$$

Manipulating with indices and using dualization equation (10)

$$G^{t\rho} = \frac{g^{\rho\rho}}{g_{tt}}G_{t\rho} - \frac{g_{t\varphi}}{g_{tt}}G^{\varphi i} = e^{-2k}\left[G_{t\rho} + \frac{f\omega}{\rho}\partial_z u\right], \tag{56}$$

one finds that in the limit $\rho \to 0$ only the second term contributes, so

$$Q_n = \frac{1}{4\sqrt{2}\pi}\int_{\Sigma_n}\omega\partial_z u\, dzd\varphi. \tag{57}$$

After integration over φ

$$M_n = \frac{\omega_n}{4}\chi\Big|_{z_n}^{z_{n+1}} + \frac{1}{4}(Au)\Big|_{z_n}^{z_{n+1}} \tag{58}$$

Similarly, for the angular momentum (54) one finds

$$J_n = \frac{\omega_n}{8}\left\{-2(z_{n+1}-z_n) + \left[\omega_n\left(\chi - \sqrt{2}\Phi_n u\right) + Au\right]\Big|_{z_n}^{z_{n+1}}\right\}. \tag{59}$$

Finally, the electric charge will be

$$Q_n = \frac{\omega_n}{2\sqrt{2}}u\Big|_{z_n}^{z_{n+1}}. \tag{60}$$

The angular velocity of a rod is defined as a limit

$$\Omega_n = \lim_{\rho\to 0}\ \omega^{-1}(\rho, z), \qquad z_n < z < z_{n+1}. \tag{61}$$

Combining the above formulas we obtain rod Smarr mass

$$M_n = \frac{L_n}{2} + 2\Omega_n J_n + \Phi_n Q_n, \tag{62}$$

where $L_n = z_{n+1} - z_n$ is the n-s rod length (for infinite rods some length regularization is needed). Please note that this formula is identical; it is valid for any rod, regardless of the specific parameter values.

5. Length versus entropy

Although it looks like a one-dimensional object, any rod with finite surface gravity has a finite surrounding cylindrical area:

$$\mathcal{A}_n = \oint d\varphi\int_{z_n}^{z_{n+1}}\sqrt{|g_{zz}g_{\varphi\varphi}|}dz = 2\pi\int_{z_n}^{z_{n+1}}\sqrt{|e^{2k|}|}\omega|dz. \tag{63}$$

The surface gravity (by definition, positive) in Weyl coordinates reads

$$\kappa_n = |\Omega_n|\sqrt{|e^{-2k}|}. \tag{64}$$

Thus the integral (63) is simply proportional to the rod's length:

$$\frac{\kappa_n}{2\pi}\mathcal{A}_n = z_{n+1} - z_n = L_n. \tag{65}$$

This is true for both timelike rods (horizons) and spacelike ones (defects). In the first case, the surface gravity is proportional to the Hawking temperature, and the area of the horizon is proportional to the entropy.

$$T_H = \kappa_H/2\pi, \qquad S_H = \mathcal{A}_H/4, \tag{66}$$

therefore

$$T_H S_H = \frac{\kappa_H}{8\pi}\mathcal{A}_H = \frac{L_H}{4}, \tag{67}$$

and the Smarr formula can be rewritten as[4]

$$M_H = 2\Omega_H J_H + 2T_H S_H + \Phi_H Q_H. \tag{68}$$

For spacelike rods such an identification does not seem justified, so we prefer to leave Smarr formua in its "length" form (62).

For multicenter solutions this mass relation holds separately for each black hole constituent. As stated in,[24,25] this is also true when black holes have magnetic and/or NUT charges. In our interpretation, the contribution of these parameters to the total asymptotic mass comes from individual rods representing the Dirac and Misner strings.

6. EMDA rotating dyon with NUT

The metric of the EMDA dyon with the NUT parameter constructed in 1994[31] can be represented in the Kerr form:

$$ds^2 = -\frac{\Delta - a^2\sin^2\theta}{\Sigma}\left(dt - \omega d\varphi\right)^2 + \Sigma\left(\frac{dr^2}{\Delta} + d\theta^2 + \frac{\Delta\sin^2\theta}{\Delta - a^2\sin^2\theta}d\varphi^2\right), \tag{69}$$

with the modified coefficient functions:

$$\begin{aligned}
&\Delta = (r - r_-)(r - 2M) + a^2 - (N - N_-)^2,\\
&\Sigma = r(r - r_-) + (a\cos\theta + N)^2 - N_-^2,\\
&\omega = \frac{-2w}{\Delta - a^2\sin^2\theta}, \quad w = N\Delta\cos\theta + a\sin^2\theta\left(M(r - r_-) + N(N - N_-)\right).
\end{aligned}$$

Two new parameters r_-, N_- depend on mass M, NUT parameter N, electric and magnetic charges Q, P as follows:

$$r_- = \frac{M(Q^2 + P^2)}{M^2 + N^2}, \qquad N_- = \frac{N(Q^2 + P^2)}{2(M^2 + N^2)}, \tag{70}$$

and a is the rotation parameter. The electric and magnetic potentials and the complex axidilaton scalar (2) depend also on the asymptotic values of dilaton and

axion $\zeta_\infty = \kappa_\infty + i\mathrm{e}^{-2\phi_\infty}$:

$$v = -\frac{\sqrt{2}e^{\phi_\infty}}{\Sigma}\mathrm{Re}\left[\mathcal{Q}(r - r_- + i\delta)\right], \qquad u = -\frac{\sqrt{2}\mathrm{e}^{\phi_\infty}}{\Sigma}\mathrm{Re}\left[\mathcal{Q}\zeta_\infty(r - r_- + i\delta)\right]$$
$$\zeta = \frac{\zeta_\infty R + \mathcal{D}\zeta^*_\infty}{R + \mathcal{D}}, \quad R = r - \frac{\mathcal{M}^* r_-}{2M} + i\delta, \quad \delta = a\cos\theta + N - N_-,$$

where the complex mass, electromagnetic and axidilaton charges are introduced

$$\mathcal{M} = M + iN, \qquad \mathcal{Q} = Q + iP, \qquad \mathcal{D} \equiv D + iA = -\frac{\mathcal{Q}^{*2}}{2\mathcal{M}}. \tag{71}$$

The explicit expressions for the axion and dilaton fields are

$$\kappa = \kappa_\infty - e^{-2\phi_\infty}\frac{2\mathrm{Im}(R\mathcal{D}^*)}{|R + \mathcal{D}|^2}, \qquad e^{-2(\phi - \phi_\infty)} = \frac{\Sigma}{|R + \mathcal{D}|^2}, \tag{72}$$

where $|R|^2 - |\mathcal{D}|^2 = \Sigma$. The dilaton asymptotics renormalizes the electric and magnetic charges, and the axion determines their mixing. Indeed, for $r \to \infty$, the electric and magnetic potentials are read as follows:

$$v \sim -\frac{\sqrt{2}\,Q\,\mathrm{e}^{\phi_\infty}}{r}, \qquad u \sim \frac{\sqrt{2}\,\left(P\,\mathrm{e}^{-\phi_\infty} - \kappa_\infty Q\mathrm{e}^{\phi_\infty}\right)}{r}. \tag{73}$$

The axion and dilaton asymptotics $r \to \infty$ read as follows:

$$\zeta \sim \zeta_\infty - 2ie^{-2\phi_\infty}\frac{\mathcal{D}}{r}, \qquad \kappa \sim \kappa_\infty + 2e^{-2\phi_\infty}\frac{A}{r}, \qquad \phi \sim \phi_\infty + \frac{D}{r}. \tag{74}$$

Combining electric and magnetic potentials, the complex potential Ψ reads

$$\Psi = \frac{\sqrt{2}\mathrm{e}^{\phi_\infty}}{\Sigma}\left[(\zeta - \kappa_\infty)\mathrm{Re}\left[\mathcal{Q}(r - r_- + i\delta)\right] + \mathrm{e}^{-2\phi_\infty}\mathrm{Im}\left[\mathcal{Q}(r - r_- + i\delta)\right]\right] \tag{75}$$

Applying the inverse dualization equations (10), we find the azimuthal component of the Maxwell four-potential For the four-potential one-form $\mathrm{A} = A_\mu dx^\mu$ we obtain:

$$A_\mu dx^\mu = \frac{\mathrm{e}^{\phi_\infty}}{\Sigma}\left(-Q(r - r_-) + P\delta\right)\left(dt + \left(2Ny - a(1 - y^2)\right)d\varphi\right) - \mathrm{e}^{\phi_\infty}Pyd\varphi. \tag{76}$$

Its norm diverges on the Misner strings $\cos\theta = \pm 1$:

$$A_\mu A^\mu\big|_{\cos\theta \to \pm 1} \sim \frac{-\mathrm{e}^{2\phi_\infty}P^2}{\Sigma\sin^2\theta}, \tag{77}$$

thus, Misner rods are also Dirac string loci.

Gravitational dualization equation (11) gives the metric twist potential

$$\chi = 2\frac{M\delta - N(r - r_-)}{\Sigma}. \tag{78}$$

The ergosphere boundary is given by

$$r_E = M + r_-/2 + \sqrt{|\mathcal{M}|^2\left(1 - r_-/2M\right)^2 - a^2\cos^2\theta}, \tag{79}$$

and the event horizon radius (the outermost root of $\Delta = 0$) is equal to

$$r_H = M + r_-/2 + \sqrt{|\mathcal{M}|^2 \left(1 - r_-/2M\right)^2 - a^2}, \tag{80}$$

so that the horizon two-surface touches the ergosphere at the polar axis.

The transformation to the Weyl coordinates ρ, z is given by

$$\rho^2 = \Delta \sin^2\theta,$$
$$z = (\Delta'/2)\,\cos\theta = (r - M - r_-/2)\cos\theta.$$

Solving the equation $\rho = 0$, we find that the rod system consists of three rods:

- l_+ : northern Misner string $r \in (r_H, \infty)$, $\cos\theta = 1$;
- l_H the horizon rod $r = r_H$, $\theta \in [0, \pi]$;
- l_+ southern Misner string $r \in (r_H, \infty)$, $\cos\theta = -1$.

The normalized directional vectors are given by the formulas (25), (27) in terms of the corresponding surface gravities and angular velocities.

It is also useful to represent the solution in terms of prolate spheroidal coordinates x, y definied as

$$r = \sigma x + M + r_-/2, \qquad \cos\theta = y, \tag{81}$$

$$\sigma^2 = |\mathcal{M}|^2 - |\mathcal{D}|^2 - |\mathcal{Q}|^2 - a^2, \tag{82}$$

One obtains:

$$ds^2 = -f\left(dt - \omega d\varphi\right)^2 + f^{-1}\left[\sigma^2 e^{2k}(x^2 - y^2)\left(\frac{dx^2}{x^2-1} + \frac{dy^2}{1-y^2}\right) + \rho^2 d\varphi^2\right], \tag{83}$$

where the metric functions now read

$$\Sigma = (\sigma x + M)^2 - |\mathcal{D}|^2 + (ay + N)^2,$$
$$\Sigma f = \sigma^2(x^2-1) - a^2(1-y^2), \quad e^{2k} = \frac{f\Sigma}{\sigma^2(x^2-y^2)},$$
$$f\Sigma\omega = -2\left[N\sigma^2(x^2-1)y + a(1-y^2)\left(M\sigma x + |\mathcal{M}|^2 - |\mathcal{Q}|^2/2\right)\right].$$

The South segment of the Misner string is $x > 1$, $y = -1$, the horizon rod is $x = 1, -1 \le y \le 1$ and the North Misner string is $x > 1$, $y = 1$. As expected, the inverse rotation function on the rods is constant on them and represents their angular velocities. It is easy to find

$$\Omega_H = \frac{2a}{\nu^2}, \qquad \Omega_\pm = \mp\frac{1}{2N}. \tag{84}$$

where a new parameter is introduced

$$\nu^2 = 2M\sigma + 2|\mathcal{M}|^2 - |\mathcal{Q}|^2, \tag{85}$$

such that the boundary values of $\Sigma(x, y)$ are

$$\Sigma_\pm \equiv \Sigma(1, \pm 1) = \nu^2 \pm 2aN. \tag{86}$$

The other ingredients of the mass formulas depend on the values of electric and magnetic potentials $v_\pm$ and $u_\pm$ of the defect rods $l_\pm$. The magnetic potential in spheroidal coordinates is

$$u = \frac{\sqrt{2}}{\Sigma}\Big\{\mathrm{e}^{\phi_\infty}\kappa_\infty[-Q(\sigma x+M-r_-/2)+P\delta]+e^{-\phi_\infty}[P(\sigma x+M-r_-/2)+Q\delta]\Big\} \quad (87)$$

Using it, we obtain:

$$v_\pm = -\frac{\sqrt{2}e^{\phi_\infty}}{\nu^2 \pm 2aN}\mathrm{Re}\left[\mathcal{Q}(\sigma \pm ia + \mathcal{M}(1-|\mathcal{Q}|^2/2|\mathcal{M}|^2))\right], \quad (88)$$

$$u_\pm = -\frac{\sqrt{2}\mathrm{e}^{\phi_\infty}}{\nu^2 \pm 2aN}\mathrm{Re}\left[\mathcal{Q}\zeta(\sigma \pm ia + \mathcal{M}(1-|\mathcal{Q}|^2/2|\mathcal{M}|^2))\right] \quad (89)$$

For surface gravities it is convenient to use Eq. (64). One finds:

$$\varkappa_H = \frac{\sigma}{\nu^2}, \qquad \varkappa_n = \mp\frac{1}{2N}. \quad (90)$$

Note that the angular velocities and surface gravities of Misner strings coincide similarly to the case of Kerr-Newman-NUT.[25] But they enter into the mass formula in a different way, so on should not consider this coincidence as a matter of interpretation.

The electric charges of the rods are given by (57). One finds the Gauss charges of the horizon and strings as:

$$Q_H = \frac{\omega_H}{2\sqrt{2}}(u_+ - u_-) = \frac{e^{-\phi\infty}\nu^2\left(2\sigma N^2 + M\nu^2\right)\mathrm{Im}\left[\zeta_\infty e^{2\phi_\infty}\mathcal{M}\mathcal{Q}\right]}{|\mathcal{M}|^2\left(\nu^4 - 4a^2N^2\right)}, \quad (91)$$

$$Q_\pm = \frac{Nu_\pm}{\sqrt{2}}. \quad (92)$$

Combining them together, we obtain

$$Q_H + Q_+ + Q_- = Qe^{-\phi_\infty} + P\kappa_\infty e^{\phi_\infty}. \quad (93)$$

This coincides with the true asymptotic charge of the configuration, with account of axion mixing and dilaton renormalization.

The electric potential on the horizon and on the strings are

$$\Phi_H = e^{\phi\infty}\frac{\nu^2(QM-NP)+2\sigma N(QN+MP)}{2\nu^2|\mathcal{M}|^2}, \qquad \Phi_\pm = -e^{\phi_\infty}\frac{P}{2N}. \quad (94)$$

Rod masses can be expressed in the form (58), using the corresponding values of the twist potential (78). One obtains

$$M_H = \nu^2\cdot\frac{M\nu^2+2\sigma N^2}{\nu^4-4a^2N^2} + \frac{1}{4}(2N(v_+u_+ + v_-u_-) - \sqrt{2}\mathrm{e}^{\phi_\infty}P(u_+ + u_-)), \quad (95)$$

$$M_\pm = N\frac{-N\sigma \pm Ma}{\nu^2 \pm 2aN} + \frac{1}{4}(2Nv_\pm - \sqrt{2}P\mathrm{e}^{\phi_\infty})u_\pm, \quad (96)$$

where the boundary values of electric and magnetic potentials are given by (88), (89). One can distinguish Dirac string contributions to the masses of defects as the parts non-vanishing for $N = 0$. Other terms are due to Misner strings. Direct substitution of (88-89) leads to long expressions, but the one can show that the Maxwell contributions to the total mass cancel out, while the remaining part non-trivially leads to the identity

$$M_\infty = M_H + M_+ + M_- = M.$$

Now we turn to the angular momentum balance, using the rod's momenta the expression (59). The length of the horizon rod is $L_H = 2\sigma$. Other rod lengths diverge. As it was shown in Ref.,[25] to overcome this issue, one can regularize the angular momentum as follows:

$$\tilde{J}_\pm = J_\pm + \frac{\omega_\pm L_\pm}{4} \tag{97}$$

We then obtain the angular momenta of the three rods as

$$J_H = \frac{\omega_H}{2}\left(-\sigma + M_H - Q_H\Phi_H\right), \qquad \tilde{J}_\pm = N^2\left(\frac{\pm N\sigma - Ma}{\nu^2 \pm 2aN} \mp \frac{v_\pm u_\pm}{2}\right). \tag{98}$$

We have explicitly checked that

$$\tilde{J}_\infty = J_H + \tilde{J}_+ + \tilde{J}_- = aM.$$

Therefore, we have constructed horizon mass, angular momentum and charge in terms of the global parameters and checked their total balance.

7. Conclusion

We have shown that the derivation of mass formulas using the Tomimatsu approach for calculating Komar integrals around rods in electrovacuum can be generalized to the EMDA theory containing scalar fields coupled to the graviphoton. Using a three-dimensional reduction of the EMDA equations, we construct magnetic and twist potentials, which allow to express the integrals over the rods in the same way as in the Einstein-Maxwell theory, where Tomimatsu used for this purpose the Ernst potentials. It should be noted that the scalar dilaton and axion fields do not contribute to the resulting mass formulas, and their asymptotics only rotates electric and magnetic charges in the parameter space. For regular asymptotically flat configurations, the dilaton and axion charges are secondary and their variations do not enter the Smarr-type formulas.

In this approach, the magnetic and NUT charges do not affect the mass and angular momentum of the black hole calculated as Komar's integrals over the horizon. They contribute to the asymptotic mass and angular momentum via the respective individual rods representing the Dirac and Misner strings. As an illustration, we considered the case of a rotating EMDA dyon equipped with NUT. In this case, as in the case of dyonic Kerr-Neumann-NUT, the Dirac string contributes to the

asymptotic mass, but not to the asymptotic angular momentum, while the Misner string contributes to both.

Holography for rotating black holes in $f(T)$ gravity

Masoud Ghezelbash
Department of Physics and Engineering Physics,

We extend the black hole holography to the case of an asymptotically anti–de Sitter (AdS) rotating charged black holes in $f(T) = T + \alpha T^2$ gravity, where α is a constant. We find that the scalar wave radial equation at the near-horizon region implies the existence of the 2D conformal symmetries. We show that choosing proper central charges for the dual CFT, we produce exactly the macroscopic Bekenstein-Hawking entropy from the microscopic Cardy entropy for the dual CFT. These observations suggest that the rotating charged AdS black hole in $f(T)$ gravity is dual to a 2D CFT at finite temperatures.*

Keywords: $f(T)$ gravity, Black holes, Holography

1. Introduction

The idea of AdS/CFT correspondence was extended to the case of extremal rotating black holes, namely, the Kerr/CFT correspondence which was proposed by Guica et al.[6] The correspondence states that the physics of the extremal Kerr black holes, which are rotating with maximum angular velocity, can be described by a 2D CFT, living on the near-horizon region of the black holes. The correspondence was established by showing that one can microscopically reproduces the Bekenstein-Hawking entropy, using the CFT Cardy entropy formula. As one would expect, the Kerr/CFT correspondence is not only a peculiar property of extremal black holes but also non-extremal Kerr black holes. However, at the near-horizon region of the non-extremal Kerr black holes, one cannot indicate any conformal symmetries. In other words, the conformal symmetries are not the symmetries of the non-extremal Kerr black hole geometry (as they are for the case of the extremal Kerr black holes). However, it turns out that the "hidden" conformal symmetries can be revealed by looking at the solution space of the radial part of the Klein-Gordon equation, for a massless scalar probe in the near-horizon region of the Kerr black holes.[7] In this case, the radial equation, can be written as the $SL(2,R)_L \times SL(2,R)_R$ Casimir eigen-equation. Subsequently, the Kerr/CFT correspondence can be established by matching the microscopic CFT Cardy entropy to the macroscopic Bekenstein-Hawking entropy

*This presentation is entirely based on the published paper in *Phys. Rev.* **D 101**, 024020 (2020) by C. Bernard and M. Ghezelbash.

of the Kerr black holes with general angular momentum and mass parameters. The correspondence has been studied for several black holes solutions, for instance, in Refs.[8–12,12–18].

The usual theory of gravity, based on the Riemannian geometry, has been extended through several gravity theories. One of them is the teleparallel gravity (TG) theory, where the Ricci scalar R, is replaced by the teleparallel torsion scalar T. Moreover, the TG has been generalized to $f(T)$ gravity by replacing the torsion scalar T, with an arbitrary function of T, such as $f(T)$. In,[19] Awad et al. find an asymptotically rotating charged AdS black hole solution, in quadratic $f(T)$ gravity, where $f(T) = T + \alpha T^2$. A very natural question to be asked, is "Do we have any $f(T)$/Hidden CFT correspondence?", that we address in this article.

The outline of this presentation is organized as follows. In Sec. 2, we review the $f(T)$-Maxwell gravity theory as well as the rotating charged AdS black hole solutions, and its thermodynamics aspects. We also consider the massless Klein-Gordon wave equation, in the background of the rotating charged AdS black holes, in quadratic $f(T)$ gravity. In Sec. 3, we study the radial wave equation in the near-horizon region of the black holes, and rewrite it as the $SL(2,R)_L \times SL(2,R)_R$ Casimir equation. We also find the central charges of the dual CFT by matching the Cardy entropy for the dual CFT to the macroscopic Bekenstein-Hawking entropy. Therefore, we present evidence that the rotating charged AdS black holes in quadratic $f(T)$ gravity, can be considered holographically dual to the CFT. In the final section, we summarize our results and address some future works. We use the Planck units, in which $c = G = \hbar = k_B = 1$.

2. f(T) Rotating Black Holes

The basic variables in TG are tetrad fields ${e_a}^\mu$, where $a = (0,1,2,3)$ is the index of internal space and $\mu = (0,1,2,3)$ is the index of spacetime. The tetrad fields satisfy

$$ {e_a}^\mu {e^a}_\nu = \delta^\mu_\nu, \ {e_a}^\mu {e^b}_\mu = \delta^b_a. \tag{1} $$

The tetrad fields are related to the spacetime metric and its inverse

$$ g_{\mu\nu} = \eta_{ab} {e^a}_\mu {e^b}_\nu, \ g^{\mu\nu} = \eta^{ab} {e_a}^\mu {e_b}^\nu, \tag{2} $$

respectively, where $\eta_{ab} = \mathrm{diag}\,(-,+,+,+)$ is the metric of 4D Minkowski spacetime. Also, it can be shown that $e = \det(e_{a\mu}) = \sqrt{-g}$, where g is the determinant of the metric. In TG, we use the Weitzenbock connection

$$ {W^\alpha}_{\mu\nu} = {e_a}^\alpha \partial_\nu {e^a}_\mu = -{e^a}_\mu \partial_\nu {e_a}^\alpha, \tag{3} $$

to define the covariant derivative, by

$$ \nabla_\nu {e_a}^\mu = \partial_\nu {e_a}^\mu + {W^\mu}_{\rho\nu} {e_a}^\rho = 0. \tag{4} $$

The Weitzenbock connection is curvature-free, but it has a non vanishing torsion

$$ {T^\alpha}_{\mu\nu} = {W^\alpha}_{\nu\mu} - {W^\alpha}_{\mu\nu} = {e_i}^\alpha \left(\partial_\mu {e^i}_\nu - \partial_\nu {e^i}_\mu \right). \tag{5} $$

We define the torsion scalar by

$$T = T^{\alpha}{}_{\mu\nu} S_{\alpha}{}^{\mu\nu}, \tag{6}$$

where the superpotential tensor is

$$S_{\alpha}{}^{\mu\nu} = \frac{1}{2}\left(K^{\mu\nu}{}_{\alpha} + \delta^{\mu}_{\alpha} T^{\beta\nu}{}_{\beta} - \delta^{\nu}_{\alpha} T^{\beta\mu}{}_{\beta}\right). \tag{7}$$

We note that the Contortion tensor $K_{\alpha\mu\nu}$ is given by

$$K_{\alpha\mu\nu} = \frac{1}{2}\left(T_{\nu\alpha\mu} + T_{\alpha\mu\nu} - T_{\mu\alpha\nu}\right). \tag{8}$$

We consider a four-dimensional rotating charged AdS black hole solution in $f(T)$-Maxwell theory with a negative cosmological constant where

$$f(T) = T + \alpha T^2. \tag{9}$$

The dimensional negative parameter α is the coefficient of the quadratic term of the scalar torsion. The action of the $f(T)$-Maxwell theory in 4D, for an asymptotically AdS spacetimes, is given by

$$\mathcal{S} = \frac{1}{2\mathfrak{K}} \int d^4x\, |e| \left(f(T) - 2\Lambda - F \wedge {}^{*}F\right), \tag{10}$$

where $\Lambda = -3/l^2$ is the 4D cosmological constant, l is the length scale of AdS spacetime. The constant $\mathfrak{K}$ in (10) is related to the 4D Newton's gravitational constant G_4, by $\mathfrak{K} = 2\Omega_2 G_4$, where $\Omega_2 = 2\pi^{3/2}/\Gamma(3/2)$, is the volume of 2D unit sphere, and $\Gamma(3/2) = \frac{1}{2}\sqrt{\pi}$.

In the action (10), $F = d\tilde{\Phi}$, where $\tilde{\Phi} = \tilde{\Phi}_{\mu} dx^{\mu}$ is the gauge potential one-form.

Varying action (10) with respect to the tetrad fields and the Maxwell potential Φ_{μ}, one finds the field equations for gravity

$$S_{\mu}{}^{\rho\nu} \partial_{\rho} T f''(T) + \left[e^{-1} e^{a}{}_{\mu} \partial_{\rho}\left(e e_{\alpha}{}^{\alpha} S_{\alpha}{}^{\rho\nu}\right) - T^{\alpha}{}_{\lambda\mu} S_{\alpha}{}^{\nu\lambda}\right] f'(T)$$

$$-\frac{\delta^{\nu}_{\mu}}{4}\left(f(T) + \frac{6}{l^2}\right) = -\frac{\mathfrak{K}}{2} \mathcal{T}_{\mathrm{em}}{}^{\nu}{}_{\mu}, \tag{11}$$

and the Maxwell's equations

$$\partial_{\nu}\left(\sqrt{-g} F^{\mu\nu}\right) = 0. \tag{12}$$

respectively.

In equation (11), $\mathcal{T}_{\mathrm{em}}{}^{\nu}{}_{\mu} = F_{\mu\alpha} F^{\nu\alpha} - 1/4 \delta_{\mu}{}^{\nu} F_{\alpha\beta} F^{\alpha\beta}$, is the energy-momentum tensor of the electromagnetic field. The rotating charged AdS black hole solution, is given by[19]

$$ds^2 = -A(r)(\Xi dt - \Omega d\phi)^2 + \frac{dr^2}{B(r)} + \frac{r^2}{l^4}\left(\Omega dt - \Xi l^2 d\phi\right)^2 + \frac{r^2}{l^2} dz^2, \tag{13}$$

where the range of coordinates are given by $-\infty < t, z < \infty$, $0 \leq r < \infty$ and $0 \leq \phi < 2\pi$.

In metric (13), we have

$$A(r) = r^2\Lambda_{eff} - \frac{M}{r} + \frac{3Q^2}{2r^2} + \frac{2Q^3\sqrt{6\,|\alpha|}}{6r^4}, \tag{14}$$

$$B(r) = A(r)\beta(r), \tag{15}$$

$$\beta(r) = \left(1 + Q\sqrt{6\,|\alpha|}/r^2\right)^{-2}, \tag{16}$$

$$\Xi = \sqrt{1 + \frac{\Omega^2}{l^2}}, \tag{17}$$

where $\Lambda_{eff} = \frac{1}{36|\alpha|}$, and M, Q, and Ω are the mass parameter, the charge parameter, and the rotation parameter, respectively. The parameter α cannot be zero, since the effective cosmological constant Λ_{eff}, and the metric functions $A(r)$ and $B(r)$ become singular. The gauge potential one-form $\tilde{\Phi}$ is given by

$$\tilde{\Phi}(r) = -\Phi(r)\left(\Omega d\phi - \Xi dt\right). \tag{18}$$

where $\Phi(r) = \frac{Q}{r} + \frac{Q^2\sqrt{6|\alpha|}}{3r^3}$. We note that the torsion scalar T, for the black hole solution (13), is given by

$$T(r) = \frac{4A'(r)B(r)}{rA(r)} + \frac{2B(r)}{r^2}, \tag{19}$$

where $A(r)$ and $B(r)$, in equations (14) and (15).

We notice that setting the rotational parameter $\Omega = 0$, we find the static charged black hole configuration, as in Ref.[20]. Moreover, turning off the mass parameter M and Q, the metric (13) reduces to, the 4D AdS metric in an uncommon coordinate system.

The horizons of the black holes are the positive roots of $A = 0$, among which, the outer one is denoted by r_+. The non-vanishing components of the contravariant metric tensor are given by

$$g^{tt} = \frac{l^4\left(A(r)\Omega^2 - r^2\Xi^2\right)}{A(r)r^2\left(\Xi^2l^2 - \Omega^2\right)^2},\ g^{rr} = B(r),\ g^{zz} = \frac{l^2}{r^2},$$

$$g^{\phi\phi} = \frac{A(r)\Xi^2l^4 - r^2\Omega^2}{A(r)r^2\left(\Xi^2l^2 - \Omega^2\right)^2},\ g^{t\phi} = g^{\phi t} = \frac{\Xi\Omega l^2\left(A(r)l^2 - r^2\right)}{A(r)r^2\left(\Xi^2l^2 - \Omega^2\right)^2}, \tag{20}$$

and the determinant of the metric is

$$\sqrt{-g} = \sqrt{\frac{A(r)}{B(r)}}\frac{r^2\left(\Xi^2l^2 - \Omega^2\right)}{l^3}. \tag{21}$$

We find the area of the outer horizon $\mathcal{A}$, by setting $dt = dr = 0$ in the metric (13), and find

$$\mathcal{A} = \int_0^{2\pi} d\phi \int_0^L dz\sqrt{-g|_{dt=dr=0}} = \frac{2\pi r_+^2\Xi L}{l}. \tag{22}$$

We discuss now the first law of black hole thermodynamics in $f(T)$ gravity. Generally, the first law of black hole thermodynamics

$$\delta\mathcal{Q} = \tau\delta S, \tag{23}$$

where $\delta\mathcal{Q}$ and δS are the heat flux and the entropy change, respectively, is violated in $f(T)$ gravity. The Hawking temperature $\tau = \kappa/2\pi$ in $f(T)$ gravity, where κ is the surface gravity, is the same as one in the Einstein gravity, since it is independent of dynamics of gravity. The black hole solutions in $f(T)$ gravity, violate the Clausius relation $dS = d\mathcal{Q}/\tau$, which suggest that black hols in $f(T)$ gravity, even in a static spacetime, are in non-equilibrium state and produce an intrinsic entropy production.[21]

The heat flux $\delta\mathcal{Q}$ along a Killing vector ξ^μ, is given by

$$\delta\mathcal{Q} = \frac{\kappa}{2\pi}\left(\frac{f'(T)\,d\mathcal{A}}{4}\right)\Big|_0^{d\lambda} + \frac{1}{8\pi}\int\limits_H k^\nu\partial^\mu f'(T)\left(\xi^\rho S_{\rho\nu\mu} - \partial_\nu\xi_\mu\right)d\mathcal{A}d\lambda, \tag{24}$$

where H is the black hole horizon, λ is the affine parameter, $k^\mu = dx^\mu/d\lambda$ is the tangent vector to H, and κ is the surface gravity of the surface H. The first term in the right-hand side of equation (24) provides the first law of black hole thermodynamics Ref.[21]. However, the second term, in general, is not equal to zero. This term maybe regarded as a contribution to the intrinsic entropy production δS_i, where

$$\frac{1}{8\pi}\int k^\nu\partial^\mu f'(T)\left(\xi^\rho S_{\rho\nu\mu} - \partial_\nu\xi_\mu\right)d\mathcal{A}d\lambda = -\tau\delta S_i. \tag{25}$$

The equation (25) suggests that the $f(T)$ black holes are in non-equilibrium thermodynamics, where

$$\delta\mathcal{Q} = \tau\delta S - \tau\delta S_i. \tag{26}$$

Miao et al.[21] showed that the first law of thermodynamics for the $f(T)$black holes can be recovered approximatively, if $f''(T) \ll 1$. In this approximation, the intrinsic entropy production term in equation (24) can be neglected, and the entropy of black holes in $f(T)$ gravity becomes

$$S = \frac{f'(T)\,\mathcal{A}}{4}. \tag{27}$$

We note that in the case of $f'(T) = 1$, the entropy production δS_i vanishes, and the entropy (27) reduces to the Bekenstein-Hawking entropy in Einstein gravity. Using equations (9) and (22) in (27), we find the entropy of black holes in equation (13), as

$$S = \frac{\pi\Xi L\left(7{r_+}^6 + 9\sqrt{6\,|\alpha|}Q{r_+}^4 + 18M\,|\alpha|\,{r_+}^3 - 54Q^2\,|\alpha|\,{r_+}^2 - 42\sqrt{6|\alpha|^3}Q^3\right)}{9l\left(Q\sqrt{6\,|\alpha|} + {r_+}^2\right)^2}. \tag{28}$$

We consider a massless scalar field ψ, in the background of the rotating charged AdS black holes (13), in quadratic $f(T)$ gravity. The scalar wave equation is given by[22]

$$\frac{1}{\sqrt{-g}}\partial_\mu\left(\sqrt{-g}g^{\mu\nu}\partial_\nu\psi\right)=0. \tag{29}$$

We consider the following ansatz for the scalar field

$$\psi\left(t,r,z,\phi\right)=e^{-i\omega t+ikz+im\phi}R\left(r\right), \tag{30}$$

where ω is the frequency of the scalar field, m is the azimuthal harmonic index, and k is the wave number. Substituting equations (20), (21), and (30) into equation (29), we find the radial equation

$$B(r)\frac{d^2R\left(r\right)}{dr^2}+\left(rB(r)\frac{dA(r)}{dr}+rA(r)\frac{dB(r)}{dr}+4A(r)B(r)\right)\frac{dR(r)}{dr}+V(r)R\left(r\right)=0, \tag{31}$$

where the potential $V(r)$, is given by

$$V(r)=\frac{r^2\left(\Xi l^2\omega-\Omega m\right)^2-A(r)l^2\left\{k^2l^4\Xi^4+k^2\Omega^4+l^2\left[m^2\Xi^2-2m\Xi\Omega\omega+\Omega^2\left(\omega^2-2\Xi^2k^2\right)\right]\right\}}{A(r)r^2\left(\Xi^2l^2-\Omega^2\right)^2}. \tag{32}$$

In the near-horizon region, we expand the metric function $A(r)$ as a quadratic polynomial in $(r-r_+)$, such as

$$A(r)\simeq K\left(r-r_+\right)\left(r-r_*\right), \tag{33}$$

where

$$K=15{r_+}^4\Lambda_{eff}-3Mr_++\frac{3Q^2}{2}, \tag{34}$$

$$r_*=r_+-\frac{2r_+\left(2{r_+}^4\Lambda_{eff}-Mr_++Q^2\right)}{10{r_+}^4\Lambda_{eff}-2Mr_++Q^2}. \tag{35}$$

We note that r_* is not necessarily any of the black hole horizons. In the near-horizon region, we consider the low-energy limit for the scalar fields, where $r_+\ll\frac{1}{\omega}$. Moreover, we consider a limit where the outer horizon r_+ is very close to r_*, in which, $|r_+-r_*|\ll r_+$. Using these two approximations, we find that the radial equation (31) simplifies to

$$\frac{d}{dr}\{\left(r-r_+\right)\left(r-r_*\right)\frac{d}{dr}R\left(r\right)\}+\left[\left(\frac{r_+-r_*}{r-r_+}\right)\mathcal{A}+\left(\frac{r_+-r_*}{r-r_*}\right)\mathcal{B}+\mathcal{C}\right]R\left(r\right)=0, \tag{36}$$

where the constants $\mathcal{A}$, $\mathcal{B}$ and $\mathcal{C}$ are given by

$$\mathcal{A}=\frac{\mathcal{D}m^2+\mathcal{E}m\omega}{K^2{r_+}^2{r_*}^3\left(\Xi^2l^2-\Omega^2\right)^2\left(r_+-r_*\right)^2\beta}+\frac{\mathcal{F}\omega^2}{K{r_+}^2\left(\Xi^2l^2-\Omega^2\right)^2\left(r_+-r_*\right)^2\beta}-C_1, \tag{37}$$

$$\mathcal{B}=\frac{\mathcal{G}m^2+\mathcal{I}m\omega}{K^2{r_+}^3r_*\left(\Xi^2l^2-\Omega^2\right)^2\left(r_+-r_*\right)^2\beta}+\frac{\mathcal{J}\omega^2}{K{r_+}^2\left(\Xi^2l^2-\Omega^2\right)^2\left(r_+-r_*\right)^2\beta}+C_2, \tag{38}$$

$$\mathcal{C}=-\frac{2m\Omega\left(\Xi l^2\omega-\Omega m/2\right)^2\left({r_+}^2+r_+r_*+{r_*}^2\right)}{\left(\Xi^2l^2-\Omega^2\right)^2K^2{r_+}^3{r_*}^3\beta}. \tag{39}$$

In equations (37)-(39), the constants C_1 and C_2 are given by $C_1 = C_2 = k^2l^2/K\beta(r_+-r_*)^2{r_+}^2$, and

$$\mathcal{D}=\Omega^2\left({r_+}^3+2{r_+}^2r_*+3{r_*}^2r_+\right)-l^4\Xi^2{r_*}^3K, \tag{40}$$

$$\mathcal{E}=2\Omega\Xi l^2\left(Kl^2{r_*}^3-{r_+}^3-2{r_+}^2r_*-3r_+{r_*}^2\right), \tag{41}$$

$$\mathcal{F}=-l^4\Omega^2, \tag{42}$$

$$\mathcal{G}=K\Xi^2l^4r_+r_*-\Omega^2\left(3{r_+}^2+2r_+r_*+{r_*}^2\right), \tag{43}$$

$$\mathcal{I}=2l^2\Xi\Omega\left[3{r_+}^2-r_+r_*\left(Kl^2-2\right)+{r_*}^2\right], \tag{44}$$

$$\mathcal{J}=l^4\Omega^2. \tag{45}$$

3. Holography for $f(T)$ Rotating Black Holes

To find the existence of the possible hidden symmetry, we introduce the following conformal coordinates ω^+, ω^- and y, in terms of the black hole coordinates t, r and ϕ

$$\omega^+=\sqrt{\frac{r-r_+}{r-r_*}}e^{2\pi T_R\phi+2n_Rt}, \tag{46}$$

$$\omega^-=\sqrt{\frac{r-r_+}{r-r_*}}e^{2\pi T_L\phi+2n_Lt}, \tag{47}$$

$$y=\sqrt{\frac{r_+-r_*}{r-r_*}}e^{\pi(T_L+T_R)\phi+(n_L+n_R)t}, \tag{48}$$

where T_L, T_R, n_L and n_R are constants. We also define the sets of *local* vector fields

$$H_1=i\partial_+, \tag{49}$$

$$H_0=i\left(\omega^+\partial_++\frac{1}{2}y\partial_y\right), \tag{50}$$

$$H_{-1}=i(\omega^{+2}\partial_++\omega^+y\partial_y-y^2\partial_-), \tag{51}$$

as well as

$$\bar{H}_1 = i\partial_-, \tag{52}$$

$$\bar{H}_0 = i\left(\omega^-\partial_- + \frac{1}{2}y\partial_y\right), \tag{53}$$

$$\bar{H}_{-1} = i(\omega^{-2}\partial_- + \omega^- y\partial_y - y^2\partial_+). \tag{54}$$

The vector fields (49)-(54) obey the $sl(2,R)_L \times sl(2,R)_R$ algebra, as

$$[H_0, H_{\pm 1}] = \mp iH_{\pm 1}, \quad [H_{-1}, H_1] = -2iH_0, \tag{55}$$

$$[\bar{H}_0, \bar{H}_{\pm 1}] = \mp i\bar{H}_{\pm 1}, \quad [\bar{H}_{-1}, \bar{H}_1] = -2i\bar{H}_0. \tag{56}$$

The quadratic Casimir operators of $sl(2,R)_L \times sl(2,R)_R$ algebra, are given by

$$\mathcal{H}^2 = \bar{\mathcal{H}}^2 = -H_0^2 + \frac{1}{2}(H_1H_{-1} + H_{-1}H_1) = \frac{1}{4}(y^2\partial_y^2 - y\partial_y) + y^2\partial_+\partial_-. \tag{57}$$

We notice that the Casimir operators (57), can be rewritten in terms of (t, r, ϕ) coordinates, as

$$\begin{aligned}\mathcal{H}^2 \;=\; & (r-r_+)(r-r_*)\frac{\partial^2}{\partial r^2} + (2r - r_+ - r_*)\frac{\partial}{\partial r} \\ & + \left(\frac{r_+ - r_*}{r - r_*}\right)\left[\left(\frac{n_L - n_R}{4\pi G}\partial_\phi - \frac{T_L - T_R}{4G}\partial_t\right)^2 + C_2\right] \\ & - \left(\frac{r_+ - r_*}{r - r_+}\right)\left[\left(\frac{n_L + n_R}{4\pi G}\partial_\phi - \frac{T_L + T_R}{4G}\partial_t\right)^2 - C_1\right],\end{aligned} \tag{58}$$

where $G = n_LT_R - n_RT_L$.

The Casimir operator (58) reproduces the radial equation (36), by choosing the right and left temperatures, as

$$T_R = \frac{r_+K\left(r_+ - r_*\right)\left(\Xi^2l^2 - \Omega^2\right)\sqrt{\beta r_+r_*\delta}}{4\pi\delta}, \tag{59}$$

$$T_L = \frac{r_+K(\Xi^2l^2 - \Omega^2)[{r_+}^4 + 2{r_+}^3r_* + 6{r_+}^2{r_*}^2 - 2{r_*}^3r_+(Kl^2 - 1) + {r_*}^4]\sqrt{\beta r_+r_*\delta}}{4\pi\left(r_+ + r_*\right)^3\delta}, \tag{60}$$

respectively, and

$$n_R = 0, \tag{61}$$

$$n_L = \frac{{r_*}^2r_+K\left(\Omega^2 - \Xi^2l^2\right)\sqrt{\beta r_+r_*\delta}}{2\Omega l^2\Xi\left(r_+ + r_*\right)^3}. \tag{62}$$

The constant δ which appears in equations (59), (60), (61) and (62), is given by $\delta = 3\Omega^2{r_+}^2 - r_+r_*\left(K\Xi^2l^4 - 2\Omega^2\right) + \Omega^2{r_*}^2$. Moreover, we find two constraints for

the parameters of the black hole solutions (13), such as

$$\frac{\Omega^2\Xi^2 l^4\left[-3{r_+}^2+r_* r_+\left(Kl^2-2\right)-{r_*}^2\right]^2}{K^2\beta {r_+}^3 r_*(r_+-r_*)^2(\Xi^2 l^2-\Omega^2)^2}=\frac{l^4\Omega^2}{{r_+}^2K(\Xi^2 l^2-\Omega^2)^2(r_+-r_*)^2\beta}, \quad (63)$$

and

$$\frac{\Omega^2\Xi^2 l^4\left(Kl^2{r_*}^3-{r_+}^3-2r_* {r_+}^2-3{r_*}^2 r_+\right)^2}{K^2\beta r_+{r_*}^5(r_+-r_*)^2(\Omega^2-\Xi^2 l^2)^2\left(Kl^4\Xi^2 r_* r_+-3\Omega^2{r_+}^2-2\Omega^2 r_* r_+-\Omega^2{r_*}^2\right)}$$
$$=\frac{l^4\Omega^2}{{r_+}^2K(\Xi^2 l^2-\Omega^2)^2(r_+-r_*)^2\beta}. \quad (64)$$

We note that equations (63) and (64) restrict the black hole parameters, in accord with existence of the real positive values for the outer horizon (and any other horizons), as the roots of the tri-quadratic algebraic equation

$$A(r)=0, \quad (65)$$

where $A(r)$ is given in (14).

We note that both right and left temperatures (59) and (60) are positive definite.[23] We emphasize that $SL(2,R)_L\times SL(2,R)_R$ is a *local* hidden symmetry, for the solution space of massless scalar field in the near region of the rotating charged AdS black holes (13), in quadratic $f(T)$ gravity. The *local* hidden symmetry is generated by the vector fields (49)–(54), which are not periodic under the angular identification $\phi\sim\phi+2\pi$. These symmetries can't be used to generate new global solutions from the old ones. This can be interpreted as a statement that the $SL(2,R)_L\times SL(2,R)_R$ symmetry is spontaneously broken down to $U(1)_L\times U(1)_R$ subgroup under the angular identification $\phi\sim\phi+2\pi$. As a result, we can identify the left and right temperatures of the dual CFT. We recall the Cardy entropy formula for the dual 2D CFT with temperatures T_L and T_R

$$S_{CFT}=\frac{\pi^2}{3}\left(c_L T_L+c_R T_R\right), \quad (66)$$

where c_L are c_R are the corresponding central charges for the left and right sectors. The central charges can be derived from the *asymptotic symmetry group* of the near-horizon (near-)extremal black hole geometry. There is no derivation for the central charges of the CFT dual to the non-extremal black holes, that we consider in this article. Of course, we expect that the conformal symmetry of the extremal black holes connects smoothly to those of the non-extremal black holes, for which the central charges are the same. The near-horizon extremal geometry for the spacetime (13) is still unknown, and it is not a straightforward task to find that, due to the tri-quadratic behaviour of the metric function $A(r)$. As a result, we turn the logic around and consider the favourite holographic situation, in which, the Cardy entropy (66) produces exactly the macroscopic entropy (27). Substituting equations (28),

(59), and (60) into equation (66), we find the central charges

$$c \equiv c_L = c_R = \frac{12\Xi\delta L\varpi(r_+ + r_*)^3}{lK{r_+}^2(\Xi^2 l^2 - \Omega^2)({r_+}^3 + 2{r_+}^2 r_* + 3r_+ {r_*}^2 - l^2 K {r_*}^3)(Q\sqrt{6|\alpha|} + {r_+}^2)^2\sqrt{\beta r_+ r_* \delta}}, \tag{67}$$

where $\varpi = {r_+}^2\left({r_+}^2 Q\sqrt{6\,|\alpha|}/2 + 7{r_+}^4/18 + M\,|\alpha|\,r_+ - 3Q^2\,|\alpha|\right) - 7\sqrt{6|\alpha|^3}Q^3/3$. We note that we only consider CFTs, in which the left and right central charges are equal, $c \equiv c_L = c_R$.[24,25]

4. Conclusions

In this presentation which is based entirely on the published paper,[23] we extend the concept of black hole holography to the non-extremal 4D rotating charged AdS black holes in $f(T)$-Maxwell theory with a negative cosmological constant. We explicitly construct the hidden conformal symmetry for the rotating black holes in$f(T)$-Maxwell theory with a negative cosmological constant. We mainly consider the near-horizon region, as the metric function which determines the event horizon, is a triple-quadratic equation. In this region, we show that the radial equation of the scalar wave function could be written as the $SL(2,R)_L \times SL(2,R)_R$ squared Casimir equation, indicating a *local* hidden conformal symmetry acting on the solution space. The conformal symmetry is spontaneously broken under the angular identification $\phi \sim \phi + 2\pi$, which suggests the rotating charged AdS black holes in quadratic $f(T)$ gravity, should be dual to the finite temperatures T_L and T_R mixed state, in the 2D CFT. Instead of calculating the central charges using the *asymptotic symmetry group*, we calculated the central charges by assuming the Cardy entropy for the dual CFT, matches the macroscopic Bekenstein-Hawking entropy. These results suggest that rotating charged AdS black holes in quadratic $f(T)$ gravity with particular values of M, Ω, Q, and $|\alpha|$, are dual to a 2D CFT.

It is an open question to find the near-horizon (near-)extremal geometry of the rotating charged AdS spacetime in quadratic $f(T)$ gravity. We may calculate the central charges using the *asymptotic symmetry group* to confirm our results in this article. We can also study on various kinds of superradiant scattering off the near-extremal black hole as a further evidence to support the holographic picture for the non-extremal 4D rotating charged AdS black holes in $f(T)$-Maxwell theory with a negative cosmological constant. We leave addressing these open questions for future articles.

The evidence is mounting that the universe is currently undergoing a phase of accelerated expansion. One possible alternative is the modification in gravity in the largest possible scales. This leads to the many questions related to black-holes: violation of Birkhoff theorem and no-hair theorem. To confirm/infirm, we need to obtain exact black-hole solutions in these modified gravity theories. In this talk, we focus on the exact spherically symmetric solutions in $f(R)$ theories of gravity. We explicitly show that some $f(R)$ models contain an infinite number of exact static, Ricci-flat spherically symmetric vacuum solutions and, hence, violate Birkhoff's theorem in $f(R)$ theories. We analytically derive two exact vacuum black-hole solutions for the same class of $f(R)$ theories. The two black-hole solutions have the event-horizon at the same point; however, their asymptotic features are different. Our results suggest that the no-hair theorem may not hold for generic modified gravity theories. We discuss the implications to distinguish modified gravity theories from general relativity.

Keywords: $f(R)$ theory, no-hair theorem, based on the work[1]

1. Introduction

General Relativity (GR) is a successful description of gravity and is in excellent agreement with experiments and observations. However, paradoxically, the very success of GR suggests that GR might have classical and quantum corrections in the strong gravity regime.[2–6] Recently, strong gravity diagnostic parameters have been proposed to distinguish GR and modified gravity theories.[7]

In GR, static black-hole solutions are the final stage of gravitationally collapsed objects. As a consequence of the no-hair theorem,[8] GR predicts that the Kerr metric represents the most general astrophysical black holes.[9] In the case of spherical symmetry, Birkhoff's theorem ensures that the most general spherically symmetric, electrovac solution of the Einstein-Maxwell equations is the static Reissner-Nordstrom solution.[10,11] The absence of spin-0 modes in the linearized field equations leads to this result. However, there is no Birkhoff theorem for the Kerr metric. Outside

a rotating star, the metric is not described by Kerr. In comparison, the Schwarzschild solution describes the space-time outside a non-rotating star.

In this talk, we show that the Schwarzschild solution is not an unique solution for $f(R)$ theories of gravity. More specifically, we show that there exists an infinite number of spherically symmetric vacuum solutions in 4-D $f(R)$ theories of gravity *without* transforming to a conformal frame.

$f(R)$ theories of gravity are the most straightforward modifications to GR.[6] The higher-order Ricci scalar terms encapsulate modifications to GR. Although the equations of motion are higher-order, they do not suffer from Oströgradsky instability.[12] A deviation from general relativity may introduce changes in both the generation and the propagation of gravitational waves. Unlike GR, $f(R)$ theories have an extra field equation and longitudinal mode.[7, 13]

Although Schwarzschild black-hole is a solution to vacuum $f(R)$ theories of gravity. The additional dynamical equation by the trace equation in $f(R)$ theories may give rise to new solutions other than GR. The reason for such assumption is that, in $f(R)$ gravity has 11 dynamical variables — 10 metric variables ($g_{\mu\nu}$) and the Ricci scalar (R). In other words, in $f(R)$ theories, the scalar curvature R, plays a non-trivial role in determining the metric itself. Recently, the effects on the extra mode are used to obtain diagnostic parameters to distinguish GR and modified gravity theories using the Quasi-normal mode spectrum of the identical black-hole solutions in the two theories.[7] Here, the focus is to test the validity of this assumption. In other words, to verify whether the black-hole solutions in the two theories are indeed identical. We show that $f(R)$ admits multiple space-time geometries with the horizon for the same stress-tensor configuration (vacuum in this case).

We use $(-,+,+,+)$ signature for the 4-D space-time metric,[14] Greek alphabets for the 4-D space-time, and $\kappa^2 = 8\pi G/c^4$ where G is the Newton's constant. We shall denote the derivative of any function with r by an overprime, and overdot denotes the partial derivative w.r.t Ricci scalar (R).

2. $f(R)$ theory and the model

The modified vacuum action for $f(R)$ gravity is:[6]

$$S[g_{\mu\nu}] = \frac{1}{2\kappa^2}\int d^4x\sqrt{-g}\, f(R) \tag{1}$$

where $f(R)$ is arbitrary function of the Ricci scalar R. Using the metric formalism[6] the modified Einstein tensor ($\mathcal{G}_{\mu\nu}$) is obtained, i.e.,

$$\mathcal{G}_{\mu\nu} \equiv \dot{f}(R)\, R_{\mu\nu} - \nabla_\mu\nabla_\nu \dot{f}(R) + g_{\mu\nu}\Box\dot{f}(R) - \frac{f(R)}{2}g_{\mu\nu} = 0\,, \tag{2}$$

where $\dot{f}(R) = \partial f/\partial R$ and $\Box = \nabla^\mu\nabla_\mu$. For the above $f(R)$ action (1), the trace of the field equation (2) is dynamical:

$$R\,\dot{f}(R) + 3\,\Box\dot{f}(R) - 2\,f(R) = 0 \tag{3}$$

In $f(R)$, the scalar curvature R, plays a non-trivial role in determining the metric itself. In general, the field equations for $f(R)$ gravity (2) are fourth-order partial differential equations, instead of second-order partial differential equations of GR. Hence, we expect more class of solutions in $f(R)$ theories of gravity.

One may still find the trivial solution where for which $R = R_0 =$ constant. In such a case, the field equations reduce to the Einstein field equations with an effective cosmological constant and an effective gravitational constant.[15] This includes the case where $R = 0$. However, our interest in this talk is to look for non-trivial solutions.

In our model, we consider $f(R)$ to be a polynomial in R, i.e.,

$$f(R) = \beta_0 + \beta_1 R + \beta_2 R^2 + \cdots , \tag{4}$$

where β_i's $(i = 0, 1, 2 \cdots)$ are constants having appropriate dimensions. The above form of $f(R)$ can be written in a binomial form, i.e.,

$$f(R) = (\alpha_0 + \alpha_1 R)^p , \tag{5}$$

where, p is the power index, we are interested in the strong-gravity corrections to GR, we take $p > 1$. In principle, p need not be an integer. The α_0 and α_1 being positive constants related to the β_i's in (4). For simplicity consider $p = 1$, the above from (3) reduces to:

$$f(R) = \alpha_0 + \alpha_1 R . \tag{6}$$

Thus, α_0 acts like the cosmological constant and α_1 is a dimensionless constant that modifies Newton's constant. [Note that α_1 is dimensionless and α_0 has dimensions of $[L]^{-2}$.]

3. A class of exact solutions for $f(R)$ theory

Consider the static, spherically symmetric metric of the form,

$$ds^2 = -A(r)e^{\delta(r)}dt^2 + \frac{dr^2}{A(r)} + r^2\left(d\theta^2 + \sin^2\theta\, d\phi^2\right) \tag{7}$$

where $A(r)$ and $\delta(r)$ are arbitrary functions of the Schwarzschild radial coordinate r. Substituting the above metric in the modified Einstein's equations (2) for the model $f(R)$ (5), leads to the following three field equations:

$$\mathcal{G}_t^t \equiv T_3[A(r), \delta(r)] = 0 \tag{8a}$$

$$\mathcal{G}_r^r \equiv T_4[A(r), \delta(r)] = 0 \tag{8b}$$

$$\mathcal{G}_\theta^\theta = \mathcal{G}_\phi^\phi \equiv T_5[A(r), \delta(r)] = 0 \tag{8c}$$

where T_3, T_4 and T_5 are functions of $A(r)$ and $\delta(r)$, and their derivatives. More specifically, (i) T_3 and T_5 are non-linear, and *contain up to 4th order derivatives* of $A(r)$ and $\delta(r)$, and (ii) T_4 is non-linear and *contain up to 3rd order derivatives* of

$A(r)$ and $\delta(r)$. (iii) Even in the special case of $\delta(r) = 0$, $\mathcal{G}_t^t \neq \mathcal{G}_r^r$. Hence, we do not expect to get identical solutions as in GR.

The field equations (8) contain up to fourth-order derivatives in $A(r)$ and $\delta(r)$. Thus, an exact solution to these equations will contain up to four independent constants.

Ref. 1 contains the details of the procedure used to reduce these highly non-trivial equations into a product of two second-order non-linear differentials in $A(r)$ and $\delta(r)$. Interestingly, both the procedures lead to the following equation:

$$\frac{2}{r}\,\frac{(p-\frac{1}{2})}{p\,(p-1)}\,\frac{T_1[A(r),\delta(r)]}{(\Phi(r)+4)}\,\frac{T_2[A(r),\delta(r)]}{(\Phi(r)-2)} = 0 \tag{9}$$

where $\Phi(r) = r\left(\delta^{'}(r) + [\ln A(r)]^{'}\right)$ and prime denotes derivative w.r.t r.

At this point, we would like to stress the following points: First, we have obtained the Eq. (9) using two different approaches. This implies that Eq. (9) is a unique differential equation for this $f(R)$ model with the metric (7). Second, Eq. (9) is a product of two second-order non-linear differentials of $T_1[A(r),\delta(r)]$ and $T_2[A(r),\delta(r)]$.[1] It simplifies the procedure to obtain the exact black-hole solutions for any value of p using $T_1[A(r),\delta(r)]$ or $T_2[A(r),\delta(r)]$. Third, the above equation imposes constrains on p, $A(r)$ and $\delta(r)$. More specifically, if for a non-trival solution,

$$p \neq 0, \frac{1}{2}, 1\,;\, \Phi(r) \neq -4 \text{ or } 2\,. \tag{10}$$

Since $p = 1$ is not allowed. It means we are looking for non-trivial solutions valid for modified theories of gravity, where $p = 1$ will give solutions of GR. While $p = 0$ and 1 will lead to divergence, $p = 1/2$ will lead to trivial solutions. Fourth, the above condition of $\Phi(r)$ implies that

$$\delta(r) + \ln A(r) \neq \ln(r^2) \text{ or } \ln(r^{-4}) \tag{11}$$

If we assume $\delta(r) =$ constant, then $A(r) \neq c_0 r^2 + c_1 r^{-4}$, where c_0, c_1 are constants. Lastly, non-trivial solutions for the above equation (9) are possible if T_1 or T_2 vanish, i.e.,

$$T_1[A(r),\delta(r)] = 0 \qquad \text{or} \qquad T_2[A(r),\delta(r)] = 0 \tag{12}$$

In principle, from Eq. (12) we can identity that for a given $A(r)$, we can have two functional forms of $\delta(r)$. Either $T_1 = 0$ or $T_2 = 0$ will give two choices of $\delta(r)$. While, the functional form of $A(r)$ can be obtained from the condition (10) on $\Phi(r)$, we get

$$\delta'(r) + (\ln[A(r)])^{'} = \mu(r) \quad \mu(r) \neq \frac{-4}{r} \text{ or } \frac{2}{r} \tag{13}$$

Thus, for a given $\mu(r)$, we have a functional relation between $A(r)$ and $\delta(r)$. Substituting this relation in the constraint relation (12), we obtain two set of differential equation in terms of $A(r)$ or $\delta(r)$.

Thus, Eq. (12) give two branches of solutions for $A(r)$ and $\delta(r)$ by setting $T_1 = 0$ or $T_2 = 0$. Using the arbitrary function $\mu(r)$, we can obtain an infinite solutions for the spherically symmetric metric (7).

At this point, it is important to validate whether any arbitrary function $\mu(r)$ satisfying $T_1 = 0$ or $T_2 = 0$ is indeed a solution to the vacuum field equations (8)?

To address this, for any p, we write a formal solution to the above equation Eq. (13) as

$$A(r) = e^{-\delta(r)}\gamma(r) \quad \text{where} \quad \gamma(r) = \exp\left(\int \mu(r)dr\right). \tag{14}$$

Substituting $A(r)$ in-terms of $\delta(r)$ in $T_2[A(r), \delta(r)] = 0$, we obtain a differential equation in $\delta''(r)$. Substituting these in Eq. (8), we get,

$$\begin{aligned} T_3[\delta(r), \gamma(r)] &= 4\alpha_1 p(p-1)(p-2)\gamma^7(r)e^{-\delta(r)}\left[\delta'(r)r - 8\right]^2 T_2[\delta(r), \gamma(r)]^2 \\ &= T_5[\delta(r), \gamma(r)] \end{aligned} \tag{15a}$$

$$T_4[\delta(r), \gamma(r)] = -2\alpha_1 p(p-1)\gamma^5(r)e^{-\delta(r)}\left[\delta'(r)r - 8\right]\left(r\ln[\gamma(r)]' + 4\right) T_2[\delta(r), \gamma(r)] \tag{15b}$$

Since, we have obtained the above expressions using the condition $T_2[A(r), \delta(r)] = 0$, we have $\mathcal{G}^t_t = \mathcal{G}^r_r = \mathcal{G}^\theta_\theta = \mathcal{G}^\phi_\phi = 0$. This implies that $A(r)$ given by Eq. (14) satisfying $T_2[A(r), \delta(r)] = 0$ is an exact solution for the $f(R)$ model (5). Since $A(r)$ depends on the arbitrary function $\mu(r)$, for the same observer with Schwarzschild time t, there are *infinite number of exact static, spherically symmetric solutions* for this model.

This is the key result of this talk. The Birkhoff theorem in GR guarantees that static Schwarzschild solution[11] is the most general spherically symmetric vacuum solution. However, the trace equation (3) provides a non-trivial dynamical structure in $f(R)$ theories. This provides an infinite set of static solutions for $f(R)$ theories of gravity. To our knowledge, such an explicit calculation is new for any modified theories of gravity. All the earlier analyses, either restrictive or use a conformal frame to confirm/infirm Birkhoff theorem.[16,17] Here, we have not made any approximation or performed a conformal transformation. Our results point that the Birkhoff theorem is not valid for all modified gravity theories.

As noted in Eq. (12), we can obtain non-trivial solutions if T_1 or T_2 vanish. Until now, we have shown that $T_2 = 0$ yields an infinitely many vacuum spherically symmetric solutions. Unlike T_2, T_1 is not a common factor of the field equations (15); hence, $T_1 = 0$ alone can not provide valid solutions. Thus, beside $T_1 = 0$, we must use either of the three equations (8) to obtain a unique solution.

4. Two vacuum black-hole solutions

In the earlier section, we showed that there exists an infinite number of spherically symmetric vacuum solutions for the $f(R)$ model (5). In this section, we obtain two black-hole solutions which satisfy the condition $T_2[A(r), \delta(r)] = 0$.

As we have mentioned earlier, $\delta(r) = 0$ is a trivial solution. Hence, setting $\delta(r) = 0$, we obtain the following solution for $A(r)$

$$A(r) = 1 + C_2 r^2 - \frac{C_3}{r^2} \quad \text{where} \quad C_2 = \frac{\alpha_0}{12\alpha_1} \tag{16}$$

which satisfies the null-energy condition.[14] C_3 is a constant of integration and can take any real value. We like to list the following important points regarding the above solution: First, it is easy to verify that the above solution satisfies the modified Einstein's equations (8). Second, C_2 is a positive constant, since, α_0 and α_1 are positive constants. Physically, C_2 acts like an effective cosmological constant. For $C_3 > 0$, the metric (7) has a horizon at

$$r_h = \sqrt{\frac{\sqrt{1 + 4C_2C_3} - 1}{2C_2}} \tag{17}$$

In the limit of $\alpha_0 \to 0$, $C_2 \to 0$, the metric (7) has a horizon at $r = \sqrt{C_3}$. Thus, $\alpha_0 \to 0$ is a smooth limit. Third, the term c_3/r^2 is a reminiscence of the charge in the Reissner-Nordström solution in GR.[14] In our case, the $1/r^2$ term is present in the absence of the $1/r$ term. While in GR, C_3/r^2 term can not exist without the mass term. This result is similar to the one obtained sometime back in the context of black-holes on the brane.[18] Physically, C_3 corresponds to the mass of the black-hole. Lastly, it is easy to verify that the above solution satisfies the modified Einstein's equations (8). The Kretschmann scalar for the above form of $A(r)$ is

$$R^{\alpha\beta\gamma\delta}R_{\alpha\beta\gamma\delta} = \frac{\alpha_0^2}{6\alpha_1^2} + \frac{56C_3^2}{r^8}. \tag{18}$$

Thus, the metric has a singularity at $r = 0$ and is finite everywhere else. For finite α_0, the Kretschmann scalar is a positive constant at asymptotic infinity, which corresponds to asymptotic de Sitter space-times in GR.[14]

To obtain second solution, assume $A(r)$ in Eq. (16) and $\delta(r) \neq 0$. Now $A(r)$ in Eq. (16) in $T_2[A(r), \delta(r)] = 0$, this leads to the following differential equation for $\delta(r)$:

$$\delta''(r) + \frac{1}{2}\delta'(r)^2 + \frac{(5C_2r^4 + 2r^2 + C_3)}{(C_2r^4 + r^2 - C_3)}\frac{\delta'(r)}{r} = 0 \tag{19}$$

This differential equation is highly non-linear; however, it has the following exact solution:

$$e^{\delta(r)/2} = \frac{C_4}{2} - \frac{C_5}{2(12\alpha_1)^{3/2}}\frac{(2C_2r^2 + 1)}{(4C_2C_3 + 1)}\frac{1}{(C_2r^4 + r^2 - C_3)^{1/2}} \tag{20}$$

where C_4 and C_5 are arbitrary constants. [C_4 is dimensionless while C_5 has dimension of $[L]$.] The horizon for this new solution is given by (17). The Kretschmann scalar again can be evaluated, and near origin is singular, i.e.

$$R^{\alpha\beta\gamma\delta}R_{\alpha\beta\gamma\delta} \sim \frac{\Gamma(C_2, C_3, C_4, C_5)}{r^8} \tag{21}$$

and is finite everywhere else. Thus, the constants C_4 and C_5 determine the behavior of the second black-hole solution. Thus, we have reconfirmed the results in the earlier section and shown that at least two black-hole solutions correspond to the same matter configuration (in this case, vacuum). To our knowledge, this is a novel result for any modified theories of gravity and confirms that Birkhoff's theorem is not valid for all modified gravity theories.

5. Conclusions and Discussion

In this talk, we obtained many exact static spherically symmetric vacuum solutions for $f(R)$ gravity. We obtained two exact vacuum black-hole solutions to the $f(R)$ model to emphasize this unique feature. We showed that two solutions have the event-horizon at the same point; however, their asymptotic features are different. Our results point that the Birkhoff theorem is not valid for all modified gravity theories. The two black-hole solutions have a space-time singularity at the origin.

Unlike in the literature, we have obtained the exact solutions *without* transforming to a conformal frame. Our analysis shows the deficiency of finding solutions in the conformally transformed frame.[1] The conformal transformations are not well-defined near $T_2 \to 0$ and, hence, the conformal frame will not be able to pick off the solutions we have obtained. However, the solution corresponding to $T_1[A(r), \delta(r)] = 0$ will be well-defined in the conformal frame.

One of the prospects of gravitational wave observations is to find signatures for the modified gravity theories. We have shown that if the modified theories belong to one of the degenerate classes with $T_2 = 0$, then our analysis shows that the prospect of detection needs different methodologies than the one that is currently used.[19]

Universe in a black hole with spin and torsion

We consider gravitational collapse of a spherically symmetric sphere of a fluid with spin and torsion into a black hole. We use the Tolman metric and the Einstein–Cartan field equations with a relativistic spin fluid as a source. We show that gravitational repulsion of torsion prevents a singularity and replaces it with a nonsingular bounce. Quantum particle production during contraction strengthens torsion in opposing shear. Particle production during expansion can produce enormous amounts of matter and generate a finite period of inflation. The resulting closed universe on the other side of the event horizon may have several bounces. Such a universe is oscillatory, with each cycle larger in size then the previous cycle, until it reaches the cosmological size and expands indefinitely. Our universe might have therefore originated from a black hole existing in another universe.

Keywords: Einstein-Cartan theory; torsion; gravitational collapse.

1. Einstein–Cartan gravity and spin fluid

In general relativity (GR), the affine connection $\Gamma_{ij}^{\ \ k}$ is constrained to be symmetric. Einstein–Cartan–Sciama–Kibble (EC) gravity removes this constraint by regarding the antisymmetric part of the connection, the torsion tensor $S^k_{\ ij} = \Gamma_{[ij]}^{\ \ \ k}$, as a variable.[1] The total Lagrangian density is $-\frac{1}{2\kappa}R\sqrt{-g} + L_{\rm m}$, where R is the Ricci scalar constructed from the connection and $L_{\rm m}$ is the Lagrangian density of matter, as in GR.[2]

Varying the Lagrangian with respect to the contortion tensor $C_{ijk} = S_{ijk} + S_{jki} + S_{kji}$ gives the Cartan equations:

$$S^j_{\ ik} - S_i\delta^j_k + S_k\delta^j_i = -\frac{1}{2}\kappa s_{ik}^{\ \ \ j},$$

where $S_i = S^k_{\ ik}$ and $s^{ijk} = 2(\delta L_{\rm m}/\delta C_{ijk})/\sqrt{-g}$ is the spin tensor. Varying the Lagrangian with respect to the metric tensor g_{ik} gives the Einstein equations with the Ricci tensor. They can be put into a GR form with the modified energy–momentum tensor:

$$G^{ik} = \kappa T^{ik} + \kappa^2\Big(-s^{ij}_{\ \ \ [l}s^{kl}_{\ \ \ j]} - \frac{1}{2}s^{ijl}s^k_{\ jl} + \frac{1}{4}s^{jli}s_{jl}^{\ \ \ k} + \frac{1}{8}g^{ik}(-4s^l_{\ j[m}s^{jm}_{\ \ \ l]} + s^{jlm}s_{jlm})\Big).$$

Dirac spinors, representing fermions, couple to torsion through the covariant derivative in the Lagrangian and therefore are the source of torsion. At macroscopic

scales, Dirac fields can be averaged and described as a spin fluid:[3]

$$s_{ij}{}^{k} = s_{ij}u^{k}, \quad s_{ij}u^{j} = 0.$$

The terms in the effective energy–momentum tensor that are quadratic in the spin tensor do not vanish after averaging:

$$G^{ij} = \kappa\Big(\epsilon - \frac{1}{4}\kappa s^2\Big)u^i u^j - \kappa\Big(p - \frac{1}{4}\kappa s^2\Big)(g^{ij} - u^i u^j),$$

where

$$s^2 = \frac{1}{2}s_{ij}s^{ij} > 0 \propto n_{\mathrm{f}}^2$$

is the averaged square of the spin density.[4] The Einstein–Cartan equations for a spin fluid are therefore equivalent to the GR Einstein equations for a perfect fluid with:

$$\tilde{\epsilon} = \epsilon - \alpha n_{\mathrm{f}}^2, \quad \tilde{p} = p - \alpha n_{\mathrm{f}}^2,$$

where ϵ and p are the thermodynamic energy density and pressure, n_{f} is the number density of fermions, and $\alpha = \kappa(\hbar c)^2/32$ with $\kappa = 8\pi G/c^4$.

2. Gravitational collapse of a fluid sphere

A spherically symmetric gravitational field is given by the Tolman metric:[5]

$$ds^2 = e^{\nu(\tau,R)}c^2 d\tau^2 - e^{\lambda(\tau,R)}dR^2 - e^{\mu(\tau,R)}(d\theta^2 + \sin^2\theta\, d\phi^2),$$

where ν, λ, and μ are functions of a time coordinate τ and a radial coordinate R. Coordinate transformations $\tau \to \tilde{\tau}(\tau)$ and $R \to \tilde{R}(R)$ do not change the form of the metric. The components of the Einstein tensor corresponding to this metric that do not vanish identically are:

$$G_0^0 = -e^{-\lambda}\Big(\mu'' + \frac{3\mu'^2}{4} - \frac{\mu'\lambda'}{2}\Big) + \frac{e^{-\nu}}{2}\Big(\dot{\lambda}\dot{\mu} + \frac{\dot{\mu}^2}{2}\Big) + e^{-\mu},$$

$$G_1^1 = -\frac{e^{-\lambda}}{2}\Big(\frac{\mu'^2}{2} + \mu'\nu'\Big) + e^{-\nu}\Big(\ddot{\mu} - \frac{\dot{\mu}\dot{\nu}}{2} + \frac{3\dot{\mu}^2}{4}\Big) + e^{-\mu},$$

$$G_2^2 = G_3^3 = -\frac{e^{-\nu}}{4}(\dot{\lambda}\dot{\nu} + \dot{\mu}\dot{\nu} - \dot{\lambda}\dot{\mu} - 2\ddot{\lambda} - \dot{\lambda}^2 - 2\ddot{\mu} - \dot{\mu}^2)$$

$$-\frac{e^{-\lambda}}{4}(2\nu'' + \nu'^2 + 2\mu'' + \mu'^2 - \mu'\lambda' - \nu'\lambda' + \mu'\nu'),$$

$$G_0^1 = \frac{e^{-\lambda}}{2}(2\dot{\mu}' + \dot{\mu}\mu' - \dot{\lambda}\mu' - \dot{\mu}\nu'),$$

where a dot denotes differentiation with respect to $c\tau$ and a prime denotes differentiation with respect to R.

In the comoving frame of reference, the spatial components of the four-velocity u^μ vanish. The nonzero components of the energy–momentum tensor for a spin fluid, $T_{\mu\nu} = (\tilde{\epsilon} + \tilde{p})u_\mu u_\nu - \tilde{p}g_{\mu\nu}$, are: $T_0^0 = \tilde{\epsilon}$, $T_1^1 = T_2^2 = T_3^3 = -\tilde{p}$. The Einstein field equations $G_\nu^\mu = \kappa T_\nu^\mu$ in this frame of reference are:

$$G_0^0 = \kappa\tilde{\epsilon}, \quad G_1^1 = G_2^2 = G_3^3 = -\kappa\tilde{p}, \quad G_0^1 = 0.$$

The covariant conservation of the energy–momentum tensor gives

$$\dot{\lambda} + 2\dot{\mu} = -\frac{2\dot{\tilde{\epsilon}}}{\tilde{\epsilon} + \tilde{p}}, \quad \nu' = -\frac{2\tilde{p}'}{\tilde{\epsilon} + \tilde{p}},$$

where the constants of integration depend on the allowed transformations $\tau \to \tilde{\tau}$ and $R \to \tilde{R}$.

If the pressure is homogeneous (no pressure gradients), then $\tilde{p}' = 0$, which gives $\nu' = 0$. Therefore, $\nu = \nu(\tau)$ and a transformation $\tau \to \tilde{\tau}$ can bring ν to zero and $g_{00} = e^{\nu}$ to 1. The system of coordinates becomes synchronous. Defining $r(\tau, R) = e^{\mu/2}$ turns the metric into[5]

$$ds^2 = c^2 d\tau^2 - e^{\lambda(\tau,R)} dR^2 - r^2(\tau, R)(d\theta^2 + \sin^2\theta \, d\phi^2).$$

Every particle in a collapsing fluid sphere is represented by a value of R that ranges from 0 (at the center) to R_0 (at the surface). The Einstein field equations reduce to

$$\begin{aligned}
&\kappa\tilde{\epsilon} = -\frac{e^{-\lambda}}{r^2}(2rr'' + r'^2 - rr'\lambda') + \frac{1}{r^2}(r\dot{r}\dot{\lambda} + \dot{r}^2 + 1),\\
&-\kappa\tilde{p} = \frac{1}{r^2}(-e^{-\lambda}r'^2 + 2r\ddot{r} + \dot{r}^2 + 1),\\
&-2\kappa\tilde{p} = -\frac{e^{-\lambda}}{r}(2r'' - r'\lambda') + \frac{\dot{r}\dot{\lambda}}{r} + \ddot{\lambda} + \frac{1}{2}\dot{\lambda}^2 + \frac{2\ddot{r}}{r},\\
&2\dot{r}' - \dot{\lambda}r' = 0.
\end{aligned}$$

Integrating the last equation gives

$$e^{\lambda} = \frac{r'^2}{1 + f(R)}, \tag{1}$$

where f is a function of R satisfying a condition $1 + f > 0$.[6] Substituting this relation into the second field equation gives $2r\ddot{r} + \dot{r}^2 - f = -\kappa\tilde{p}r^2$, which is integrated to

$$\dot{r}^2 = f(R) + \frac{F(R)}{r} - \frac{\kappa}{r}\int \tilde{p}r^2 dr,$$

where F is a positive function of R. Substituting the last two equations into the first field equation gives a relation $\kappa(\tilde{\epsilon} + \tilde{p}) = F'(R)/(r^2 r')$, leading to

$$\dot{r}^2 = f(R) + \frac{\kappa}{r}\int_0^R \tilde{\epsilon} r^2 r' dR. \tag{2}$$

If the mass of the sphere is M, then the Schwarzschild radius $r_g = 2GM/c^2$ of the black hole that forms from the sphere is equal to

$$r_g = \kappa \int_0^{R_0} \tilde{\epsilon} r^2 r' dR.$$

These two equations give $\dot{r}^2(\tau, R_0) = f(R_0) + r_g/r(\tau, R_0)$. If $r_0 = r(0, R_0)$ is the initial radius of the sphere and the sphere is initially at rest, then $\dot{r}(0, R_0) = 0$. Consequently, the value of R_0 is determined by

$$f(R_0) = -\frac{r_g}{r_0}.$$

Substituting $r = e^{\mu/2}$ and (1) into the first conservation law gives the first law of thermodynamics for the effective energy density and pressure:

$$\frac{d}{d\tau}(\tilde{\epsilon} r^2 r') + \tilde{p}\frac{d}{d\tau}(r^2 r') = 0. \tag{3}$$

3. Collapse of a spin fluid sphere

If we assume that the spin fluid is composed of an ultrarelativistic matter in kinetic equilibrium, then $\epsilon = h_\star T^4$, $p = \epsilon/3$, and $n_{\mathrm{f}} = h_{n\mathrm{f}} T^3$, where T is the temperature of the fluid, $h_\star = (\pi^2/30)(g_{\mathrm{b}} + (7/8)g_{\mathrm{f}})k^4/(\hbar c)^3$, and $h_{n\mathrm{f}} = (\zeta(3)/\pi^2)(3/4)g_{\mathrm{f}}k^3/(\hbar c)^3$. For standard-model particles, $g_{\mathrm{b}} = 29$ and $g_{\mathrm{f}} = 90$. The effective energy density and pressure are thus:

$$\tilde{\epsilon} = h_\star T^4 - \alpha h_{n\mathrm{f}}^2 T^6, \quad \tilde{p} = \frac{1}{3} h_\star T^4 - \alpha h_{n\mathrm{f}}^2 T^6.$$

Since the pressure has no gradient, the temperature only depends on τ, and so does the energy density. This scenario describes a homogeneous sphere. The first law of thermodynamics (3) gives

$$r^2 r' T^3 = g(R), \tag{4}$$

where g is a function of R. Putting this relation into (2) gives

$$\dot{r}^2 = f(R) + \frac{\kappa}{r}(h_\star T^4 - \alpha h_{n\mathrm{f}}^2 T^6) \int_0^R r^2 r' dR. \tag{5}$$

Equations (4) and (5) give the function $r(\tau, R)$, which with (1) gives $\lambda(\tau, R)$.[7] The integration of (5) also contains the initial value $\tau_0(R)$. The metric therefore depends on three arbitrary functions: $f(R)$, $g(R)$, and $\tau_0(R)$.

We seek a solution of (4) and (5) as

$$f(R) = -\sin^2 R, \quad r(\tau, R) = a(\tau)\sin R, \tag{6}$$

where $a(\tau)$ is a nonnegative function of τ. For this choice of functions, (4) gives $a^3 T^3 \sin^2 R \cos R = g(R)$, in which separation of the variables τ and R leads to

$$g(R) = \mathrm{const} \cdot \sin^2 R \cos R, \quad a^3 T^3 = \mathrm{const}.$$

Consequently,

$$aT = a_0 T_0, \quad \frac{\dot{T}}{T} + \frac{H}{c} = 0, \tag{7}$$

where $a_0 = a(\tau = 0)$ and $T_0 = T(\tau = 0)$ are the values at the initial time, and $H = c\dot{a}/a$. Substituting (6) into (5) gives

$$\dot{a}^2 + 1 = \frac{\kappa}{3}(h_\star T^4 - \alpha h_{n\mathrm{f}}^2 T^6)a^2, \tag{8}$$

which has a form of the Friedmann equation for the scale factor a as a function of the cosmic time τ in a closed, homogeneous universe. The quantity H is the Hubble parameter of this universe. Using (7) in (8) yields[8]

$$\dot{a}^2 = -1 + \frac{\kappa}{3}\Big(\frac{h_\star T_0^4 a_0^4}{a^2} - \frac{\alpha h_{nf}^2 T_0^6 a_0^6}{a^4}\Big). \tag{9}$$

The relations (6) determine the constants:

$$\sin R_0 = \Big(\frac{r_g}{r_0}\Big)^{1/2}, \quad a(0) = \Big(\frac{r_0^3}{r_g}\Big)^{1/2}.$$

Substituting the initial values $a(0)$ and $\dot{a}(0) = 0$ into (8), in which the second term on the right-hand side is negligible, gives $Mc^2 = (4\pi/3)r_0^3 h_\star T_0^4$. This relation indicates the equivalence of mass and energy of a fluid sphere with radius r_0 and determines T_0. An event horizon for the entire sphere forms when $r(\tau, R_0) = r_g$, which is equivalent to $a = (r_g r_0)^{1/2}$. Equation (9) has two turning points, $\dot{a} = 0$, if

$$\frac{r_0^3}{r_g} > \frac{3\pi G\hbar^4 h_{nf}^4}{8h_\star^3} \sim l_{\text{Planck}}^2,$$

which is satisfied for astrophysical systems that form black holes.[9]

Substituting (6) into (1) gives $e^{\lambda(\tau,R)} = a^2$. Consequently, the square of an infinitesimal interval in the interior of a collapsing spin fluid is given by

$$ds^2 = c^2 d\tau^2 - a^2(\tau) dR^2 - a^2(\tau)\sin^2 R(d\theta^2 + \sin^2\theta\, d\phi^2).$$

This metric has a form of the closed Friedmann–Lemaître–Robertson–Walker metric and describes a part of a closed universe with $0 \le R \le R_0$ (like dust).

4. Nonsingular bounce

Equation (9) can be solved analytically in terms of an elliptic integral of the second kind, giving the function $a(\tau)$ and then $r(\tau, R) = a(\tau)\sin R$. The value of a never reaches zero because as a decreases, the right-hand side of (9) becomes negative, contradicting the left-hand side. The change of the sign occurs when $a < (r_g r_0)^{1/2}$, that is, after the event horizon forms. Consequently, all particles with $R > 0$ fall within the event horizon but never reach $r = 0$ (the only particle at the center is the particle that is initially at the center, with $R = 0$). A singularity is replaced with a nonsingular bounce.[7] Nonzero values of a give finite values of T and thus finite values of ϵ, p, and n_{f}.

After the bounce, the matter expands on the other side of the event horizon as a new universe. This universe has a closed geometry (constant positive curvature). The quantity $a(\tau)$ is the scale factor. The universe is oscillatory: the value of a oscillates between the two turning points. The value of R_0 does not change. A turning point at which $\ddot{a} > 0$ is a bounce, and a turning point at which $\ddot{a} < 0$ is a crunch. This universe has an infinite number of identical cycles.

The Raychaudhuri equation for a congruence of geodesics without four-acceleration and rotation is $d\theta/ds = -\theta^2/3 - 2\sigma^2 - R_{\mu\nu}u^\mu u^\nu$, where θ is the expansion scalar, σ^2 is the shear scalar, and $R_{\mu\nu}$ is the Ricci tensor. For a spin fluid, the last term in this equation is equal to $-\kappa(\tilde{\epsilon} + 3\tilde{p})/2$. Consequently, the necessary and sufficient condition for avoiding a singularity in a black hole is $-\kappa(\tilde{\epsilon} + 3\tilde{p})/2 > 2\sigma^2$. For a relativistic spin fluid, $p = \epsilon/3$, this condition is equivalent to

$$2\kappa\alpha n_{\mathrm{f}}^2 > 2\sigma^2 + \kappa\epsilon. \tag{10}$$

Without torsion, the left-hand side of (10) would be absent and this inequality could not be satisfied, resulting in a singularity. Torsion may provide a necessary condition for preventing a singularity.[10] In the absence of shear, this condition would be also sufficient.[11]

The presence of shear opposes the effects of torsion. The shear scalar σ^2 grows with decreasing a like $\sim a^{-6}$, which is the same power law as that for n_{f}^2. Therefore, if the initial shear term dominates over the initial torsion term in (10), then it will dominate at later times during contraction and a singularity will form. To avoid a singularity if the shear is present, n_{f}^2 must grow faster than $\sim a^{-6}$. Consequently, fermions must be produced in a black hole during contraction.

The production rate of particles in a contracting or expanding universe[12] can be phenomenologically given by

$$\frac{1}{c\sqrt{-g}}\frac{d(\sqrt{-g}n_{\mathrm{f}})}{dt} = \frac{\beta H^4}{c^4}, \tag{11}$$

where $g = -a^6 \sin^4 R \sin^2\theta$ is the determinant of the metric tensor and β is a nondimensional production rate. With particle production, the second equation in (7) turns into[8]

$$\frac{\dot{T}}{T} = \frac{H}{c}\Big(\frac{\beta H^3}{3c^3 h_{n\mathrm{f}} T^3} - 1\Big). \tag{12}$$

Particle production changes the power law $n_{\mathrm{f}}(a)$:

$$n_{\mathrm{f}} \sim a^{-(3+\delta)},$$

where δ varies with τ. Putting this relation into (11) gives

$$\delta \sim -a^\delta \dot{a}^3.$$

During contraction, $\dot{a} < 0$ and thus $\delta > 0$. The term $n_{\mathrm{f}}^2 \sim a^{-6-2\delta}$ grows faster than $\sigma^2 \sim a^{-6}$ and a singularity is avoided. Particle production and torsion together reverse the effects of shear, generating a bounce.[7]

5. Closed universe in a black hole

The dynamics of the nonsingular, relativistic universe in a black hole is described by equations (8) and (12), where $H = c\dot{a}/a$. These equations, with the initial conditions $a(0) = (r_0^3/r_g)^{1/2}$ and $\dot{a}(0) = 0$, give the functions $a(\tau)$ and $T(\tau)$.

The shear would enter the right-hand side of the first equation as an additional positive term that is proportional to a^{-4}. When the universe becomes nonrelativistic, the term $h_\star T^4$ changes into a positive term proportional to a^{-1}. The cosmological constant enters as a positive term proportional to a^2.

Particle production increases the maximum size of the scale factor that is reached at a crunch. Consequently, a new cycle is larger and lasts longer then the previous cycle. R_0 is given by $\sin^3 R_0 = r_g/a(0)$, where $a(0)$ is the maximum scale factor in the first cycle. Since the maximum scale factor in the next cycle is larger, the value of $\sin R_0$ decreases. As cycles proceed, R_0 approaches π (the value for a completely closed universe).

A parent black hole creating a new, baby universe becomes an Einstein–Rosen bridge (unidirectional wormhole) to that universe.[13] If the universe is closed, it is analogous to the 2-dimensional surface of a 3-dimensional baloon (sphere). The universe would be mathematically the 3-dimensional hypersurface of a 4-dimensional hypersphere. The 3-dimensional space in which the balloon expands is not analogous to any higher dimensional space. Points off the surface of the balloon are not in the universe in this analogy. The balloon radius represents the scale factor a. The universe expands, which can be described locally by the Hubble law.

This scenario occurs also if the fermionic matter is described by the Dirac Lagrangian density instead of the spin fluid.[14]

6. Inflation and oscillations

During expansion ($H > 0$), if β is too big, then the right-hand side of (12) could become positive. In this case, the temperature would grow with increasing a, which would lead to eternal inflation. Consequently, there is an upper limit to the production rate: the maximum of the function $(\beta H^3)/(3c^3 h_{nf} T^3)$ must be lesser than 1.

If $(\beta H^3)/(3c^3 h_{nf} T^3)$ increases after a bounce to a value that is slightly lesser than 1, then T would become approximately constant. Accordingly, H would be also nearly constant and the scale factor a would grow exponentially, generating inflation.[8] Since the energy density would be also nearly constant, the universe would produce enormous amounts of matter and entropy. Such an expansion would last until the right-hand side of drops below 1. Consequently, inflation would last a finite period of time. After this period, the effects of torsion weaken and the universe smoothly enters the radiation-dominated expansion, followed by the matter-dominated expansion.

Torsion and particle production can therefore generate finite inflation without scalar fields and reheating, which is consistent with the astronomical data.[15] If quantum effects in the gravitational field near a bounce do not produce enough matter, then the closed Universe reaches the maximum size and then contracts to another bounce, beginning the new cycle. Because of matter production, a new cycle reaches larger size and last longer than the previous cycle.[16] When the Universe reaches a

size at which the cosmological constant becomes dominant, it avoids another contraction and expands to infinity.[17]

7. Our universe in a black hole

These results suggest that every black hole may create a new, closed, baby universe. Accordingly, our Universe may be closed and may have born in the interior of a black hole existing in a parent universe.[13,18] Its energy would be equal to zero minus the energy of the wormhole connecting the Universe to the parent universe.[19] This hypothesis could solve the black hole information paradox: the information goes through the Einstein–Rosen bridge to the baby universe on the other side of the black hole's event horizon. The motion of matter through an event horizon is unidirectional: it defines the past and future. Time asymmetry at the event horizon may induce time asymmetry everywhere in the baby universe and could explain why time flows in one direction. Recent astronomical data seem to favor the closed geometry of the Universe,[20] thus providing some support for the black-hole cosmology.

8. Summary

The conservation law for total angular momentum in curved spacetime, consistent with Dirac equation, may require torsion.[2] The simplest theory with torsion, the Einstein–Cartan gravity, has the same Lagrangian as GR, but the affine connection contains the torsion tensor, generated by spin. Gravitational collapse of a sphere of a spin fluid creates an event horizon. The matter within the horizon collapses to extremely high densities, at which torsion acts like gravitational repulsion. Semiclassically and without shear, torsion prevents a singularity and replaces it with a nonsingular bounce. With shear, torsion prevents a singularity if the number of fermions increases during contraction through quantum particle production.[7] Particle production during expansion produces enormous amounts of matter and can generate a finite period of inflation. The resulting closed universe on the other side of the event horizon may have several bounces. Such a universe is oscillatory, with each cycle larger in size then the previous cycle, until it reaches a size at which the cosmological constant dominates, and then expands indefinitely.

In addition to eliminating gravitational singularities, torsion may also remove loop divergences in Feynman diagrams in quantum electrodynamics, resulting in finite values of bare (before renormalization) quantities such as the mass and electric charge of the electron.[21] Consequently, torsion may be a physical phenomenon that ensures physics is finite.

From time to time, different observations suggest that Einstein's theory of general relativity (GR) may not be the ultimate theory of gravity. Various researchers have suggested that the $f(R)$ theory of gravity is the best alternative to replace GR. Using $f(R)$ gravity, one can elucidate the various unexplained physics of compact objects, such as black holes, neutron stars, and white dwarfs. Researchers have already put effort into finding the vacuum solution around a black hole in $f(R)$ gravity. However, for a long time, they could not find an asymptotically flat vacuum solution. In this article, we show that the asymptotically flat vacuum solution of $f(R)$ gravity is possible and thereby use it to explain the spherical accretion flow around the black hole.

Keywords: Black hole, modified gravity, spherical accretion.

1. Introduction

Einstein's theory of general relativity (GR) is undoubtedly the most beautiful theory to explain gravity. It can easily explain a large number of phenomena where Newtonian gravity falls short, such as the deflection of light in strong gravity, generation of the gravitational waves, perihelion precession of Mercury's orbit, gravitational redshift of light, to mention a few. However, following several recent observations in cosmology and the high-density regions in the universe, such as the vicinity of compact objects, it seems that GR may not be the ultimate theory of gravity. Starobinsky first used one of the modified theories of gravity, namely R^2-gravity,[1] to explain the cosmology of the very early universe. Eventually, researchers have proposed different modifications of GR, e.g., various models of $f(R)$ gravity, to elaborate on various unexplained physics related to compact objects. Capozziello and his collaborators used different forms of $f(R)$ gravity to explain the massive neutron stars.[2] Similarly, Kalita & Mukhopadhyay used $f(R)$ gravity to unify the physics of all white dwarfs, including those possessing sub- and super-Chandrasekhar limiting masses,[3] and show that they can be detected by various proposed gravitational wave detectors.[4]

According to Birkhoff's theorem, the spherically symmetric vacuum solution in GR is static, which is the famous Schwarzschild solution. In the same context, the vacuum solution of $f(R)$ gravity is also an interesting problem. Multamäki & Vilja first obtained the solutions for a static, spherically symmetric vacuum spacetime in $f(R)$ gravity,[5] and argued that for a large class model, Schwarzschild-de Sitter metric is an exact solution of the field equations. Eventually, many researchers have

obtained several solutions for different modified theories of gravity in various spacetime geometries. Capozziello and his collaborators obtained spherically symmetric as well as axially symmetric vacuum solutions in $f(R)$ gravity using Noether symmetry.[6,7] These new solutions alter the black hole's event horizon, thereby various critical orbits, such as marginally stable, marginally bound, and photon orbits. In this way, modified theories of gravity change the dynamics of the particles moving around the black hole.

The above-mentioned solutions, introduced in these literatures, always contain some diverging terms in the metric components. Hence these solutions never reduce to the Minkowski metric at the asymptotically flat limit. This asymptotic flatness is essential in the context of physical problems such as accretion disc, as a disc is expected to extend in a vast region around the compact object. Therefore, at the outermost portion of the disc, which is very far from the compact object, no physics should be violated as given by the Schwarzschild/Minkowski metric. Many of the models mentioned above assume scalar curvature, $R \neq 0$ throughout the spacetime, which is again questionable as for the Schwarzschild metric, $R = 0$, which needs to be satisfied at the asymptotic flat limit. Kalita & Mukhopadhyay, for the first time, obtained the spherically symmetric asymptotically flat vacuum solution in the premise of $f(R)$ gravity.[8] In this article, we primarily discuss this solution and its applications in the spherical accretion flow around a black hole.

2. Basic formalism

The 4-dimensional action for $f(R)$ gravity in vacuum is given by[9]

$$S = \frac{c^4}{16\pi G} \int \sqrt{-g}\; f(R)\, \mathrm{d}^4x\,, \tag{1}$$

where c is the speed of light, G is Newton's gravitational constant, R is the scalar curvature, and $g = \det(g_{\mu\nu})$ is the determinant of the metric $g_{\mu\nu}$. Varying this action with respect to $g_{\mu\nu}$, with appropriate boundary conditions, we obtain the modified Einstein equation for the $f(R)$ gravity, given by

$$f'(R)G_{\mu\nu} + \frac{1}{2}g_{\mu\nu}\left[Rf'(R) - f(R)\right] - \left(\nabla_\mu\nabla_\nu - g_{\mu\nu}\Box\right) f'(R) = 0, \tag{2}$$

where $\Box$ is the d'Alembertian operator given by $\Box = \nabla^\mu\nabla_\mu$ and ∇_μ is the covariant derivative. For $f(R) = R$, Equation (2) reduces to the well-known Einstein field equation in GR.

3. Asymptotically flat vacuum solution in $f(R)$ gravity

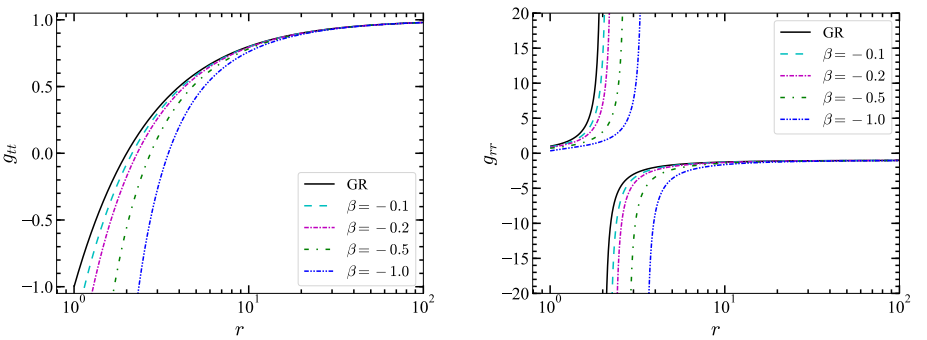
To obtain the spherically symmetric solution of the modified Einstein equation, we first assume $g_{\mu\nu} = \mathrm{diag}(s(r), -p(r), -r^2, -r^2\sin^2\theta)$, where s, p are the functions of the radial coordinate r only. We know that far from the compact objects, the metric should reduce first to the Schwarzschild metric, and at very far from the compact object, it should reduce to the Minkowski metric as the effect of gravity is

negligible there. Using these conditions at the asymptotic limit, one can show that for $f'(R) = 1 + \beta/r$ with β being a constant, in $c = G = M = 1$ unit, the temporal and radial components of the metric are given by[8]

$$g_{tt} = s(r) = 1 - \frac{2}{r} - \frac{\beta(\beta-6)}{2r^2} + \frac{\beta^2(13\beta-66)}{20r^3} - \frac{\beta^3(31\beta-156)}{48r^4} + \ldots, \tag{3}$$

$$g_{rr} = -p(r) = -\frac{16r^4}{(\beta+2r)^4}\frac{1}{s(r)}. \tag{4}$$

It is, of course, obvious from the above expressions that as $\beta \to 0$, it reduces to the Schwarzschild metric, and as $r \to \infty$, it reduces to the Minkowski metric, i.e., the flat spacetime.



(a) temporal component (b) radial component

Fig. 1. Variation of temporal and radial metric elements as functions of distance r. All the quantities are in dimensionless units of $c = G = M = 1$.

From Equations (3) and (4), it is observed that in $f(R)$ gravity, the vacuum solution is different from the Schwarzschild metric. This deviation indicates the violation of Birkhoff's theorem, which states that any spherically symmetric vacuum solution is essentially the Schwarzschild solution. Figure 1 describes the variations of the metric elements g_{tt} and g_{rr} with respect to r for different β. It is evident from the figure that as $r \to \infty$, the solutions reduce to the flat Minkowski metric, which, however, deviates near the black hole. $\beta = 0$ represents the Schwarzschild solution, with the radius of the event horizon $r_{\rm H} = 2$. In $f(R)$ gravity, as β deviates from 0, the solution is no longer the Schwarzschild solution, and the physics related to these solutions alter. For example, one can easily obtain the event horizon from Equations (3) and (4) by solving $g_{rr} \to \infty$, which shows that $r_{\rm H}$ shifts from 2 as β deviates from 0. Not only the radius of the event horizon, but one can also obtain the various marginal orbits in $f(R)$ gravity from Equations (3) and (4). Table 1 shows the radii of various orbits and their critical angular momenta for different β. We choose β to be negative because it guarantees that gravity is always attractive.

Table 1. Various characteristic parameters of space-time for different values of β: $r_{\rm H}$ is the event horizon, $r_{\rm MB}$ the marginally bound orbit, $r_{\rm MS}$ the marginally stable orbit, $L_{\rm MB}$ and $L_{\rm MS}$ are their corresponding specific angular momenta, and $r_{\rm ph}$ is the photon orbit. All the values are in dimensionless unit considering $c = G = M = 1$.

β	$r_{\rm H}$	$r_{\rm MB}$	$r_{\rm MS}$	$r_{\rm ph}$	$L_{\rm MB}$	$L_{\rm MS}$
0 (GR)	2.00	4.00	6.00	3.00	4.00	3.46
-0.1	2.15	4.30	6.45	3.20	4.15	3.61
-0.2	2.30	4.60	6.90	3.40	4.29	3.75
-0.5	2.74	5.52	8.28	3.98	4.71	4.15
-1.0	3.47	7.07	10.64	4.94	5.37	4.78
-1.5	4.18	8.66	13.08	5.89	5.99	5.37

4. Spherical accretion flow in $f(R)$ gravity

The vacuum solution for the $f(R)$ gravity can be used to understand the physics of black hole accretion. Here we explore the simplest class of it, i.e., spherical accretion flow around a black hole. In the Newtonian framework, such a flow is known as the Bondi accretion flow.[10] Since this flow is spherically symmetric, it does not possess any angular momentum, i.e., the flow is not rotating. The equations for conservation of energy and mass flux are respectively given by

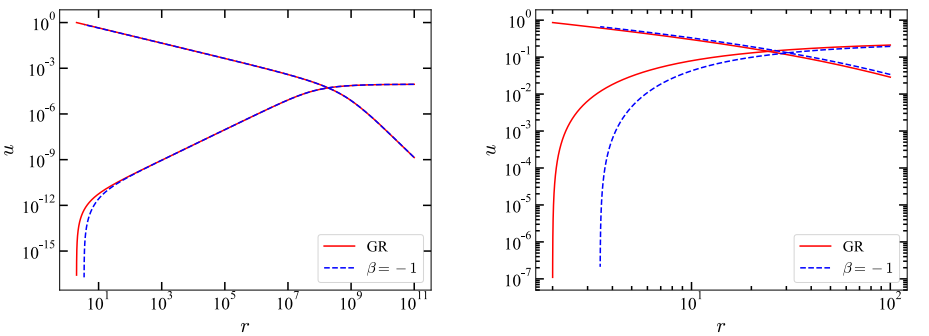
$$T^{\mu}_{0;\mu} = 0, \quad \text{and} \quad (\rho U^{\mu})_{;\mu} = 0, \tag{5}$$

where T^{μ}_{ν} is the stress-energy tensor, ρ is the density, and U^{μ} is the four-velocity of the fluid. Using these equations, for a spherically symmetric metric, $g_{\mu\nu} = \mathrm{diag}(-e^{2\phi(r)}, e^{2\lambda(r)}, r^2, r^2\sin^2\theta)$, the radial velocity ($u$) gradient equation for such flow is given by[8,11]

$$\frac{\mathrm{d}u}{u}\left[V^2 - \frac{u^2}{u^2+e^{-2\lambda}}\right] + \frac{\mathrm{d}r}{r}\left[2V^2 + r(V^2-1)(\phi'+\lambda') + \frac{r\lambda' e^{-2\lambda}}{u^2+e^{-2\lambda}}\right] = 0, \tag{6}$$

where $u = \mathrm{d}r/\mathrm{d}t$, $V^2 = 4T/3(1+4T)$ with T being the temperature of the fluid. The general idea of an accretion disc is that there is a Keplerian disc outside, where the matter has a minimal radial velocity. As the Keplerian disc terminates at a smaller distance from the black hole, the matter has a significant radial velocity, and it starts falling faster to the black hole. We assume that in this region, matter starts exhibiting spherical accretion flow. In other words, we assume that as the matter comes close enough to the black hole, it loses all its angular momentum, resulting in radial fall to the black hole (in reality, matter exhibits some angular momentum, even if sub-Keplerian). Figure 2 shows the accretion and wind flows for the spherical accretion flow in $f(R)$ gravity, which are obtained by solving the Equation (6). It is evident from the figure that the velocity is highly dependent on the outside temperature ($T_{\rm out}$), where matter starts behaving as a spherical accretion flow. The flow reaches the speed of light at the event horizon. As the event horizon shifts in

the presence of $f(R)$ gravity, the flow reaches this maximum speed at different radii for different values of β. However, since the solution is asymptotically flat, both the accretion and wind curves match the well-known case for the Schwarzschild solution far from the black hole.



(a) $T_{\text{out}} = 10^4\,\text{K}$ (b) $T_{\text{out}} = 10^{11}\,\text{K}$

Fig. 2. Spherical accretion flow in modified gravity: red solid line corresponds to the Schwarzschild spacetime and blue dashed line corresponds to the $f(R)$ gravity with $\beta = -1$.

5. Conclusions

$f(R)$ gravity is one of the best bets to replace GR, and researchers have already proposed different models to explain various exciting phenomena related to cosmology and compact objects. For more than a decade, various researchers have put effort into obtaining the vacuum solution of $f(R)$ gravity. However, none of those solutions are asymptotically flat, which means they do not reduce to the Minkowski metric as one moves very far from any gravity source, and hence they may not be applicable to astrophysical phenomena. In this article, we have argued that asymptotically flat vacuum spacetime is also possible in $f(R)$ gravity. We have shown here that the vacuum solution in $f(R)$ gravity is not the Schwarzschild solution, which indicates the violation of Birkhoff's theorem in the presence of the modified gravity. Since the solution is no longer the Schwarzschild solution, the quantities related to the event horizon and marginal orbits also alter, which further affects the spherical accretion flow around a black hole.

A certain type of matter with anisotropic pressures can add to the Reissner-Nordström metric a term proportional to a power of the radial coordinate. Using the standard method of separating variables for the Hamilton-Jacobi equation, we study the shadow of the corresponding rotating solution, obtained through the Newman-Janis algorithm. We define and calculate three observables in order to characterize the position, size and shape of the shadow.

Keywords: Black hole shadow; anisotropic fluid; electromagnetic field.

1. Introduction

There has been a renewed interest in the study of black hole shadows since the release of the first reconstructed image of the surroundings of the supermassive black hole M87* by the Event Horizon Telescope (EHT) collaboration.[1,2] While the shadow of a non-rotating black hole is a circle, a rotating black hole has an asymmetric shadow[3] whose shape depends on the black hole mass and spin, as well as the inclination angle of the observer. In alternative theories of gravity the shadow also presents characteristics that depend on the parameters of the specific model.[4]

Anisotropic fluids in general relativity have been studied in the context of compact objects such as stars or black holes, and in particular spherically symmetric black holes surrounded by an anistropic fluid have recently been introduced.[5] The anisotropy allows the matter around the black hole to remain static by means of a negative radial pressure, and the resulting metric has a very general form, also being found in some alternative theories of gravity.[6] In this work we study the shadows of the charged and rotating version[7] of these black holes. We adopt units such that $G = c = 1$.

2. Black hole solution

The energy-momentum tensor corresponding to the anisotropic fluid adopted by Cho & Kim[5] has the form

$$T_{\mu}{}^{\nu} = \mathrm{diag}(-\rho, p_1, p_2, p_2) \tag{1}$$

in spherical coordinates, with a radial pressure p_1 and an angular pressure p_2. A barotropic equation of state

$$p_i = w_i \rho \tag{2}$$

is assumed. It can be shown that in order to have a static black hole solution the value $w_1 = -1$ must be chosen, leaving w_2 as the only free parameter, which we will simply name w. It is also possible to add to the black hole an electric charge,[8] leading to the solution

$$ds^2 = -f(r)dt^2 + f(r)^{-1}dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\varphi^2), \tag{3}$$

with

$$f(r) = 1 - \frac{2m(r)}{r}, \tag{4}$$

$$m(r) = M - \frac{Q^2}{2r} + \frac{K}{2r^{2w-1}}, \tag{5}$$

where M, Q, and K are integration constants. M and Q are the mass and the electric charge of the black hole, respectively, while K is related to the energy density of the anisotropic fluid. It can be seen that by changing the equation of state of the fluid—that is, by changing w—one arrives at a different power of r in the last term of $f(r)$. The squared charge Q^2 is clearly positive; however, there is no impediment to continuing the solution to negative values, replacing Q^2 by a parameter q which may take either sign, and we will do so in the following. When q is negative the second term in $m(r)$ can no longer be interpreted as arising from an electric charge, but it can be found for example in some braneworld models.[9]

Applying the Newman-Janis algorithm to the spherically symmetric solution (3) leads to the corresponding axisymmetric metric

$$ds^2 = -\frac{\rho^2\Delta}{\Sigma}dt^2 + \frac{\Sigma\sin^2\theta}{\rho^2}(d\varphi - \Omega\, dt)^2 + \frac{\rho^2}{\Delta}dr^2 + \rho^2 d\theta^2, \tag{6}$$

where

$$\rho^2 = r^2 + a^2\cos^2\theta, \tag{7}$$

$$\Delta = r^2 - 2m(r)r + a^2, \tag{8}$$

$$\Sigma = (r^2 + a^2)^2 - a^2\Delta\sin^2\theta, \tag{9}$$

$$\Omega = \frac{2am(r)r}{\Sigma}, \tag{10}$$

and

$$m(r) = M - \frac{q}{2r} + \frac{K}{2r^{2w-1}}, \tag{11}$$

as in the spherically symmetric case. When $K = 0$ the Kerr-Newman metric is recovered, with q replaced by Q^2. It is important to keep in mind that outside of general relativity, the metric obtained through the Newman-Janis algorithm may

correspond to a different energy-momentum tensor than that of the original spherically symmetric metric.[10] We will assume throughout this work that $w > 0$ so that the spacetime is asymptotically flat. The weak, strong and dominant energy conditions impose various restrictions[5,7] on the allowed values of w and K, but since they do not affect the calculation of the shadow we will not take them into account.

We require the presence of an event horizon, so that the spacetime does not contain a naked singularity. The event horizon is located at the largest solution of $\Delta(r) = 0$, so that its disappearance corresponds to parameter values for which $\Delta(r)$ has a double root. The values of w and K for which this happens can be found parametrically as functions of the radius r of the double root,[11] and are given by

$$w = \frac{a^2 + q - Mr}{\Delta_{\mathrm{KN}}} \tag{12}$$

and

$$K = \frac{\Delta_{\mathrm{KN}}}{r^{2r(r-M)/\Delta_{\mathrm{KN}}}}, \tag{13}$$

where $\Delta_{\mathrm{KN}} = r^2 - 2Mr + a^2 + q$ is the functional form of Δ in a Kerr-Newman-like spacetime. Plotting these curves for various values of $a^2 + q$ shows the regions in parameter space for which an event horizon exists, as seen in Figure 1, in which we have set $M = 1$ for simplicity. It can be seen from the figure that unlike for the Kerr-Newman spacetime, where $a^2 + q \leq M^2$ is a necessary condition for the existence of an event horizon, the presence of the fluid allows for black holes with $a^2 + q > M^2$.

3. The black hole shadow

We will briefly review the standard method for finding the null geodesics for photons and the shadow, adapted to our selected spacetime.[3,11] The metric (6) is independent of the t and φ coordinates, leading to the conserved quantities $E = -p_t$ and $L = p_\varphi$; however, there is an additional hidden symmetry with an associated conserved quantity, the Carter constant $\mathcal{Q}$. This constant can be found by assuming a separable solution for the Hamilton-Jacobi equation, leading to the first-order equations of motion

$$\rho^2 \dot{t} = \frac{r^2 + a^2}{\Delta} P(r) + aL - a^2 \sin^2\theta\, E, \tag{14}$$

$$\rho^2 \dot{\varphi} = \frac{aP(r)}{\Delta} + \frac{L}{\sin^2\theta} - aE, \tag{15}$$

$$(\rho^2 \dot{r})^2 = \mathcal{R}(r), \tag{16}$$

$$(\rho^2 \dot{\theta})^2 = \Theta(\theta), \tag{17}$$

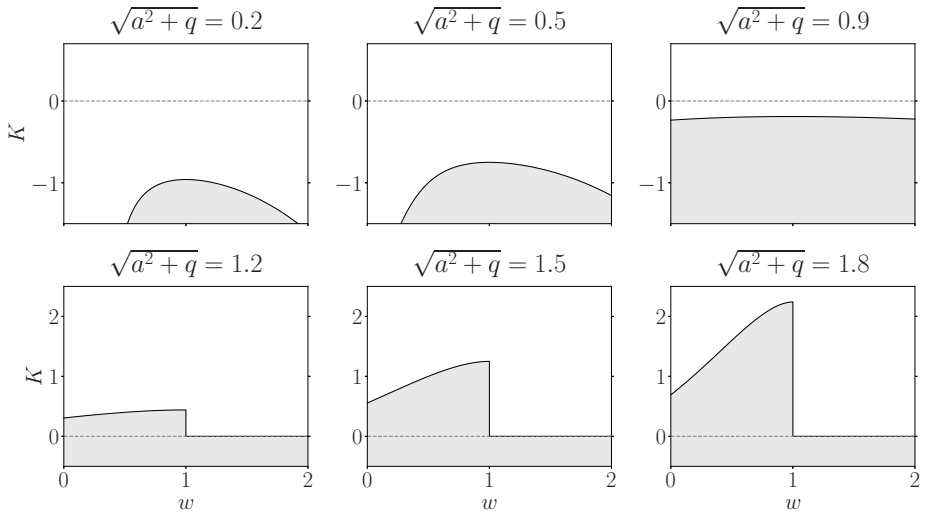

Fig. 1. Presence of an event horizon for our adopted metric. The shaded regions indicate the parameter values for which the spacetime contains a naked singularity, while in the white regions there is an event horizon. The solid curves separating them are described paremetrically by Eqs. (12) and (13). We have set $M = 1$, so that all parameters are dimensionless.

where

$$P(r) = E(r^2 + a^2) - aL, \tag{18}$$

$$\mathcal{R}(r) = P(r)^2 - \Delta[(L - aE)^2 + \mathcal{Q}], \tag{19}$$

$$\Theta(\theta) = \mathcal{Q} + \cos^2\theta \left(a^2E^2 - \frac{L^2}{\sin^2\theta}\right). \tag{20}$$

For convenience, we define the impact parameters $\xi = L/E$ and $\eta = \mathcal{Q}/E^2$. The trajectories that make up the shadow contour have the same impact parameters as the spherical photon orbits—that is, the solutions of the equations of motion that stay at a constant value of r. These can be found by solving $\mathcal{R}(r) = 0 = \mathcal{R}'(r)$, and the corresponding impact parameters are given parametrically by

$$\xi = \frac{4m(r)r^2 - (r + m(r) + m'(r)r)(r^2 + a^2)}{a(r - m(r) - m'(r)r)} \tag{21}$$

$$\eta = r^3 \frac{4a^2(m(r) - m'(r)r) - r(r - 3m(r) + m'(r)r)^2}{a^2(r - m(r) - m'(r)r)^2}. \tag{22}$$

A distant observer at an inclination angle $\theta = \theta_{\rm o}$ can use the celestial coordinates (α, β), which are given by

$$\alpha = -\frac{\xi}{\sin\theta_{\rm o}}, \tag{23}$$

$$\beta = \pm\sqrt{\eta + \cos^2\theta_{\rm o}\left(a^2 - \frac{\xi^2}{\sin^2\theta_{\rm o}}\right)}; \tag{24}$$

they correspond to horizontal and vertical displacement in the image plane, respectively.

Figure 2 shows the shadows produced by a black hole with spin $a/M = 0.9$ as seen by a distant equatorial observer, for various values of the parameters w, K and q. We find the expected behaviors from the Kerr and Kerr-Newman spacetimes: the shadow is asymmetrical and displaced as a consequence of the spin of the black hole, and its size decreases as the charge increases.

To better characterize the size and shape of the shadow, we define three observables[11,12] that can be calculated from a given shadow contour: the area of the shadow, its oblateness, and its horizontal displacement. The area is simply

$$A = 2\int \beta\, d\alpha, \tag{25}$$

where the plus sign in Eq. (24) has been chosen; the oblateness measures the deviation of the shadow from circularity and is defined as

$$D = \frac{\Delta\alpha}{\Delta\beta}, \tag{26}$$

where $\Delta\alpha$ and $\Delta\beta$ are the extent of the shadow in the horizontal and vertical directions respectively; finally, the horizontal displacement is more properly described as the α-coordinate of the centroid, given by

$$\alpha_c = \frac{1}{A}\int 2\alpha\beta\, d\alpha. \tag{27}$$

Working with observables has the benefit of making it easier to explore larger areas of parameter space at once; this can be seen in Figs. 3, 4 and 5, showing the values of A, D and α_c for $a/M = 0.9$ and various values of the other parameters. All plots are shown as functions of q, whose maximum value is determined by the requirement that there exist an event horizon.

It is clear from Fig. 3 that the shadow becomes smaller as q increases or as K decreases. This is to be expected, since both parameters appear with opposite signs in the metric. The oblateness and horizontal displacement show more interesting features. For $w < 1$ we see that the shadow becomes more compressed and more displaced as the charge increases. For $w = 2$ and $K > 0$, though, the charge can become large enough to reach a region where the behavior reverses, with D becoming greater than one and α_c becoming greater than zero, reflecting a shadow

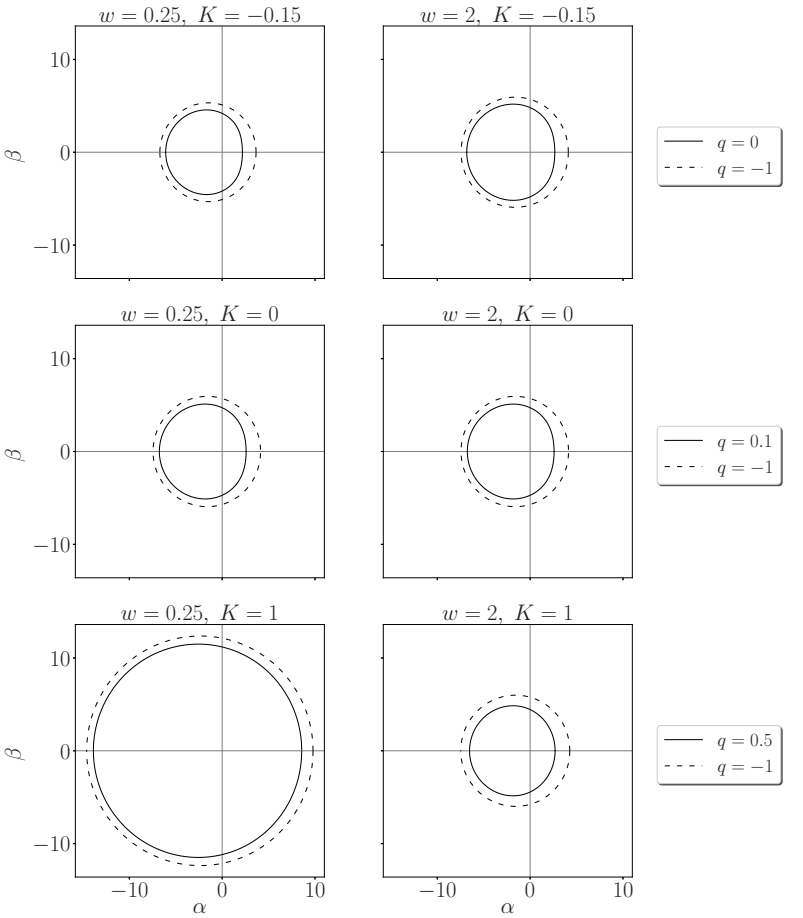

Fig. 2. The shadows of a black hole with $a/M = 0.9$ for an observer at $\theta_{\rm o} = \pi/2$, for various values of the parameters. All quantities have been adimensionalized by setting $M = 1$.

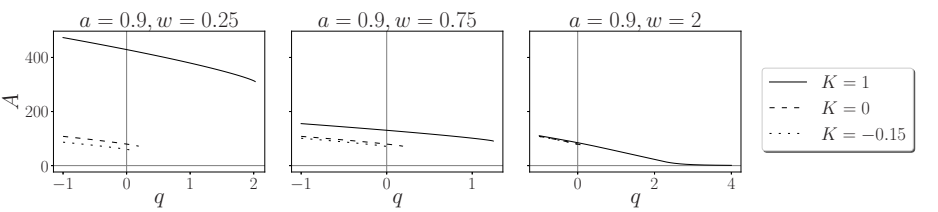

Fig. 3. The area of the black hole shadow for some values of the parameters. We set $M = 1$, so that all quantities are dimensionless.

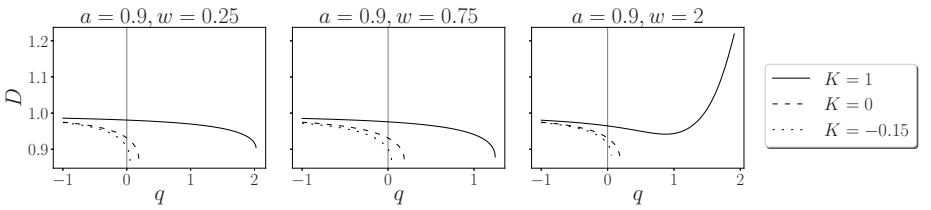

Fig. 4. The oblateness of the black hole shadow for some values of the parameters. We set $M = 1$.

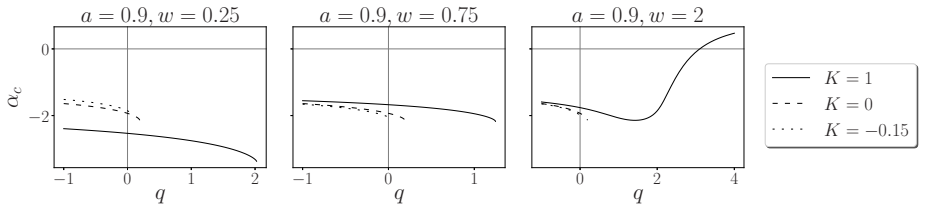

Fig. 5. The horizontal position of the shadow centroid for some values of the parameters. We set $M = 1$.

that is wider than it is tall—unlike the Kerr shadow—and displaced in the opposite direction. However, the energy-momentum tensor of the fluid can have the physically undesirable property of having negative energy[7, 11] in this region of parameter space, so the corresponding shadows should be interpreted with care.

4. Discussion

In this work we have considered the effect of a fluid with anisotropic pressure on the shadow of a charged and rotating black hole. The fluid makes a contribution to the gravitational field of the black hole, and the resulting Hamilton-Jacobi equation for the geodesics is separable, so that a standard method for finding the shadow contour can be used. We have produced plots of the shadow for various values of the charge as well as the fluid anisotropy and density, and we have found that for many values of the parameters the shadow is qualitatively similar to the well known Kerr-Newman case, exhibiting the typical deviation from circularity due to the spin and shrinking as the charge increases or the energy density of the fluid decreases. However, in some regions of parameter space where the fluid has negative energy, the opposite behavior is seen, with the shadow becoming narrow and displaced in the opposite direction.

We review the constraints modified theories of gravity must satisfy to be compatible with the spherically symmetric black hole solutions of semiclassical gravity that describe the formation of an apparent horizon in finite time of a distant observer. The constraints are satisfied in generic modified gravity theories with up to fourth-order derivatives in the metric, indicating that the semiclassical solutions correspond to zeroth-order terms in perturbative solutions of these theories. As a result, it may not be possible to distinguish between the semiclassical theory and modifications including up to fourth-order derivatives based on the observation of an apparent horizon alone.

Keywords: Black holes; general relativity; modified gravity; alternative theories of gravity; quantum aspects of black holes.

1. Introduction

The predictions of general relativity (GR) have been confirmed in numerous experiments and are so far compatible with all currently available astrophysical and cosmological data. In particular, strong evidence for the existence of astrophysical black holes (ABHs) — massive dark compact objects — has accumulated over the last few decades. The precise nature of ABHs is still under debate, but contemporary models describe them as ultra-compact objects (UCOs) with or without a horizon.[1] Due to their compactness, they provide excellent opportunities to probe strong gravity.[2]

The development of alternative theories of gravity has received much attention in recent years in an attempt to alleviate some of the perceived shortcomings of GR (such as the presence of singularities) and incorporate quantum gravitational effects.[3,4] As a preliminary test, any modified theory of gravity (MTG) should be compatible with the observed ABHs candidates and provide a model to describe them. Present-day astrophysical observations such as the detection of gravitational waves from coalescing compact systems[5,6] and measurements of the M87 black hole shadow[7] probe the (dynamic) strong-field regime of gravity and limit the extent to which MTG can deviate from GR while still being compatible with observational data.

There is no single, unanimously agreed upon definition of what exactly constitutes a black hole as different lines of research focus on different aspects. Consequently, the most useful and/or practical definition of a black hole depends on the context and highlights the relevant features. Nevertheless, a widely accepted feature of black holes is the presence of a trapped spacetime region from which nothing can escape.[8] We adapt the terminology of Ref. 9 and refer to a trapped region that is bounded by an apparent horizon as a physical black hole (PBH). The definition of an apparent horizon (see Sec. 2) is an observer-dependent notion that is, at least in principle, physically observable (in contrast to the global, observer-independent notion of an event horizon).[10] It is therefore possible that GR and various MTG can be distinguished observationally based on distinct properties of PBHs and their horizons in these models.

2. Mathematical preliminaries

We work in units where $\hbar = c = G = 1$, use the $(-+++)$ signature of the metric, and describe dynamics using the semiclassical Einstein equations $G_{\mu\nu} = 8\pi T_{\mu\nu}$ or modifications thereof, where $T_{\mu\nu} \equiv \langle \hat{T}_{\mu\nu} \rangle_\omega$ on the rhs denotes the expectation value of the renormalized energy-momentum tensor (EMT) that describes both the collapsing matter and the produced excitations. No assumptions are made about the matter content or the quantum state ω.

The field equations of a generally covariant metric theory of gravity can be derived from its action.[11] Here, we omit discussions of the matter Lagrangian and boundary conditions and focus on the gravitational action

$$\mathcal{S} = \int \sqrt{-g}\, \mathcal{L}_{\mathrm{g}}\, d^4x \tag{1}$$

determined by the gravitational Lagrangian density $\mathcal{L}_{\mathrm{g}}(g^{\mu\nu}, R_{\mu\nu\rho\sigma})$. In classical GR and semiclassical gravity, it is strictly linear in the Ricci scalar, i.e. $\mathcal{L}_{\mathrm{g}}(g^{\mu\nu}, R_{\mu\nu\rho\sigma}) = R$. Modifications typically include higher-order curvature corrections, which we organize according to powers of derivatives in the metric, i.e.

$$\begin{aligned} \mathcal{L}_{\mathrm{g}}\sqrt{-g} &= \frac{{M_{\mathrm{Pl}}}^2}{16\pi}\big(R + \lambda\mathcal{F}(g^{\mu\nu}, R_{\mu\nu\rho\sigma})\big) \\ &= \frac{{M_{\mathrm{Pl}}}^2}{16\pi}R + a_1 R^2 + a_2 R_{\mu\nu}R^{\mu\nu} + a_3 R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} + \ldots, \end{aligned} \tag{2}$$

where λ sets the scale of the perturbative analysis, the cosmological constant term was omitted, M_{P} denotes the Planck mass, and the coefficients a_1, a_2, a_3 are dimensionless.

We limit our exposition to spherical symmetry and work with a general spherically symmetric metric in Schwarzschild coordinates given by

$$ds^2 = -e^{2h(t,r)}f(t,r)dt^2 + f(t,r)^{-1}dr^2 + r^2 d\Omega, \tag{3}$$

where

$$f(t,r) := \partial_\mu r \partial^\mu r \equiv 1 - C(t,r)/r \tag{4}$$

provides a coordinate-independent definition of the Misner–Sharp mass[12] $C(t,r)/2$, r denotes the areal radius, and the function $h(t,r)$ plays the role of an integrating factor in coordinate transformations, such as

$$dt = e^{-h}\left(e^{h_+}dv - f^{-1}dr\right). \tag{5}$$

Explicit calculations can be simplified by introducing the effective EMT components

$$\tau_t := e^{-2h}T_{tt}\,, \qquad \tau_t{}^r := e^{-h}T_t{}^r, \qquad \tau^r := T^{rr}. \tag{6}$$

The apparent horizon plays a central role in our analysis. Its outer component is located at the Schwarzschild radius $r_g(t)$ that is defined as the largest root of $f(t,r) = 0$.[13] Albeit an observer-dependent notion in general, it is unambiguously defined in spherical symmetry. To be of physical relevance, it must form in finite time according to the clock of a distant observer.[14,15] Moreover, to maintain predictability of the theory, it must be a regular surface,[16,17] i.e. the curvature scalars

$$\mathrm{T} := T^\mu{}_\mu = -R/8\pi + \mathcal{O}(\lambda), \qquad \mathfrak{T} := T^{\mu\nu}T_{\mu\nu} = R^{\mu\nu}R_{\mu\nu}/64\pi^2 + \mathcal{O}(\lambda^2), \tag{7}$$

must be finite at $r = r_g$. Mathematically, this requirement is expressed as

$$\mathrm{T} = (\tau^r - \tau_t)/f \;\to\; g_1(t)f^{k_1}, \tag{8}$$

$$\mathfrak{T} = \left[(\tau_t)^2 - 2(\tau_t{}^r)^2 + (\tau^r)^2\right]/f^2 \;\to\; g_2(t)f^{k_2}, \tag{9}$$

for some functions $g_{1,2}(t)$ and $k_{1,2} \geqslant 0$. While there a infinitely many solutions in principle, only two distinct classes of dynamic solutions that satisfy the regularity requirement were found to be self-consistent.[18,19] With respect to the scaling behavior $\tau \sim f^k$ of the effective EMT components of Eq. (6), they correspond to the values $k \in \{0,1\}$, where $k \equiv k_1 \equiv k_2$. Both of them violate the null energy condition (NEC) in the vicinity of the outer apparent horizon.[15,18,20] We briefly summarize their properties in what follows.

3. Semiclassical PBH solutions in spherical symmetry

In spherical symmetry, the relevant components G_{tt}, $G_t{}^r$, G^{rr} of the semiclassical Einstein equations can then be written as

$$\partial_r C = 8\pi r^2 \tau_t/f, \tag{10}$$

$$\partial_t C = 8\pi r^2 e^h \tau_t{}^r, \tag{11}$$

$$\partial_r h = 4\pi r(\tau_t + \tau^r)/f^2, \tag{12}$$

respectively.

3.1. $k = 0$ *solutions*

Close to the horizon (i.e. as $r \to r_g$), the limiting form of the effective EMT components is given by

$$\tau_t = -\Upsilon^2 + \sum_{j\geqslant\frac{1}{2}}^{\infty} e_j x^j, \qquad {\tau_t}^r = \pm\Upsilon^2 + \sum_{j\geqslant\frac{1}{2}}^{\infty} \phi_j x^j, \qquad \tau^r = -\Upsilon^2 + \sum_{j\geqslant\frac{1}{2}}^{\infty} p_j x^j \quad (13)$$

for some time-dependent function $\Upsilon(t) > 0$, where $j \in \mathbb{Z}\frac{1}{2}$ labels half-integer and integer coefficients and powers of the coordinate distance $x \coloneqq r - r_g$ from the apparent horizon, and the lower signature of ${\tau_t}^r$ corresponds to evaporation (accretion). Taking $\tau_t \to \tau^r \to +\Upsilon^2 + \mathcal{O}(\sqrt{x})$ results in complex-valued solutions of the Einstein equations Eqs. (10)–(12).[20] The leading terms of the metric functions that solve Eqs. (10) and (12) are given by

$$C = r_g - c_{12}\sqrt{x} + \sum_{j\geqslant 1}^{\infty} c_j x^j, \tag{14}$$

$$h = -\frac{1}{2}\ln\frac{x}{\xi} + \sum_{j\geqslant\frac{1}{2}}^{\infty} h_j x^j, \tag{15}$$

where the leading coefficient $c_{12} = 4\sqrt{\pi} r_g^{3/2}\Upsilon$, $\xi(t)$ is determined by the choice of time variable, and higher-order terms must be matched with those of the EMT expansion. Eq. (11) then necessitates that the dynamic behavior of the horizon is governed by

$$r_g' = \pm c_{12}\sqrt{\xi}/r_g \tag{16}$$

where the lower (upper) sign corresponds to evaporation (accretion).

3.2. $k = 1$ *solution*

For $k = 1$, the limiting form of the effective EMT components close to the horizon (i.e. as $r \to r_g$) is given by

$$\tau_t = Ef + \sum_{j\geqslant 2}^{\infty} e_j x^j, \qquad {\tau_t}^r = \Phi f + \sum_{j\geqslant 2}^{\infty} \phi_j x^j, \qquad \tau^r = Pf + \sum_{j\geqslant 2}^{\infty} p_j x^j, \tag{17}$$

where E, Φ, and P denote energy density, flux, and pressure at the horizon. The metric functions that solve Eqs. (10) and (12) are given by

$$C = r - c_{32}x^{3/2} + \mathcal{O}(x^2), \tag{18}$$

$$h = -\frac{3}{2}\ln\frac{x}{\xi} + \mathcal{O}(\sqrt{x}), \tag{19}$$

where the leading coefficient $c_{32} = 4r_g^{3/2}\sqrt{-\pi e_2/3}$, and e_2 denotes the $\mathcal{O}(x^2)$ coefficient of τ_t, see Eq. (17). According to Eq. (11), the dynamic behavior of the

horizon is governed by

$$r_g' = \pm c_{32}\xi^{3/2}/r_g. \tag{20}$$

where the lower (upper) sign corresponds to evaporation (accretion). For $k = 1$, only one solution is self-consistent. It describes PBHs at the instant of their formation[19] and is uniquely defined by the energy density $E := -T^t_{\ t}$ and pressure $P := T^r_{\ r}$ at the horizon, which take on their maximal possible values $E = -P = 1/(8\pi r_g^2)$. Hence, we refer to it as extreme-valued $k = 1$ solution.

4. Modified Einstein equations in spherical symmetry

The modified Einstein equations are obtained through variation of the gravitational action[11] [cf. Eqs. (1)–(2)], and can be represented schematically as

$$G_{\mu\nu} + \lambda\mathcal{E}_{\mu\nu} = 8\pi T_{\mu\nu}\,, \tag{21}$$

where the terms $\mathcal{E}_{\mu\nu}$ denote deviations from the Einstein equations that result from the variation of $\mathcal{F}(g^{\mu\nu}, R_{\mu\nu\rho\sigma})$ [cf. Eq. (2)]. The explicit form of the Einstein equations in MTG then immediately follows from Eqs. (10)–(12):

$$fr^{-2}e^{2h}\partial_r C + \lambda\mathcal{E}_{tt} = 8\pi T_{tt}\,, \tag{22}$$

$$r^{-2}\partial_t C + \lambda\mathcal{E}_t^{\ r} = 8\pi T_t^{\ r}, \tag{23}$$

$$2f^2 r^{-1}\partial_r h - fr^{-2}\partial_r C + \lambda\mathcal{E}^{rr} = 8\pi T^{rr}. \tag{24}$$

The metric functions that solve the modified Einstein equations Eq. (21) are

$$C_\lambda =: \bar{C}(t,r) + \lambda\Sigma(t,r), \tag{25}$$

$$h_\lambda =: \bar{h}(t,r) + \lambda\Omega(t,r), \tag{26}$$

where Σ and Ω denote the perturbative corrections, and the bar labels the semiclassical metric functions introduced in Sec. 3. Schematically, substitution of Eqs. (25)–(26) into the modified Einstein equations Eq. (21) yields an equation of the form

$$\bar{G}_{\mu\nu} + \lambda\tilde{G}_{\mu\nu} + \lambda\bar{\mathcal{E}}_{\mu\nu} = 8\pi\left(\bar{T}_{\mu\nu} + \lambda\tilde{T}_{\mu\nu}\right), \tag{27}$$

where objects labeled by the tilde correspond to first-order terms in the expansion of λ that involve the perturbative corrections Σ and Ω, and terms of order $\mathcal{O}(\lambda^2)$ and higher have been omitted. The modified gravity contributions can be expressed solely in terms of unperturbed quantities, i.e. $\bar{\mathcal{E}}_{\mu\nu} \equiv \mathcal{E}_{\mu\nu}(\bar{C}, \bar{h})$. For a detailed account of the perturbative analysis, the reader is referred to Ref. 21.

5. Constraints for modified gravity theories

Any arbitrary MTG must satisfy several constraints[21] to be compatible with the spherically symmetric PBH solutions of semiclassical gravity described in Sec. 3. The constraints are twofold: first, the terms $\bar{\mathcal{E}}_{\mu\nu}$ that encode deviations from the semiclassical theory must follow a particular structure when expanded in terms of

the coordinate distance $x := r - r_g$ from the apparent horizon. Second, several identities between their coefficients must hold.

To be compatible with PBH solutions of the $k = 0$ type (Sec. 3.1), the MTG terms $\bar{\mathcal{E}}_{\mu\nu}$ must conform to the expansion structures prescribed by

$$\bar{\mathcal{E}}_{tt} = \frac{æ_{\bar{1}}}{x} + \frac{æ_{\overline{12}}}{\sqrt{x}} + æ_0 + \sum_{j\geqslant\frac{1}{2}}^{\infty} æ_j x^j, \tag{28}$$

$$\bar{\mathcal{E}}_t{}^r = \frac{œ_{\overline{12}}}{\sqrt{x}} + œ_0 + \sum_{j\geqslant\frac{1}{2}}^{\infty} œ_j x^j, \tag{29}$$

$$\bar{\mathcal{E}}^{rr} = ø_0 + \sum_{j\geqslant\frac{1}{2}}^{\infty} ø_j x^j, \tag{30}$$

and the three identities

$$æ_{\bar{1}} = \sqrt{\bar{\xi}} œ_{\overline{12}} = \bar{\xi} ø_0, \qquad æ_{\overline{12}} = 2\sqrt{\xi} œ_0 - \xi ø_{12}, \tag{31}$$

between their lowest-order coefficients must be satisfied.

Similarly, to be compatible with the extreme-valued $k = 1$ solution (Sec. 3.2), the MTG terms must follow the expansion structures prescribed by

$$\bar{\mathcal{E}}_{tt} = \frac{æ_{\overline{32}}}{x^{3/2}} + \frac{æ_{\bar{1}}}{x} + \frac{æ_{\overline{12}}}{\sqrt{x}} + æ_0 + \sum_{j\geqslant\frac{1}{2}}^{\infty} æ_j x^j, \tag{32}$$

$$\bar{\mathcal{E}}_t{}^r = œ_0 + \sum_{j\geqslant\frac{1}{2}}^{\infty} œ_j x^j, \tag{33}$$

$$\bar{\mathcal{E}}^{rr} = \sum_{j\geqslant\frac{3}{2}}^{\infty} ø_j x^j, \tag{34}$$

and the two identities

$$æ_{\overline{32}} = 2\bar{\xi}^{3/2} œ_0 - \bar{\xi}^3 ø_{32}, \qquad æ_{\bar{1}} = 2\bar{\xi}^{3/2}\left(h_{12} œ_0 + œ_{12}\right) - \bar{\xi}^3\left(2h_{12} ø_{32} + ø_2\right). \tag{35}$$

between their lowest-order coefficients must hold.

For both types of solutions $k \in \{0, 1\}$, no additional constraints can be obtained through the consideration of higher-order terms ($\geqslant \mathcal{O}(x^{3/2})$) in the metric functions as in this case the modified Einstein equations contain too many additional independent variables. A comprehensive analysis of this result and a detailed derivation of Eqs. (28)–(35) is provided in Ref. 21.

If a particular MTG does not satisfy the constraints for one or both classes of semiclassical PBHs, the theory in question may still possess solutions corresponding to PBHs, but their underlying mathematical description must then differ from that of Sec. 3.1 and/or Sec. 3.2, which may or may not lead to observable differences based on properties of the associated near-horizon geometry.

So far, the constraints imposed by Eqs. (28)–(35) have been investigated in MTG with up to fourth-order derivatives in the metric.[22] In particular, it has been demonstrated that

(1) generic $\mathfrak{f}(R)$ theories, where $\mathcal{L}_{\rm g} = \mathfrak{f}(R)$, $\mathfrak{f}(R) =: R + \lambda\mathcal{F}(R)$ [cf. Eq. (2)], $\mathcal{F}(R) = \beta R^q$, and $\beta, q \in \mathbb{R}$
(2) generic MTG with up to fourth-order derivatives in the metric, where the particular choice of $\mathcal{L}_{\rm g} = (-\alpha R_{\mu\nu}R^{\mu\nu} + \beta R^2 + \gamma\kappa^{-2}R)$ in the action is motivated by the desire to avoid ghosts (massive states of negative norm that result in an apparent lack of unitarity),[23,24] and $\kappa^2 = 32\pi$

satisfy all of the constrains identically (i.e. without requiring any additional conditions) and are thus compatible with the existence of spherically symmetric semiclassical PBHs. The procedure for obtaining explicit expressions for the MTG terms $\bar{\mathcal{E}}_{\mu\nu}$ in terms of unperturbed quantities is outlined in Ref. 22, and explicit expressions for the relevant MTG coefficients of Eqs. (31) and (35) in these two theories are provided in the following linked Github repository.

6. Discussion

We have outlined a procedure to test the compatibility of arbitrary metric MTG with the PBH solutions of semiclassical gravity, which are characterized by the formation of a regular apparent horizon in finite time of a distant observer. We find that generic MTG with up to fourth-order derivatives in the metric identically satisfy all of the constraints for both classes of solutions, indicating that the semiclassical PBHs correspond to zeroth-order terms in perturbative solutions of these models. As a result, the observation of an apparent horizon by itself is insufficient to distinguish between the semiclassical theory and modifications including up to fourth-order derivatives in the metric. A detailed analysis of the response of the near-horizon geometry to perturbations is required, and may allow to identify potentially observable differences between PBHs of various theoretical frameworks.

Penrose suggestion as to pre-Planck-era black holes showing up in present universe data sets discussed, with a possible candidate as to GW radiation which may provide initial CMBR data

A. W. Beckwith

Physics Department, College of Physics, Chongqing University, City, State ZIP/Zone, People's Republic of China
E-mail: rwill9955b@gmail.com, abeckwith@uh.edu

What we are doing is three-fold. First, we examine the gist of the Penrose suggestion as to signals from a prior universe showing up in the CMBR. That is, this shows up as data in the CMBR. Second, we give a suggestion as to how super massive black holes could be broken up s of a prior universe cycle by pre-big-bang conditions, with say millions of pre-Planck black holes coming up out of a breakup of prior universe black holes. Three, we utilize a discussion as to Bose–Einstein condensates set as gravitons as to composing the early universe black holes. The BEC formulation gives a number N of gravitons, linked to entropy, per black hole, which could lead to contributions to the alleged CMBR perturbations, which were identified by Penrose et al.

Keywords: Minimum scale factor, Cosmological constant, Space-time bubble, Penrose singularity, Prior universe black holes.

1. First, What Does Penrose Suggest About the CMBR Data Set and Preuniverse Massive Black Holes?

The abstract has a clue, as part of Ref. 1 states as to what we want to explain in the CMBR, i.e., circular rings in the CMBR "data."

In Ref. 1 there is a well crafted suggestion by Gurzadyan and Penrose as to an initial quote:

> The significance of individual low-variance circles in the true data has been disputed; yet a recent independent analysis has confirmed CCC's expectation that CMB circles have a non-Gaussian temperature distribution. Here we examine concentric sets of low-variance circular rings in the WMAP data, finding a highly nonisotropic distribution.

Here is the nuts and bolts as to what Penrose cosmology is about Ref. 2.

1.1. *There is initial inflationary expansion of the universe, but the caveat is that matter–energy is sucked up in super-massive black holes*

That is, rather than have a purported infinite expansion, and we see the following dynamic. We connect a countable sequence of open Friedmann–Lemaître–Robertson–Walker metric (FLRW) spacetimes, each representing a big bang followed by an

infinite future expansion. Penrose noticed that the past conformal boundary of one copy of FLRW spacetime can be "attached" to the future conformal boundary of another, after an appropriate conformal rescaling. result g_{ab} reset in a conformal reset with matter from black holes collected and reset to a new value of g_{ab} at the start of cosmological expansion with matter–energy from black holes being recycled conformally to a new expansion cycle.[2]

1.2. *Next, let us view the Penrose suggestion as to black holes from a prior universe*

In order to see this, consider a suggestion as to black holes, being the template for a start to the present universe,[2] and also Ref. 3 which has the Penrose suggestion of an imprint of a prior universe black holes having an effect upon the CMBR spectrum. The CMBR spectrum is a real datum, but the worth of getting this information would be in terms of having what was said in Ref. 3 as to the "ghost" of prior universe black hole radiation. To get a glimpse of where this is going the author invites readers to look at Ref. 4 as to the cosmic maelstrom such "signals" would have to pass through.

> Figure 1 shows a conformal diagram representing the effect of a highly energetic event occurring at the space-time point H. In CCC, H is taken to be a Hawking point, where virtually the entire Hawking radiation of a previous-aeon supermassive black hole is concentrated at H by the conformal compression of the hole's radiating future. The horizontal line at the bottom stands for the crossover surface dividing the previous cosmic aeon from our own and describes our conformally stretched big bang. In conventional inflationary cosmology, X would represent the graceful exit turn-off of inflation. In each case, the future light cone of H represents the outer causal boundary of physical effects initiated at H, and such effects can reach D only within the roughly 0.08 radian spread indicated at the top of the diagram.[3]

2. What Can We Expect from the Transition from a Prior Universe to the Planckian Regime of Micro Black Holes? A Transition from Initially Gigantic Black Holes to Micro Black Holes

2.1. *In a word, we would likely have in the prior universe a massive black hole, which would be broken up into millions (billions?) of Planck-sized black holes*

In a word the GW radiation and thermal/photonic input would have to fight through a thicket of pairs of micro black holes which would be in binary configuration generating their OWN GW background.

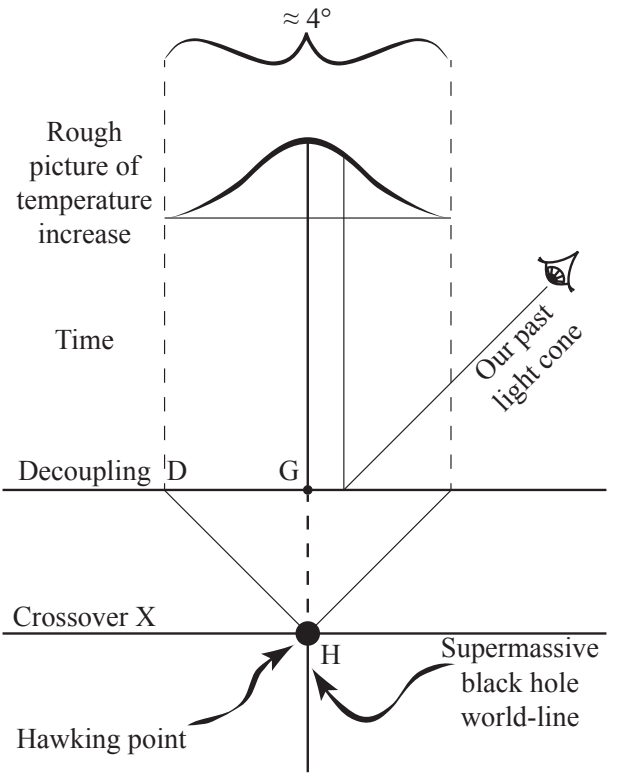

Fig. 1. Competing black hole radiation, and can we see this today in the CMBR?

We first will discuss this "binary black holes" signal background which the Planckian early universe stars would have to impinge upon, in order to come to our attention.

Now for the discussion of the millions (more than that) of micro-sized black hole pairs which would create a generalized GW signature.

To evaluate the above in terms of our model, we need to refer to a formula given in Ref. 4, 18, on page 16 of that document which reads as a change in power from rotating Planck-sized black holes separated say by a Planck length.

$$\dot{E} = GW - (\Delta \text{ in energy}) = \frac{32(M_1 M_2)^2 (M_1 + M_2)}{5R^2 M_{\text{Planck}}^5} \xrightarrow[M_1 = M_2 = M_{\text{Planck}}]{} \frac{64}{5R_{\text{Planck}}^2}$$
$$\equiv (\Delta \text{ in power from rotating binary black holes}). \tag{1}$$

For M about the size of a Planck-sized black hole, it likely would fade out almost too quickly to be very measurable.

2.2. *We also can consider the following gravitons as a Bose–Einstein condensate in low mass black holes, and its relevance to signal propagation*

This is a way to get measurable GW signals from a black hole, which have a chance of being detected.

We will be looking at Ref. 5, specifically page 181, where we have the following scaling arguments to work through, if gravitons are Bose–Einstein condensates (BECs) for small black holes. The following are scaling value to consider, if we want BEC.

Why we consider BECs and Eq. (2)–Eq. (6), i.e., if there is a break up of massive black holes into say Planck mass-sized black holes, as or about the Planck era, very likely will not have a surviving signal which has a chance of being measurable in the CMBR data. That is, the discussion of Eq. (2)–Eq. (6) below uses the device of having BEC condensation in gravitons for masses up to about 10 grams or so, and in doing so a dodge as to getting entropy counts per black hole.

That is after the black hole masses, as given in Eq. (2)–Eq. (6) are likely built up by the consolidation of two mini black holes going through an inspiral collapse, as has been modeled in GW.

$$m \approx \frac{M_{\mathrm{P}}}{\sqrt{N_{\mathrm{graviton}}}} \tag{2}$$

$$M_{\mathrm{BH}} \approx \sqrt{N_{\mathrm{graviton}}} \cdot M_{\mathrm{P}} \tag{3}$$

$$R_{\mathrm{BH}} \approx \sqrt{N_{\mathrm{graviton}}} \cdot l_{\mathrm{P}} \tag{4}$$

$$S_{\mathrm{BH}} \approx k_B N_{\mathrm{graviton}} \tag{5}$$

$$T_{\mathrm{BH}} \approx \frac{T_{\mathrm{P}}}{\sqrt{N_{\mathrm{graviton}}}}. \tag{6}$$

Here, the first term, m, is in the effective mass of a graviton. This is my take as to how to make all this commensurate as to special relativity.

$$m \approx \frac{m_g}{\sqrt{1-\left(\frac{\nu_g}{c}\right)^2}} \approx \frac{M_{\mathrm{P}}}{\sqrt{N_{\mathrm{graviton}}}} \approx 10^{-10}\,\mathrm{g} \tag{7}$$

$$\therefore N_{\mathrm{graviton}} \approx 10^{10} \tag{8}$$

With this, if say one has a 1 gram black hole, about 10^5 times larger than a Planck mass, one would be having say an entropy generated this way of about 10^{10}, assuming Planck normalization.

3. So, Then What are the Number of Gravitons Emitted via a Spinning Planck-Sized Black Holes Component Binary in Terms of Gravitons?[6] What Does This Say About an Optimal Black-Hole Size as to Perhaps See Measurable GW/Graviton Generation Effects

Likely from the situation in Ref. 6 for items as of about a Planck length, and involving Planck-sized masses, we would see the following equation for a rotating rod, of mass M, and of velocity V, of its end, for graviton production.

$$N_g \approx \frac{32G}{45\hbar c} M_{\text{rod}}^2 \cdot \left(\frac{V_{\text{tip}}}{c}\right)^4 \propto 7.5 \times 10^{-8} M_{\text{rod}}^2 \Rightarrow N_g \geq 1 \text{ iff } M_{\text{rod}} \geq 4 \times 10^6 \text{ g}. \quad (9)$$

If we have an equivalent situation with respect to two black holes in a binary state, we would likely need to have approximately black holes of masses 10^5 g to 10^6 g—i.e., 10^{10} to 10^{11} times larger than Planck mass—to have a measurable GW/Graviton signal which would be commensurate with experimental data sets. If we had say 10^5 to 10^6 g black holes, then the value of gravitons released per second, from a BEC condensate of gravitons for a mini black hole would me many times larger than Eq. (8) above.

We don't know the exact values, but this leads to our next point, which is the stages of black holes, before the Planckian era, to at the point of time (and space) where 1 to 10^5 g black holes would be composed of gravitons by BEC condensation of gravitons, for a release in.

Considering this, what can we say about the regimes of black-hole masses, just before the Planckian era, during the Planckian era, and right after the Planckian era?

We are assuming the following. A moderately large number (10^6 or more) of super massive black holes which would be in the center of galaxies, and which would be broken up and recycled in the CCC cosmology regime, with masses dropping from about 10^{41} g, down to about 10^{-4} to 10^{-5} g, before recombination by Planck era recombination into a tier of black holes which would be at least 1 gram in mass, scaling up to 10^5 g in mass so as to allow for BEC generation of gravitons through entropy production as in Eq. (2)–Eq. (7) above.

In doing so, we purport to use the datum given in Ref. 6 that masses of say much lower than 10^5 to 10^6 g for black holes likely do not have much chance of producing gravitons which would be detectable in the present era. Indeed, a minimum mass of about 1 to 10 grams for a black hole would be needed for a Bose–Einstein condensation via gravitons for a "light, low-mass" black hole which would be able to by Eq. (2)–Eq. (6), Eq. (8), and Eq. (9) to have at least 10^{10} gravitons per second generated (entropy for a BEC black hole).

We then would to a round off approximation state this hierarchy of black-hole behavior and size to consider.

Table 1. Scaling of mass of black holes, and their purported number, If CCC cosmology (Penrose) assumed for GW radiation release (may affect the CMBR)

End of prior universe time frame	Super massive end-of-time black hole 10^{41} to 10^{44} g.	10^6 to 10^9 of black holes, usually from centers of galaxies
Planck era black hole formation assuming merging of micro black-hole pairs	Micro black holes 10^{-5} to 10^{-4} g (approximately the Planck mass value).	10^{40} to 10^{45} black holes, assuming not too much destruction of matter–energy from pre-Planck to Planck conditions
Post-Planck era black holes: Can use Eq. (2)–Eq. (6) to have 10^{10} gravitons/second released per black hole	Normal-sized black holes 10 g to 10^6 g	10^{20} to, at most, 10^{25} black holes with repeated black-hole pairs forming a single black hole multiple times.

4. Why We Would Have the Figures from Table 1 to Consider for Contributions to the CMBR and the Penrose Suggestion

The formula which is for luminosity from a black hole and in page 16 of Ref. 4 the text states that the two black holes emit GW with a wave frequency 2 times the rotation frequency of the orbit of the two black holes to each other.

If we assume that we are still using this approximation above,[4] we can see support for our choice of Planck length as the minimum separation distance between the two black holes via using Planck units normalized to 1 as yielding

$$R\ (\text{separation}) \simeq r_g^{\text{eff}} = \frac{M_1 + M_2}{M_{\text{Planck}}^2} \xrightarrow[M_1=M_2=M_{\text{Planck}}=1]{} 1 \equiv R_{\text{Planck}}. \tag{10}$$

Going to Clifford Will,[7] we see on page 252 a loss or shrinkage of the period for the rotating black hole pair defined by P

$$\frac{\dot{P}}{P} = \frac{\mathrm{d}P}{\mathrm{d}t} \cdot \frac{1}{P} = -\frac{3}{2}\frac{\dot{E}}{E}. \tag{11}$$

Whereas, with the mechanics version of P for a sphere to be defined by, where M is a mass of a star, and we assume a binary system with two masses of equal mass M, so that, if R is the separation between the two masses[8] on page 188 would be

$$P = R\sqrt{\frac{2\pi^2 R}{GM}} \xrightarrow[M_1=M_2=M_{\text{Planck}}=1]{} R_{\text{Planck}}\sqrt{\frac{2\pi^2 R_{\text{Planck}}}{GM_{\text{Planck}}}}. \tag{12}$$

For Planck-sized masses, this means that the period of the binary Planck mass black hole pair would be vanishingly small.

The frequency of rotation would be half that of the GW emitted by these two Planck mass black holes which would collapse into each other. Note that the frequency we have stated for this last step, is given in Eq. (13). That is, could we have the following quantization contribution to initial frequency?

Our final concluding point to this chapter is to review the physics of Fig. 1, and then to ask, can we ascertain the GW radiation of Planck era black hole stars in a

binary configuration contributing to a buildup of generating frequency getting. If

$$\Delta E \Delta t \approx \hbar \Rightarrow \hbar\omega\Delta t \approx \hbar\omega \left(\frac{2}{3a_{\min}}\right)^{\frac{1}{\gamma}} \Rightarrow \omega \approx \hbar^{-1}\left(\frac{2}{3a_{\min}}\right)^{-\frac{1}{\gamma}}. \tag{13}$$

We claim that if we take the energy as consistent with a change in value as given by Eq. (1) that this will lead to a frequency which may, if $a_{\min} \approx 10^{-25}$–$10^{-20}$ (range from 10^{-25} to 10^{-20}) lead to

$$\omega \approx \hbar^{-1}\left(\frac{3}{2}\right)^{\frac{1}{\gamma}} \cdot 10^{\frac{25}{\gamma}} \propto \left(\frac{3}{2}\right)^{\frac{1}{\gamma}} \cdot 10^{\frac{25}{\gamma}}\,\text{Hz}. \tag{14}$$

Whereas note that the frequency is, say dependent upon the choice of γ and that this could be very different from the Planck frequency

$$\omega_{\text{P}} \approx 1.885 \times 10^{43}\,\text{Hz}. \tag{15}$$

We have then that if one had a redshift, of $z \approx 10^{25}$, that this would mean a present value of frequency as of about 1 Hz, whereas we can consider what would be gained by looking at the contribution near the CMBR, $z \approx$ 1,100 or so for the CMBR, whereas this would mean roughly that we would be looking in the regime of the CMBR:

$$\omega_{\text{signal from Planck to CMBR}} \propto \left(\frac{3}{2}\right)^{\frac{1}{\gamma}} 10^{\frac{25}{\gamma}} \times 10^{-3}\,\text{Hz}. \tag{16}$$

However, we have in doing this, that the duration of this frequency signal would be very minimal, due to the decay of the period, this would be going on for less than a nanosecond.

If so then we would need to refer to Eq. (2)–Eq. (6) and the value of

$$E_{\text{BEC–Graviton}} \approx \frac{k_B T_{\text{BH}}}{2} \approx \frac{k_B \times 10^{-5} \times T_{\text{P}}}{2}$$
$$\Rightarrow \omega_{\text{BEC–Graviton}} \approx 10^{38}\,\text{Hz} \Rightarrow \omega_{\text{BEC–Graviton-to-CMBR}} \approx 10^{38}\,\text{Hz}. \tag{17}$$

Needless to state, that unlike the case of (12), one would likely have the duration of the signal last long enough as to imprint directly on the CMBR. That is, look at Ref. 8. Also, for this I refer to the Zeldovich 4 conference Abhay Ashtekar presentation.[9] Ashtekar referred to a removal of bogus data points in the CMBR (Figure 1[9]).

Now looking at what was discussed by Abhay Ashtekar in Zeldovich 4, on September 7, 2020.[9]

In our Fig. 2, we copy what was done by Ashtekar, in Zeldovich 4 as to what was part of anisotropic fits to the E and B polarization, as given is made easier, if there is a nonsingular start to the universe which I discussed in detail in Ref. 10, and that further polarization states which may be analyzed in detail could be ascertained in Ref. 11.

If one has a nonsingular start to the universe, modeled on a multiverse generalization of Penrose CCC cosmology[10] then the details of a break up of black holes

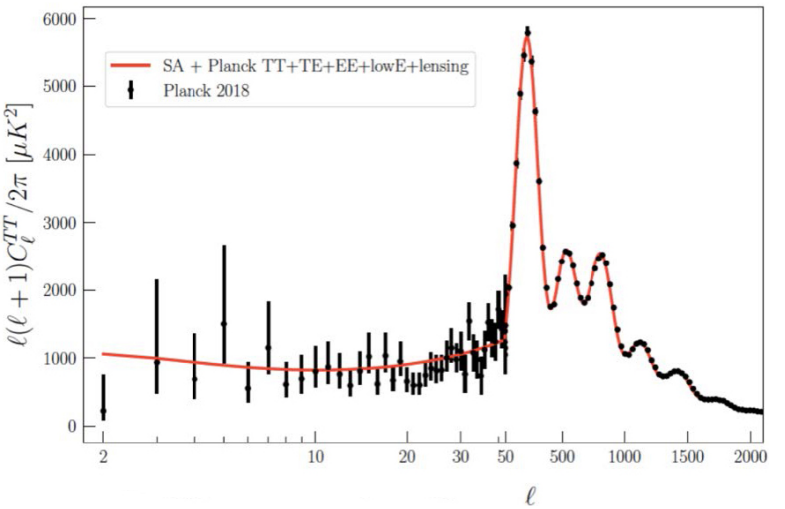

Fig. 2. Filling in the data points left out in terms of CMBR cosmic microwave background[9]

would not be so startling, i.e., these are the details from Ref. 10 as given by the following generalization of CCC cosmology.[10]

4.1. *Looking now at the modification of the Penrose CCC (cosmology)*

We now outline the generalization for Penrose CCC (Cosmology) just before inflation which we state we are extending Penrose's suggestion of cyclic universes, black hole evaporation, and the embedding structure our universe is contained within. This multiverse has black holes and may resolve what appears to be an impossible dichotomy. The text following is largely from Ref. 10 and has serious relevance to the final part of the conclusion. That there are N universes undergoing Penrose "infinite expansion"[2] contained in a mega universe structure. Furthermore, each of the N universes has black hole evaporation, with Hawking radiation from decaying black holes. If each of the N universes is defined by a partition function, called $\{\Theta_i\}_{i=N}^{i=1}$, then there exist an information ensemble of mixed minimum information correlated about 10^7–10^8 bits of information per partition function in the set $\{\Theta_i\}_{i=N}^{i=1}\big|_{\text{before}}$, so minimum information is conserved between a set of partition functions per universe.[12]

$$\{\Theta_i\}_{i=N}^{i=1}\big|_{\text{before}} \equiv \{\Theta_i\}_{i=N}^{i=1}\big|_{\text{after}} \tag{18}$$

However, there is nonuniqueness of information put into partition function $\{\Theta_i\}_{i=N}^{i=1}$. Also Hawking radiation from black holes is collated via a strange attractor collection in the mega universe structure to form a new inflationary regime for each of the N universes represented.

Our idea is to use what is known as CCC cosmology,[12] which can be thought of as the following. First. Have a big bang (initial expansion) for the universe which is represented by $\{\Theta_i\}_{i=N}^{i=1}$. Verification of this mega structure compression and expansion of information with stated nonuniqueness of information placed in each of the N universes favors ergodic mixing of initial values for each of N universes expanding from a singularity beginning. The n_f stated value, will be $S_{\text{entropy}} \approx n_f$.[12,13] How to tie in this energy expression, as in Eq. (16) will be to look at the formation of a nontrivial gravitational measure as a new big bang for each of the N universes as by $n(E_i)$. The density of states at energy E_i for partition function.[12,14]

$$\{\Theta_i\}_{i=1}^{i=N} \propto \left\{ \int_0^\infty \mathrm{d}E_i \cdot n(E_i) \cdot \mathrm{e}^{-E_i} \right\}_{i=1}^{i=N} . \tag{19}$$

Each E_i identified with Eq. (13) above, are with the iteration for N universes.[2,12] Then the following holds, by asserting the following claim to the universe, as a mixed state, with black holes playing a major part.

4.1.1. *Claim 1*

See the below representation[12] of mixing for assorted N partition function per CCC cycle.

$$\frac{1}{N}\sum_{j=1}^{N} \Theta_j\big|_{j \text{ before nucleation regime}} \xrightarrow[\text{vacuum–nucleation transfer}]{} \Theta_i\big|_{i \text{ fixed after nucleation regime}} \tag{20}$$

For N number of universes, with each $\Theta_j\big|_{j \text{ before nucleation regime}}$ for $j = 1$ to N being the partition function of each universe just before the blend into the right-hand side of Eq. (20) above for our present universe. Also, each independent universes as given by $\Theta_j\big|_{j \text{ before nucleation regime}}$ is constructed by the absorption of one to ten million black holes taking in energy.[2] Furthermore, the main point is done in Ref. 10 in terms of general ergodic mixing.[12]

4.1.2. *Claim 2*

$$\Theta_j\big|_{j \text{ before nucleation regime}} \approx \sum_{k=1}^{\max} \widetilde{\Theta}_k\Big|_{\text{black holes } j\text{th universe}} \tag{21}$$

What is done in Claims 1 and 2[10] is to come up as to how a multi dimensional representation of black hole physics enables continual mixing of spacetime largely as a way to avoid the anthropic principle,[10] as to a preferred set of initial conditions.

5. Conclusion

If one has a nonsingular start of expansion of the universe and ergodic mixing of initial conditions of space-time from other universes, how does this relate to the

breaking up of black holes from Table 1? In Ref. 10 in order to do away with the anthropic principle, the following references in terms of ergodic mixing of the partition function of the universe was utilized, as far as a multiverse. But there is one final piece. Assume that we have

$$\omega_{\text{Earth}} \leq 10^{-25}\omega_{\text{initial}}. \tag{22}$$

We will be of course assuming an equivalence between a graviton count and information,[16] and we can in future work compare this with the Rosen[3] value of energy for a mini universe of (from a Schrödinger equation) with ground state mass of $m = \sqrt{\pi}M_{\text{Planck}}$ and an energy of

$$E_{\hat{n}} = \frac{-Gm^5}{2\pi^2\hbar^2\hat{n}^2}. \tag{23}$$

Our preliminary supposition is that Eq. (23) could represent the initial energy of a pre-Planckian universe and that Eq. (24) would be thermally based energy dumped into the space-time bubble assumed in Ref. 10. That is,

$$E_{\text{universe}} = 10^{41} \times E_{\text{BEC–Graviton}} \approx 10^{41} \times \left(\frac{k_B T_{\text{BH}}}{2} \approx \frac{k_B \times 10^{-5} \times T_{\text{P}}}{2}\right) \tag{24}$$

is the thermal energy dumped in due to the use of cyclic conformal cosmology. Here we specify that initially it would have that the value of Eq. (24) would exactly counter balance the energy given in a negative form by Rosen as of Eq. (23).

Now use the following approximation of the universe, initially having the entropy of a black hole. That is, we are using Ng infinite quantum statistics,[18] while area denotes the surface area of the regime of space-time:

$$S_{\text{universe}} \propto S_{\text{BH}} \simeq \frac{A}{4l_{\text{Planck}}^2} \approx \frac{9n_Q}{4} \approx n_{\text{graviton}}. \tag{25}$$

This way of noting entropy and the signals of the prior universe black holes being generated secondarily is a surface area which is commensurate with the utilization of Eq. (2)–Eq. (6) for BEC condensation by gravitons for early-universe black holes. This is in tandem with the quantum fluctuations as seen in Figure 2 below. Also see Appendix A as well as the physics.[3,17,18]

The bubble nucleation, plus the details of cosmology leading to black holes from a prior universe showing up:

> For thirty years Oxford mathematician Roger Penrose has challenged one of the key planks of cosmology, namely the concept of inflation, now over 40 years old, according to which our universe expanded at an enormous rate immediately after the big bang. Instead, fifteen years ago, Penrose proposed a counterconcept of conformal cyclic cosmology by which inflation is moved to before the big bang and which introduces the idea of preceding eons. The concept has been disputed by most physicists, but Penrose and colleagues believe that new evidence has come to light which requires closer inspection

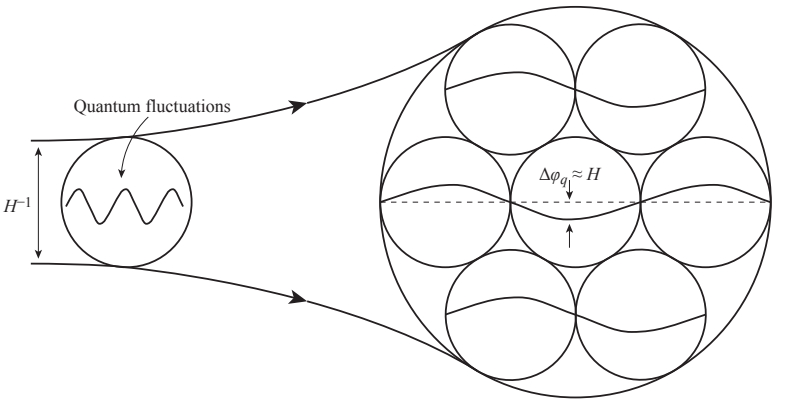

Fig. 3. We here are examining how the universe has self replicating regimes of spacetime[10, 14]

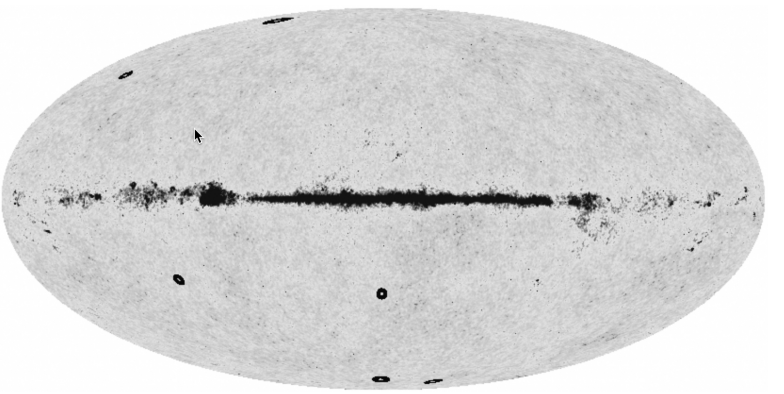

Fig. 4. Mollweide view showing how the CMBR spectrum has "rings" in it from black holes from a prior universe

Source: This from Ref. 19 with Ref. 3 having the data points used to construct this image in.

and argument—the research is published today in the Monthly Notices of the Royal Astronomical Society.[19]

Recent analysis of the cosmic microwave background (CMB) by Penrose, An, Meissner, and Nurowski has revealed, both in the Planck and WMAP satellite data (at 99.98% confidence), a powerful signal that had never been noticed previously, namely numerous circular spots $\approx$ 8 times the diameter of the full moon. The brightest six (Figure 1) are $\approx$ 30 times the average CMB temperature variations seen at precisely the same locations in the Planck and WMAP data. These spots were overlooked previously owing to a belief that the very early exponentially expanding *inflationary* phase of standard cosmology should have obliterated any such features.

Judicious application of Eq. (2)–(6) plus Table 1 above leads to this phenomenon.

Appendix A. Examining How Many Gravitons Might Be Produced by Initially Planck-Sized Black Holes

Alexander D. Dolgov and Damian Ejlli[4] inform us that a mass of a primordial black hole is

$$M_{\text{early black hole}} \approx 4 \times 10^{38} t \frac{\text{g}}{\text{s}}. \tag{26}$$

A Planck mass is of the value 10^{-5} g, i.e., almost, is then obtainable when

$$t_{\text{formation}} \approx 10^{-43}\,\text{s} \Rightarrow M_{\text{early black hole}} \approx 10^{-5}\text{g}. \tag{27}$$

Note that $t_{\text{formation}} \approx 10^{-43}\,\text{sec} \geq 5.39 \times 10^{-44}\,\text{s}$ leads to almost a Planck mass, $2.176434(24) \times 10^{-5}\,\text{g} = M_{\text{Planck}}$.

The mechanism of how Planck-sized black holes could generate GW comes from,[4] initial friction in the early universe environment, leading to coupling of early primordial binary black hole systems which in turn would collapse and form larger black holes—i.e., in fact the argument in Ref. 18 is stated on page 15 as follows.

> For PBH masses below a few grams dynamical friction would be an efficient mechanism of PBH cooling leading to frequent binary formation. Moreover, dynamical friction could result in the collapse of small PBHs into much larger black holes with the mass of the order of Mb (18). This process would be accompanied by a burst of GW emission

What is called Mb in this situation is given in Ref. 4 on page 4.

> As we see in what follows, generation of gravitational waves would be especially efficient from such high density clusters of primordial black holes. Let us assume that the spectrum of perturbations is the flat Harrison–Zeldovich one and that a perturbation with some wavelength λ crossed horizon at moment t_{in}. The mass inside horizon at this moment was
>
> $$Mb(t_{\text{in}}) = m_2 Plt_{\text{in}}.\ (4) \tag{28}$$
>
> It is the mass of the would-be high density cluster of PBHs.

We then from here have the mechanism of black hole formation comes from binary pair formation of small black holes which collapse into a larger set of black holes. This chain of black-hole pair production and collapse would then lead to an accretion procedure along the lines of Eq. (25). Eventually these black hole clusters would form the mega black holes as seen in the center of spiral galaxies.

We summarize the talks presented at the BH3 session (Black Holes in Alternative Theories of Gravity) of the 16th Marcel Grossmann Meeting held online on July 5-10 2021.

Keywords: Gravity; Alternative theories; Black holes.

1. Introduction

Black holes have received tremendous interest in recent years, originating on the one hand from the discovery of gravitational waves, generated in the merger of stellar black holes, by the LIGO collaboration,[1] and on the other hand from the observation of the shadow of the supermassive black hole at the center of M87 by the EHT collaboration.[2] The analysis of observational data of black holes is typically based on the *Kerr hypothesis*, namely the assumption that rotating black holes are well described by the Kerr solution of General Relativity. Just like General Relativity itself, also the *Kerr hypothesis* is still consistent with all available data.

However, there are a number of reasons suggesting that General Relativity will be superseded by a new theory of gravity, which would reduce to General Relativity in a limit. From a theoretical side these reasons include the problem of quantization of gravity and the presence of singularities in solutions of General Relativity, while from an observational side the need for *Dark Matter* and *Dark Energy* in a cosmological context seem most provoking.

All these reasons have led to a large number of suggestions for alternative theories of gravity based on deep theoretical reasoning or simply phenomenological modelling, see e.g.,[3–6] While alternative theories of gravity should be consistent with observations in the weak gravity regime, thus in particular, with observations in the solar system, the strong gravity regime is so far much less constrained. In the strong gravity regime there exist certainly high precision data from pulsar observations (see, e.g.[7]), but the unknown equation of state of matter at extreme densities and pressures may lead to degeneracies with the unknown theory of gravity. Therefore black holes may present cleaner probes of the strong gravity regime.

In General Relativity black holes are remarkably simple objects in terms of the characterization of the space-times, as expressed by the *no-hair theorem* (see, e.g.[8]). Consequently, Kerr black holes are uniquely determined by their mass and their angular momentum, and all their higher multipole moments can be fully expressed by these two lowest moments. Moreover, when considering the fields of the Standard Model of Particle Physics, no astrophysical rotating black holes other than the *bald* Kerr black holes arise. Only microscopic black holes might carry fields of the Standard Model as hair (see, e.g.[9,10]). However, if one allows for a hypothetical complex massive scalar field or Proca field, then General Relativity allows for rotating Kerr black holes with scalar or Proca hair that might be of astrophysical relevance.[11,12]

Alternative theories of gravity typically introduce further degrees of freedom, often in the form of gravitational scalar or vector fields.[3–6] Prominent theories with additional scalar fields are Horndeski and beyond Horndeski theories,[13–16] while their counterparts with vector fields are generalized Proca and beyond generalized Proca theories.[17–20] But further degrees of freedom may also be present when the tensorial part of gravity is modified, yielding, for instance, de Rham-Gabadadze-Tolley massive gravity[21] and bigravity theories.[22,23] While General Relativity can be formulated in terms of curvature, torsion or non-metricity, as expressed by the *geometrical trinity of gravity*,[24] the associated generalizations of these formulations are no longer equivalent.

Up to now most work on black holes in alternative theories of gravity has been done in metric theories. Here the recent years have witnessed the emergence of new types of black holes due to newly discovered phenomena. These are, for instance, curvature-induced spontaneously scalarized black holes that arise in certain Horndeski models with higher curvature terms, when curvature is sufficiently strong to induce a tachyonic instability in the background of a Schwarzschild or Kerr black hole solution.[25–29] Similarly, spin-induced spontaneously scalarized black holes emerge in the presence of sufficient curvature and spin.[30–33] While these solutions satisfy circularity, this is not necessarily true for rotating black holes in beyond Horndeski theories, where also so-called disformed black holes with a non-circular geometry can arise (see, e.g.[34,35]).

A very important aspect of black holes in alternative theories of gravity is of course their stability and their response to perturbations. In particular, the study of quasi-normal modes (QNMs) is very valuable here, since these are also of relevance for the analysis of the ringdown phase of black hole mergers. Whereas the QNMs of the Schwarzschild and Kerr black holes are known since quite some time (see, e.g.[36–40]), the study of the QNMs of black holes in alternative theories of gravity is still in its infancy. While some work has been done for static black holes (see, e.g.[41]), very little is known so far even for the case of slow rotation only. The presence of additional degrees of freedom in alternative theories of gravity, yields a much more intricate spectrum, though, since various modes forbidden in General Relativity will be present in alternative theories of gravity.

In the following we will summarize the progress on black holes in alternative theories of gravity reported in our session of the 16th Marcel Grossmann Meeting.

2. Summary of the presentations

The 16th Marcel Grossmann Meeting was held online on July 5-10 2021. This was the first time that the meeting was held completely online, mainly because of the COVID-19 pandemic around the world. In the parallel session "Black Holes in Alternative Theories of Gravity" abbreviated as BH3, 16 physicists presented their recent research activities in two days, Tuesday 06 July 2021 09:30-12:30 and Thursday 08 July 2021 16:30-19:30 CEST. Here we recall the main points of the talks in BH3, and provide a summary of the presentations.

2.1. *Asymptotically flat hairy black holes in massive bigravity*

Presented by: Mikhail Volkov
In collaboration with: Romain Gervalle
Based on the Ref.[42].

The ghost-free theories of bigravity were first introduced by Hassan and Rosen in Ref.[43]. In these theories, there are two metrics denoted by $g_{\mu\nu}$ and $f_{\mu\nu}$. Both of the metrics have the usual Einstein-Hilbert action, and there is an interaction term between the two metrics. The metric $g_{\mu\nu}$ can be coupled to some matter, while $f_{\mu\nu}$ is not coupled to any matter. Analyzing the propagating degrees of freedom, there are two gravitons in such theories, one massive and one massless. These family of theories have been shown to be able to describe the accelerating expansion of the universe without a cosmological constant.

Any black hole as a vacuum solution in general relativity is a solution to bigravity theories by the choice of $g_{\mu\nu} = f_{\mu\nu}$. For example, the Schwarzschild metric is a solution to these theories if one chooses $g_{\mu\nu} = f_{\mu\nu}$ be equal to the Schwarzschild metric. However, this solution is not a stable solution in these theories. An interesting question arises here: if one relaxes the constraint $g_{\mu\nu} = f_{\mu\nu}$, is it possible to have spherically symmetric asymptotically flat solutions other than the Schwarzschild. The terminology "hairy black holes" has been used for such solutions in bigravity, and the "bald Schwarzschild" for the special case of $g_{\mu\nu} = f_{\mu\nu}$ to be Schwarzschild. It has been a debate to answer this question[44–46] whether there are hairy black holes in ghost-free bigravity or not. Romain Gervalle and Mikhail Volkov in Ref.[42] have tried to answer this interesting question by constructing spherically asymptotically flat black hole solutions numerically. They have found that there exist such black hole solutions (as pairs of solutions, one for $g_{\mu\nu}$ and one for $f_{\mu\nu}$) with the same horizon and surface gravity. Free parameters of the Schwarzschild hairy black holes are constrained by studying the stability of the solution. To this end, the $g_{\mu\nu}$ metric should be close to the Schwarzschild metric, the $f_{\mu\nu}$ metric should not be coupled to the matter, and the mass of the black hole should be between $0.2M_{\odot}$ and $0.3 \times 10^6 M_{\odot}$.

2.2. *An overview of quasinormal modes in modified and extended gravity*

Presented by: Aurélien Barrau
In collaboration with: Flora Moulin and Killian Martineau
Based on the Ref.[47].

Quasi-normal modes (QNMs) are dissipative perturbations around a black hole background solution. They satisfy purely outgoing and ingoing boundary conditions at infinity and at the event horizon respectively. The oscillatory time dependence of these modes is described by

$$\psi \propto e^{i\omega t} = e^{i(\omega_R + i\omega_I)t}. \tag{1}$$

The frequency ω_R characterizes the oscillatory behavior of the mode, while for the $\omega_I > 0$ and $\omega_I < 0$ the mode grows or decays exponentially, respectively. The main question in the QNM analysis is to find the behavior of the complex function ω.

In this talk, Aurélien Barrau provided an overview on QNMs, and presented their results for perturbations around a spherically symmetric black hole in some alternative theories of gravity. Their analysis is based on Wentzel-Kramers-Brillouin (WKB) approximation method.[48–50] The theories under consideration have been chosen to be the massive gravity,[21,22,51,52] Modified Scalar-Tensor-Vector (STV) Gravity,[53] Horava-Lifshitz,[54–57] $\hbar$-correction (quantum correction),[58] and loop quantum gravity (based on the model presented in Ref.[59]). For each one of these choices, the diagrams of ω_R and ω_I for some suitable multipole number ℓ and overtone number n were illustrated and compared qualitatively.

2.3. *Constraining modified gravity theories with physical black holes*

Presented by: Sebastian Murk
In collaboration with: Daniel R. Terno
Based on the Ref.[60].

In this work, the authors emphasize that a physical black hole is a celestial object which has a smooth apparent horizon and trapped surface.[61] Requesting the smoothness of these surfaces constrains the gravitational models which govern the dynamics of such solutions. To be more accurate, the existence of semiclassical physical black holes in modified theories of gravity induces some necessary conditions.

In order to find such necessary conditions, Sebastian Murk as a PhD student and his colleague have focused on the spherically symmetric black hole solutions which are presented as expansions in the coordinate distance from the apparent horizon and do not require a General Relativity solution as the zeroth-order perturbative solution of the modified theory. The only condition which they impose is the regularity of apparent horizon for black hole solutions. They pick finiteness of T^{μ}_{μ} and $T^{\mu\nu}T_{\mu\nu}$ as the regularity condition on the trapped horizon. By perturbing the Einstein equation with a new term $G_{\mu\nu} + \lambda\epsilon_{\mu\nu} = 8\pi T_{\mu\nu}$ and a generic ansatz for a

spherically symmetric black hole metric, the necessary conditions on the component of the $\epsilon_{\mu\nu}$ are investigated. In the end, the results are studied more for a special modified gravity, the Starobinsky model.[62]

2.4. *Black holes, stationary clouds and magnetic fields*

Presented by: Nuno Santos
In collaboration with: Carlos A.R. Herdeiro
Based on the Ref.[63].

Stationary bosonic clouds are stable configuration of scalar fields around a black hole resulting in a bound state. Suggested by many examples, in order to have such a bound state, two conditions are necessary: (1) the possibility for superradiance, (2) a confinement mechanism. The former is necessary to synchronize the bosonic cloud with the black hole rotation, and the latter is needed to make the configuration stable. Interestingly, stationary clouds are characterized by a discrete number of nodes in the radial direction, n, the orbital angular momentum, ℓ , and the azimuthal harmonic index m. In this regard, they resemble orbital configurations in a Hydrogen atom.[11,12,64,65]

In this presentation, the bosonic clouds are studied around a Reissner-Nordström black hole immersed in a magnetic field. These family of black hole solutions are called Reissner-Nordström-Melvin black holes.[66] They are solutions to Einstein-Maxwell theory, and their asymptotics resemble a magnetic Melvin universe. These black holes are stationary and axially symmetric. The presence of an external magnetic field provides both of the conditions for the stability of a bosonic cloud, i.e., the ergoregion and the confinement mechanism. The scalar field in this analysis has been considered to be complex, massless and minimally coupled to gravity. So, the theory is described by the action:

$$\mathcal{I} = \frac{1}{4\pi}\int d^4x\sqrt{-g}\big[\frac{R}{4} - \frac{F^2}{4} - (\nabla^\mu\Psi^*)(\nabla_\mu\Psi)\big]. \tag{2}$$

The bosonic clouds in this model, and on the Reissner-Nordström-Melvin solution are studied, and it is shown that for specific mass to charge ratios, there exist stable bosonic clouds.

2.5. *Bardeen black hole from a self-dual radius in spacetime*

Presented by: Michael Florian Wondrak
In collaboration with: Marcus Bleicher, Piero Nicolini, and Euro Spallucci
Based on the Ref.[67,68].

String T-duality is an equivalence between two string theories on spacetimes with at least one compactified extra dimension – provided that the compactification radii are inversely related to each other, i.e. $R_1 = R$ and $R_2 = \frac{(R^\star)^2}{R}$. The special case of $R = R^\star$ is called self-dual radius. Beginning from T-duality in bosonic string theory, Michael Florian Wondrak first gave an overview on how quantum

field propagators are deformed.[69] The scalar propagator obtained via Schwinger's proper time formalism is read to be

$$G(k) = -\frac{\ell_0 K_1(\ell_0\sqrt{k^2+m^2})}{\sqrt{k^2+m^2}}. \tag{3}$$

In this relation, $K_\nu(x)$ is the Modified Bessel function of second kind, and ℓ_0 is the zero point length.[70] Studying the potential induced by this propagator, a spherically symmetric black hole solution was derived,

$$ds^2 = -f(r)dt^2 + \frac{dr^2}{f(r)} + r^2 d\Omega^2, \qquad f(r) = 1 - \frac{2Mr^2}{(r^2+\ell_0^2)^{3/2}}. \tag{4}$$

This metric resembles the Bardeen black hole with a new interpretation of the UV cut-off in terms of the zero point length ℓ_0 instead of a magnetic monopole charge. Then, the thermodynamics of this black hole was studied and it was shown that at the end of evaporation process, the evaporation stops with a cold remnant instead of a final explosion. The remnants of these black holes were investigated regarding a possible fraction of dark matter. With a mass below $5\times10^{-8}\,M_\odot$, they comply with recent constraints on primordial black holes.[71] In the rest of the talk, observability of ℓ_0 was discussed: From the hydrogen energy spectrum, an upper bound of 4×10^{-19} meter was deduced.

2.6. *Asymptotically flat black hole solution in modified gravity*

Presented by: Surajit Kalita
In collaboration with: Banibrata Mukhopadhyay
Based on the Ref.[72].

$f(R)$ gravities are among alternative theories of gravity which have observational motivations to be studied. In these theories, one replaces the Ricci scalar R in the Lagrangian of General Relativity by a function of R, which is called $f(R)$.

$$\mathcal{I} = \frac{1}{16\pi}\int d^4x\sqrt{-g}f(R). \tag{5}$$

Although the equations of motion are higher-order in derivatives, they do not suffer from Ostrogradsky instability. In this presentation, Surajit Kalita presented the construction of spherically symmetric asymptotic flat black hole solutions to a subset of $f(R)$ theories. This subset is parametrized by a constant B in the relation $\frac{df}{dR} = 1 + \frac{B}{r}$. The metric ansatz is chosen to be $g_{\mu\nu} = \mathrm{diag}(g_{tt}, g_{rr}, r^2, r^2\sin^2\theta)$. By inserting this ansatz in the equations of motion of $f(R)$ gravities, the unknown components (g_{tt}, g_{rr}) are found as an expansion if powers of B and $\frac{1}{r}$. Then, some properties of these solutions are analyzed, including marginally stable and bound orbits, and spherical accretion flows. Moreover, from these solutions it is deduced that the Birkhoff theorem can be violated in $f(R)$ gravities.

2.7. *Infinitely degenerate exact Ricci-flat solutions in $f(R)$ gravity*

Presented by: Semin Xavier
In collaboration with: Jose Mathew and S. Shankaranarayanan
Based on the Ref.[73].

In this talk, Semin Xavier presented their results for an infinite number of solutions to a subset of $f(R)$ gravities. The theory is described by the action

$$\mathcal{I} = \frac{1}{16\pi}\int d^4x\sqrt{-g}f(R), \qquad f(R) = (\alpha_0 + \alpha_1 R)^p, \tag{6}$$

for a real number $p > 1$, and constants α_0 and α_1. The metric ansatz is chosen to be spherically symmetric:

$$ds^2 = -A(r)e^{\delta(r)}dt^2 + \frac{dr^2}{A(r)} + r^2(d\theta^2 + \sin^2\theta d\varphi^2). \tag{7}$$

Solving the equations of motion for the unknown functions $A(r)$ and $\delta(r)$ it is shown that there are an infinite number of possibility for these functions. As a result, it is discussed that in $f(r)$ gravities the Birkhoff theorem may be violated. In order to show this explicitly, two black hole solutions are constructed and studied.

2.8. *Does the Penrose suggestion as to black holes from a prior universe showing up in today's universe have credibility? Examined from a singular, and nonsingular beginning of cosmological expansion*

Presented by: Andrew Walcott Beckwith
Based on the Ref.[74].

Conformal Cyclic Cosmology (CCC) is a cosmological model in the framework of General Relativity, which is proposed by Roger Penrose.[75] In this model of cosmology, the universe iterates through infinite cycles, with the future timelike infinity of each previous iteration being identified with the past timelike infinity of the next universe. From the observational point of view, it has been suggested that the black holes in the previous universe can have implications in our universe, imprinted in the cosmic microwave background (CMB).[76,77]

In this talk, Andrew Walcott Beckwith discussed on the feasibility and credibility of the proposed methods for checking CCC using CMB data. He discussed the Penrose singularity theorem, and investigated the two cases of the CCC: cycling through singular or non-singular starting/ending points.

2.9. *Analytical computation of quasi-normal modes of slowly-rotating black-holes in dCS gravity*

Presented by: Manu Srivastava
In collaboration with: Yanbei Chen and S. Shankaranarayanan
Based on the Ref.[78].

Gravitational waves have provided interesting data about the inspiral and ring-down phases of black hole mergers. The waves in the ring-down phase are quasi-normal modes of the black hole merger. Therefore, by studying the data in the ring-down phase we can investigate the quasi-normal modes of the system.[36,37,40] However, quasi-normal mode frequencies depend on the gravitational theory. So, they provide a new tool to distinguish and examine alternative theories of gravity.

In this line of research, Manu Srivastava and his collaborators have focused on dynamical Chern-Simons gravity (dCS), which is described by the following action:[79]

$$\begin{aligned}\mathcal{I} =&\frac{1}{16\pi}\int d^4x\sqrt{-g}R - \frac{\beta}{2}\int d^4x\sqrt{-g}(\nabla_\mu\vartheta\nabla^\mu\vartheta + V(\vartheta))\\ &+\frac{\alpha}{4}\int d^4x\sqrt{-g}\vartheta * RR + \mathcal{I}_{\rm matter},\end{aligned} \tag{8}$$

in which ϑ is a pseudo-scalar field, and $*RR$ is the Pontryagin density

$$*RR \equiv \frac{1}{2}\epsilon^{cdef}R^a{}_{bef}R^b{}_{acd}. \tag{9}$$

where ϵ^{cdef} is the Levi-Civita tensor. The background is chosen to be a slowly rotating black hole introduced in Ref.[80]. The parameter of slow rotation is denoted by a. In the analysis, quasi-normal modes in the axial and polar sectors are studied up to linear order in a and quadratic order in α. The results of this study, along with the data from gravitational wave observations, can be used as a test for dCS gravity and to constrain coupling parameters.

2.10. *Scalar perturbations of Kerr black-holes in hybrid metric-Palatini gravity*

Presented by: João Luís Rosa
In collaboration with: José P. S. Lemos and Francisco S. N. Lobo
Based on the Ref.[81].

In General Relativity, the connection $\Gamma^\lambda_{\mu\nu}$ is assumed to be the metric connection, which is related to the metric by the relation

$$\Gamma^\lambda_{\mu\nu} = \frac{1}{2}g^{\lambda\sigma}\left(\partial_\mu g_{\sigma\nu} + \partial_\nu g_{\sigma\mu} - \partial_\sigma g_{\mu\nu}\right). \tag{10}$$

However, in the Palatini formulation of gravity (see a review in Ref.[82]), the connection $\hat{\Gamma}^\lambda_{\mu\nu}$ is considered independent of the metric. If we denote the Ricci scalar which is built upon $\hat{\Gamma}$ by $\mathcal{R}$, then the generalized hybrid metric-Palatini (GHMP) gravity[83–85] (see a review in Ref.[86]) is described by the following action:

$$\mathcal{I} = \frac{1}{16\pi}\int d^4x\sqrt{-g}f(R,\mathcal{R}) + \mathcal{I}_{\rm matter}. \tag{11}$$

By the equations of motion, it turns out that the $\mathcal{R}$ is the Ricci scalar calculated for a metric which is conformal to $g_{\mu\nu}$. Motivated by this, João Luís Rosa and his

collaborators have shown that for any vacuum solution to GR, there is a non-trivial function $f(R, \mathcal{R})$ such that it is a solution to the GHMP too.

In this context, the Kerr black hole can also be considered as a solution to the GHMP. The stability of the Kerr constrains the $f(R, \mathcal{R})$, and this is analyzed in this presentation by studying massive scalar perturbations around the Kerr black hole. In particular, it is shown that the Kerr black hole is stable for some specific $f(R, \mathcal{R})$ theories and masses for the scalar perturbation.

2.11. *Emergent magnetic monopoles in degenerate theory*

Presented by: Suvikranth Gera
In collaboration with: Sandipan Sengupta
Based on the Ref.[87].

Magnetic monopoles are theoretical counterparts for electric charges in electric-magnetic duality.[88,89] Although they have been studied extensively, there is not yet observational evidence for their existence in nature.

In this talk, Suvikranth Gera presented a non-invertible metric which resembles a magnetic monopole in the first-order formulation of gravity.[90–92] Unlike the usual metric formulations, the non-invertible metric is well-defined in the tetrad formulations. In the presentation, he first presented the metric explicitly, and then followed by the calculation the spin-connection and its field strength in the first-order formulation. The magnetic charge is calculated, and the topological origin and its observability is discussed at the end, and it is mentioned that this solution has not any curvature singularity. Moreover, for the observers moving on timelike geodesics, this emergent magnetic charge is not accessible observationally, although it affects the curvature of the space-time.

2.12. *Black holes in metric-affine gravity: properties and observational discriminators*

Presented by: Diego Rubiera-Garcia
Based on the Ref.[93].

A generic connection $\Gamma^{\lambda}_{\mu\nu}$ can be independent of the metric (see the review in Ref.[82]). Such a generic connection is called affine connection. Accordingly, it can be regarded as an independent field in the Lagrangian. These models of gravity are called metric-affine gravities. In a subset of such models, which is called "Ricci based gravities," the connection $\Gamma^{\lambda}_{\mu\nu}$ appears in the Lagrangian only through a symmetric Ricci tensor $R_{\mu\nu}$,

$$\mathcal{I} = \frac{1}{16\pi}\int d^4x\sqrt{-g}\mathcal{L}_G[g_{\mu\nu}, R_{\mu\nu}(\Gamma)] + \mathcal{I}_{\text{matter}}[g_{\mu\nu}, \psi_m]. \tag{12}$$

In this talk, Diego Rubiera-Garcia presented an overview on recent results for the black holes in these models of gravity. It is shown that for spherically symmetric black holes, the curvature singularity can be smoothed out, and the geodesic

completeness is restored. Moreover, for such solutions there exist "double critical curves." This feature makes the shadow of the black hole to appear as two or more bright rings.

2.13. *Holography for rotating black holes in $f(T)$ gravity*

Presented by: Masoud Ghezelbash
In collaboration with: Canisius Bernard
Based on the Ref.[94].

General relativity is based on the Riemann curvature, while the torsion and non-metricity are considered to vanish. However, it is equivalent to make gravitational theories solely based on torsion, or non-metricity. These equivalent formulations in the literature are referred as Teleparallel and Symmetric Teleparallel (or coincident) gravities respectively. Similar to the Ricci scalar R which is made from the Riemann tensor, one can appropriately define the torsion scalar T, or the non-metricity scalar Q. According to the equivalence alluded to above, one can have analogous theories for $f(R)$, namely $f(T)$ or $f(Q)$.

It is useful to study gravitational features in GR, in the Teleparallel gravity or Symmetric Teleparallel gravity. In this talk, Masoud Ghezelbash has focused on the Kerr/CFT correspondence in $f(T)$ gravities. Kerr/CFT is a correspondence between the near horizon region of extremal black holes (originally Kerr black hole[95]) with a (chiral) two dimensional CFT. In this correspondence, the entropy of the black hole is calculated via the Cardy-formula for the entropy in a CFT:[96,97]

$$S = \frac{\pi^2}{3}(c_L T_L + c_R T_R), \tag{13}$$

in which the c's are the central charge of the left and right sectors, and the T's are Frolov-Thorne temperatures.[98] The result of such analyses shows that the entropy is proportional to the angular momentum associated with the axial symmetry which eventually enhances to the Virasoro sectors in the CFT (a review on Kerr/CFT and its extensions can be found in Ref.[99]). Besides, there are many works attempting to realize black hole microstates from the CFT using the Kerr/CFT correspondence (see e.g.[100–108]).

In this study, the model of gravity has been chosen to be

$$\mathcal{I} = \frac{1}{16\pi}\int d^4x\sqrt{-g}\left(f(T) - 2\Lambda - F^2\right), \tag{14}$$

in which Λ is the cosmological constant, and F^2-term is the Maxwell theory. A rotating charged black hole as a solution to this theory (introduced in Ref.[109]) is chosen to be studied, and the wave equation for a massless scalar field is approximated in the near horizon geometry of this black hole. Instead of a chiral Virasoro, a full Virasoro algebra is reported in this near horizon, and the Cardy formula (13) is used to reproduce the black hole entropy.

2.14. *Universe in a black hole with spin and torsion*

Presented by: Nikodem Poplawski
Based on the Ref.[110].

The Einstein-Cartan theory (EC) of gravity[111–115] is the simplest theory with torsion and curvature. In this theory, the Lagrangian is the same as the Einstein gravity

$$\mathcal{I} = \frac{1}{2\kappa}\int d^4x\sqrt{-g}(R + \mathcal{L}_{\rm matter}), \tag{15}$$

but in addition to the metric, the torsion is considered as a dynamical field. In this talk, Nikodem Poplawski studies the collapse of spherically symmetric fermionic matter to form a black hole in EC. He explains that if a fermionic field is considered as a perfect fluid with energy density ϵ and pressure p as the matter in this theory, the effect of the dynamics of torsion can be absorbed in the energy-momentum tensor[116] by

$$T_{\mu\nu} = \epsilon u_\mu u_\nu - p(g_{\mu\nu} - u_\mu u_\nu) \quad \rightarrow \quad \tilde{T}_{\mu\nu} = \tilde{\epsilon} u_\mu u_\nu - \tilde{p}(g_{\mu\nu} - u_\mu u_\nu), \tag{16}$$

in which

$$\tilde{\epsilon} = \epsilon - \alpha n_f^2, \qquad \tilde{p} = p - \alpha n_f^2. \tag{17}$$

In this relation, u_μ is the four-velocity, n_f is the number density of fermions, and $\alpha = \frac{\kappa}{32}$. Using $\tilde{T}_{\mu\nu}$, the equation of motion can be written as the usual Einstein equation:

$$G_{\mu\nu} = \kappa\tilde{T}_{\mu\nu}. \tag{18}$$

In this setup, the collapse is studied by the Tolman ansatz[117] for the metric:

$$ds^2 = e^{\nu(\tau,R)}d\tau^2 - e^{\lambda(\tau,R)}dR^2 - e^{\mu(\tau,R)}(d\theta^2 + \sin^2\theta d\varphi^2), \tag{19}$$

and solved for the unknown functions (ν, μ, λ). The results show that in this collapse, the singularity is prevented by the effects of the torsion. The geometry of the universe on the other side of the horizon is calculated, and it is shown that the geometry is an oscillating FLRW metric and it describes a closed universe. It is also calculated that due to the pair particle production, the frequency of the oscillation is reduced in time.

2.15. *Absorption by deformed black holes*

Presented by: Renan B. Magalhães
In collaboration with: Luiz C.S. Leite and Luís C.B. Crispino
Based on the Ref.[118].

The usual way to study alternative theories of gravity is to change the Lagrangian or the dynamical fields. Then, the equations of motion follow, and one can study the solutions to the new equations. However, in Ref.[119], Johannsen and

Psaltis introduced a parametric deviation approach, which is the reverse of the procedure mentioned above. They deform black holes by some parameters such that the black holes remain smooth, free of pathology, and have some suitable properties. Then, the equations of motion which could have such solutions are investigated. Following this method, Konoplya and Zhidenko in Ref.[120] have deformed the Kerr black hole by some parameters, while keeping its suitable features intact.

In this talk, Renan B. Magalhães presented the analysis of the absorption cross section of a massless scalar field for the static Konoplya-Zhidenko black hole. The metric of this black hole is similar to the Schwarzschild black hole with a deformed mass:

$$ds^2 = -f dt^2 + \frac{dr^2}{f} + r^2 d\Omega^2, \qquad f = 1 - \frac{2M}{r}, \qquad M \to M + \frac{1}{2}\sum_i \frac{\eta_i}{r^i}, \tag{20}$$

with the special choice of $\eta_i = \delta_{i2}$. So, the f is chosen to be $f = 1 - \frac{2M}{r} + \frac{\eta}{r^3}$ for some parameter η. In order to have a horizon, $\eta_{\min} < \eta < 0$ in which $\eta_{\min} = \frac{-32}{27M^3}$. On this specific background, Renan B. Magalhães and his collaborators have studied the wave equation for a scalar field $\Box\psi = 0$. He presented the result of the radial potential for different spherical harmonic modes, illustrating them from numerical calculations. Moreover, the absorption cross sections are derived numerically.

2.16. *Shadow of a charged black hole surrounded by an anisotropic matter field*

Presented by: Javier Badía
In collaboration with: Ernesto F. Eiroa
Based on the Ref.[121].

Observation of the shadow of a supermassive black hole at the center of galaxy M87 has been one of the main progresses in black hole physics in recent years.[122] In parallel with this observation, theoretical studies of black hole shadows have been one of the active lines of research (see Ref.[123] for a review). Especially, the presence of matter fields surrounding black holes, and its effect on their shadows has been investigated (see e.g.[124–127]).

In this talk, Javier Badía presents the results of the calculation of shadows for rotating charged black holes surrounded by an anisotropic matter field.[128,129] In the spherical coordinates (t, r, θ, φ) the anisotropic matter is considered to be a perfect fluid which is described by the energy-momentum tensor

$$T_\mu^{\ \nu} = \mathrm{diag}(-\rho, p_1, p_2, p_2), \qquad p_1 = -\rho, \quad p_2 = \mathrm{w}\rho. \tag{21}$$

The rotating charged black hole surrounded by this matter is derived by the Newman-Janis algorithm to the following spherically symmetric spacetime:

$$ds^2 = -f(r)dt^2 + \frac{dr^2}{f(r)} + r^2 d\Omega^2, \qquad f(r) = 1 - \frac{2m(r)}{r}, \qquad m(r) = M - \frac{Q^2}{2r} + \frac{K}{2r^{2\mathrm{w}-1}}. \tag{22}$$

The M, Q, and K are integration constants, and w is restricted to be $\frac{1}{2} < \mathrm{w} < 1$ by physical energy conditions. The resulting metric by the Newman-Janis algorithm is the Kerr metric in which $M \to m(r)$, i.e.

$$\begin{aligned} ds^2 =& -(1-f)dt^2 + \frac{\rho^2}{\Delta}dr^2 + \rho^2 d\theta^2 - 2fa\sin^2\theta\, dt d\varphi \\ &+ \left(r^2 + a^2 + fa^2\sin^2\theta\right)\sin^2\theta\, d\varphi^2, \\ \rho^2 =& r^2 + a^2\cos^2\theta\,, \qquad \Delta = r^2 - 2m(r)r + a^2\,, \qquad f = \frac{2m(r)r}{\rho^2}, \end{aligned} \tag{23}$$

and $m(r) = M - \frac{Q^2}{2r} + \frac{K}{2r^{2\mathrm{w}-1}}$.

On this background, the Hamilton-Jacobi equation for the null geodesics is separable, and reduces to ordinary differential equations with radial derivatives. The result of the shadow calculations for an asymptotic observer on the equator is presented by illustrations. Moreover, three observables which characterize the shadows, named as the area, oblateness, and centroid of the shadows are discussed.[121,130]

Acknowledgments

We would like to thank the organizers of MG16 for making this interesting meeting with numerous inspiring talks and discussions possible in spite of the pandemic, and we would like to thank the speakers of our session for their notable contributions and for sharing with us their latest results. K.H. thanks also the administration of Hanse-Wissenschaftskolleg (Institute for Advanced Study) for the extension of his fellowship. J.K. gratefully acknowledges support by the DFG Research Training Group 1620 *Models of Gravity* and the COST Actions CA15117 *CANTATA* and CA16104 *GWverse*.

The detection of the merger of a neutron star binary in both gravitational waves and a broad spectrum of electromagnetic waves (GW170817) provided the most compelling evidence to date that such mergers produce heavy r-process elements. The inferred rate of these mergers coupled to the estimated r-process production suggests that these mergers could produce nearly all of the r-process elements in the universe. However, uncertainties in the merger rate and the amount of r-process production per merger means that scientists can not constrain the fraction of the merger r-process contribution to better than 1–100% of the total amount in the universe. The total r-process mass synthesized is best constrained by the observations themselves and uncertainties in the inferred production quantity follows from the uncertainties in modeling the emission from the NSM ejecta. In this paper, we review these modeling uncertainties.

Keywords: Neutron Stars; Gravitational Waves, r-Process

1. Kilonovae, a Key to Understanding r-Process

Many of the heaviest elements in the universe are produced through a process of rapid neutron capture (r-process), building isotopes far from stability that then decay to the long-lived heavy isotopes observed in the universe. This rapid neutron capture requires extreme conditions with high densities and large fractions of free neutrons. Scientists identified neutron star mergers (NSMs) as a potential source of these r-process elements over 40 years ago[1,2] and evidence has been growing steadily to argue that these mergers could dominate the r-process production.

Although the evolution of the ejecta from these mergers reaches ideal conditions (high densities, temperatures and neutron fractions) for the production of r-process elements, observational validation of r-process production in NSMs has been much more difficult to obtain. Until recently, theoretical and observational evidence relied on galactic chemical evolution arguments and their associated uncertainties.[3,4]

This situation changed with the joint electromagnetic- and gravitational-wave observations of NSM GW170817.[5] Between the gamma-, x-, optical, infra-red, and radio emission, it became clear that the NSM in GW170817 produced both a relativistic jet and a lower-velocity mass ejecta that argued for both neutron-rich dynamical ejecta and higher electron-fraction wind ejecta components.

Although initial analyses argued strongly that GW170817 produced a large fraction of r-process ($0.04M_\odot$), as more studies were completed, uncertainties in the inferred r-process production from GW170817 grew.[6] Many of these differences arose from different assumptions about the properties of the outflow material and a difference in which observations were used to constrain the data. But these are just some of the uncertainties in the analysis of the optical and infra-red emission from NSMs. In this paper, we review these uncertainties. In section 2, we review the uncertainties in the properties (distributions of the velocity, density, entropy and neutron fraction) of the outflow from these mergers. Section 3 reviews some of the microphysics uncertainties in these calculations. Section 4 details alternative power sources that can alter the mass inferred from observations.

2. Uncertainties in the Outflows

The emission from astrophysical transients depends upon the ejecta properties (e.g. composition, velocity and angular distributions). Unlike many transients that are produced by a single outburst, the ejecta from NSMs arises from multiple components including ejecta from the initial tidal tails produced in the dynamical merger and a outflow arising from a disk. The disk outflow is driven by viscous forces and neutrino emission from a post-disruption torus of material (Figure 1). We will refer to the former as *dynamical* ejecta and the latter as *wind* ejecta. The bulk of the dynamical material is ejected along the orbital plane. This material has a high-neutron fraction, ideally suited for the production of the most massive elements (heavy r-process). In contrast, the wind ejecta is more isotropic and consists of material spanning a broad range of neutron fractions that depend on both the properties of the disk and the fate of the merged core.

Many of the initial studies of GW170817 used spherically-symmetric models, varying the fraction of heavy r-process to lighter elements.[6] Some of these initial models used two components to differentiate between the dynamical ejecta primarily flowing along the orbital plane and a more symmetric or axis-aligned wind outflow[7] shown in Figure 1. However, even these two-component models made simplifying assumptions using a single composition for each component and a fixed velocity distribution of the ejecta. These assumptions oversimplify the nature of the ejecta and can have order-of-magnitude effects on the inferred mass of r-process ejecta. Before we study how these two components fit together, we first review some of the outflow uncertainties in the individual dynamical and wind components.

Although models of the dynamical ejecta have produced a range of ejecta masses, e.g. compare the results in,[8,9] these numerical differences are slowly diminishing as

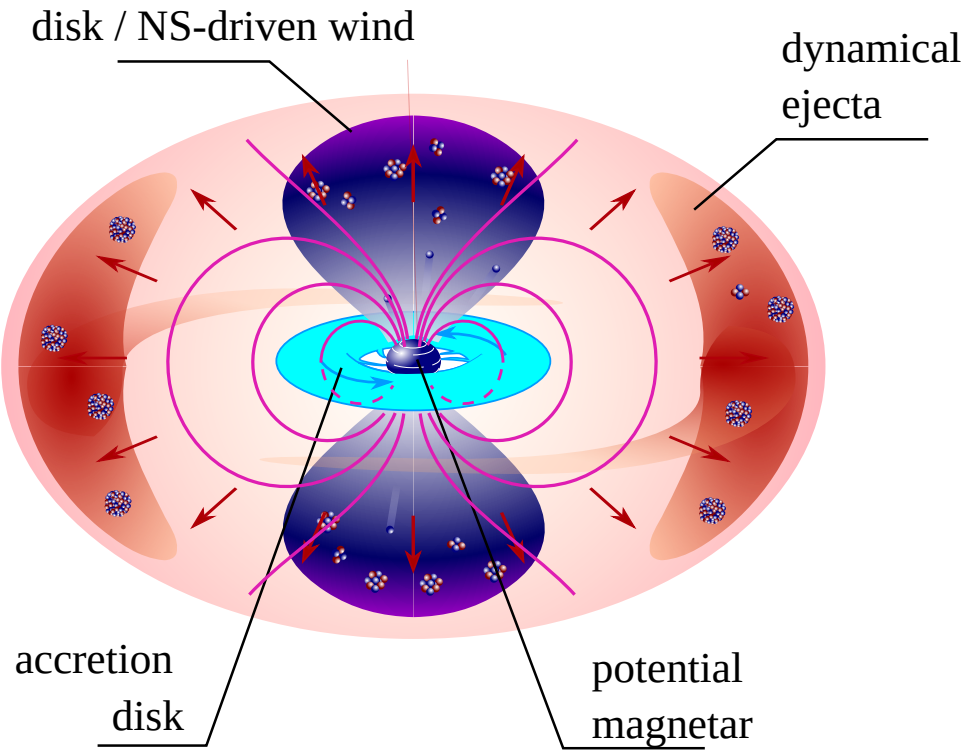

Fig. 1. Anatomy of the NSM outflows. The material ejected in the merger phase flows predominantly along the orbital plane and is very neutron rich. The merged object produces a neutron star or black hole core surrounded by a torus of high angular-momentum material. Outflows driven by viscous forces in this disk, coupled with neutrino emission, produce the "wind" ejecta with its lower neutron fraction. These outflows produce the observed kilonova light-curve emission from the ultra-violet to the infra-red powered by radioactive decay. When material falls back on this merged core and/or if a magnetar forms, an additional power source can contribute additional energy to the observed transient.

computational methods improve. Even with this convergence, the ejecta mass will vary with the individual masses of the merging compact objects.[8] The composition of this ejecta is much better constrained than the ejecta mass. At high neutron fractions (above 0.8), the final composition does not depend sensitively on the neutron fraction. Because of this, the small variation in the neutron fraction does not alter the Lanthanide composition considerably and the composition of this ejecta is fairly stable. In addition, the final composition is also less sensitive to the details of the outflow (density and temperature evolution). For this reason, the composition of this ejecta is well-understood with the dominant uncertainties depending on our lack of understanding of the nuclear physics (Sec. 3). Finally, due to the dense forest of absorption lines in the opacity produced by the heavy r-process lanthanides and actinides, the light curves do not depend sensitively on the exact relative abundance

of these elements.[10] The primary uncertainties in models of the dynamical ejecta emission lie in our understanding of the total ejecta mass and outflow properties (velocity distribution).

The properties of the wind ejecta are much more uncertain. The mass, velocity distribution and composition of this ejecta varies considerably from model to model. Whereas the neutron fraction is high and exhibits only small variations for dynamical ejecta, the neutron fraction ranges across a broad range in the wind ejecta. Further, at the lower neutron fractions (between 0.5-0.8), the yields become much more sensitive to the exact value of the neutron fraction, so the composition of the wind ejecta can vary wildly. To further complicate these light-curve models, disk models of this wind predict a range of compositions that vary with angle and time.[11] This composition variation is not taken into account in most of the two-component models currently in the literature. In addition, current wind models typically only follow the wind out to, at most, 1 second and much of the ejecta is below the escape velocity (but still accelerating) at this time. Although models are being constructed to follow this outflow to later times, we still do not have accurate models of this ejecta's velocity distribution.

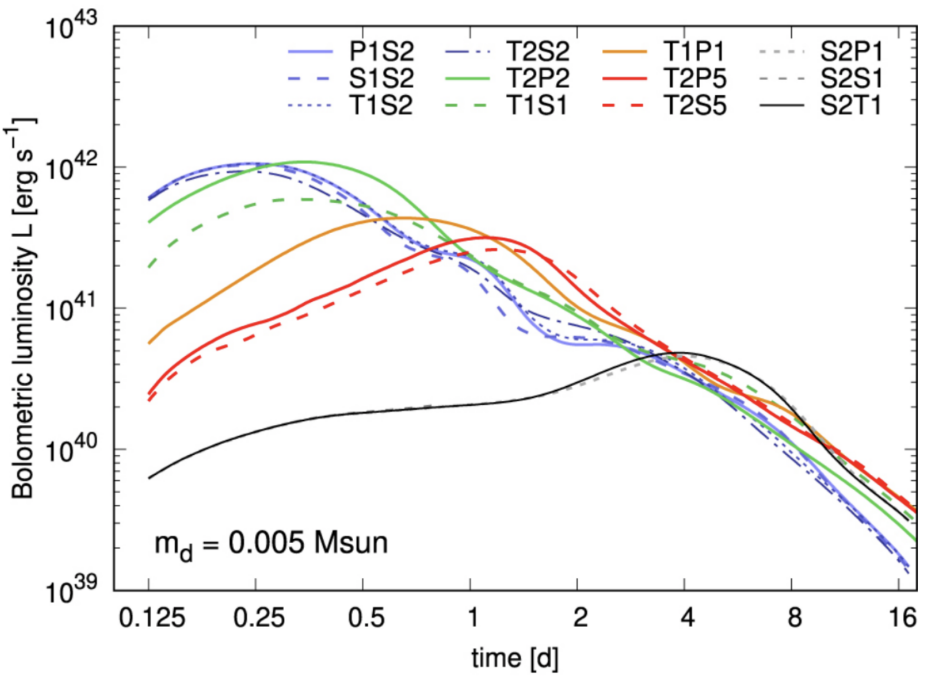

Fig. 2. Bolometric Light curves versus time for a broad range of models varying the morphology of the two components in a dynamical plus wind model.[12] Varying the morphology alone can change the bolometric luminosity by over an order of magnitude.

Although we have mostly discussed the role of the composition, the morphology of the ejecta (velocity and angular distribution) may be even more important. Figure 2 shows a broad set of models with the same explosion energy and mass, but varying the angular morphology of the ejecta.[12] In this study, two-component models were developed, each with a different morphology. In these models, although the energy of the ejecta is the same, the velocity distribution of the ejecta can vary. Changing the morphology alters both the peak luminosity and the time of that peak, varying both by an order of magnitude.

At this time, a complete study of all the outflow uncertainties has not been done. We end this section with the discussion of a final study varying ejecta mass and velocity of a two-component model.[13] This grid of models used a single dynamical ejecta composition and one of two wind compositions. It focused on a primary pair of morphologies for these two components, using a default r-process composition for the dynamical ejecta and two different compositions for the wind. But the compositions were fixed for each component. Although the peak velocity was changed, the velocity distribution was unaltered. Depending on the relative velocities of the two components, the dynamical ejecta, with its high-opacity lanthanides, can obscure the wind ejecta. In these cases, the luminosity can depend sensitively on the viewing angle. In other cases, the wind ejecta is sufficiently fast that the light-curve is similar, regardless of viewing angle. Although more massive ejecta models are, on average, brighter, lower mass models can be brighter than higher mass models based on this viewing angle.

3. Uncertainties in the Microphysics and its Implementation

The outflow models depend on detailed general-relativistic, magneto-hydrodynamic models including neutrino transport (and the related neutrino microphysics). We do not have enough space to discuss all of this microphysics in detail. Instead we focus on the uncertainties in the nuclear physics and atomic physics with a brief discussion on each.

Unstable neutron-rich nuclei participating in the r-process have many unmeasured properties that consequently influence kilonova signals.[14,15] Uncertainties in nuclear binding energies and reaction rates impact the flow of material to heavier mass regions as well as the subsequent flow back towards lighter mass regions in ejecta with low electron fraction.[16] Properties that depend on excited nuclear states, including half-lives and branching ratios, additionally control the timescale over which energy is released as well as potentially stored.[17,18] The creation of the heaviest elements in merger events[19] may produce distinct observable signals, e.g. via the production of long-lived species like ^{254}Cf or via unique electromagnetic signatures.[20,21,21,22] Central to the reduction of large nuclear uncertainties that impact kilonovae are experimental studies undertaken at radioactive beam facilities around the world, see e.g.[23,24]

A major uncertainty in the application of atomic physics to the modeling of kilonovae concerns the bound-bound (line absorption) contribution to the radiative opacity. While photons traveling through a plasma can be absorbed in a number of atomic processes, line absorption is the dominant mechanism in the dynamical ejecta due to the dense forest of lines associated with near-neutral lanthanide and actinide elements. Complete sets of lanthanide opacities have been recently produced for the purpose of kilonova modeling[25–27] using different atomic physics methods, which is another potential source of uncertainty. In an effort to mitigate this issue, we have made available to the public our lanthanide opacites[28] so that kilonova modelers can use a consistent set of opacities, thereby ruling out emission differences that could arise from atomic physics implementations. As a specific illustration of these concepts, we present in Figure 3 the opacity of Nd, calculated under the assumption of local thermodynamic equilibrium (LTE), at a temperature of $T = 0.5$ eV and mass density $\rho = 10^{-13}$ g/cm^3, using four different models (see[26] for details). Note that the line features enhance the opacity by six to eight orders of magnitude compared to what would occur if only free-electron processes were included. The Planck mean opacity, $\kappa^{\rm P}$, is also displayed for each model, indicating a maximum discrepancy of about 40% between the various models for this integrated quantity. Detailed light-curve and spectral comparisons were carried out with these four models.[26] Only

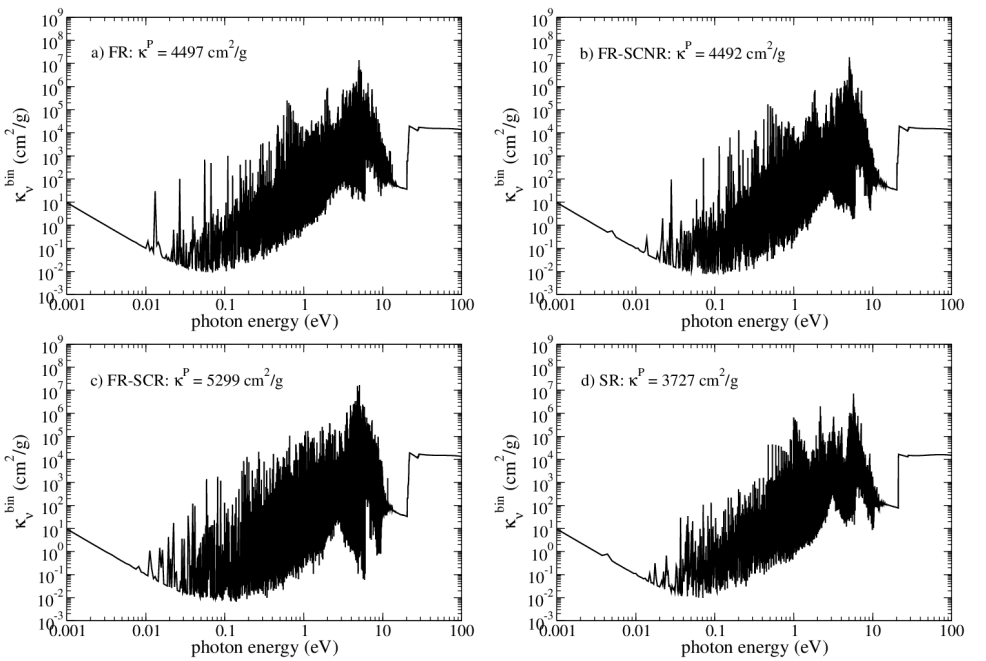

Fig. 3. The LTE line-binned opacity for neodymium at $T = 0.5$ eV and $\rho = 10^{-13}$ g/cm^3 using four different models described in:[26] a) FR, b) FR-SCNR, c) FR-SCR, and d) SR. The Planck mean opacity, obtained via integration of the line-binned opacity, is also listed in each panel.

modest differences were noted in the light-curves, i.e. differences of 10–20% in the peak of the light curve and a maximum shift of half a day in the time of peak luminosity. Similar, modest differences were observed in the spectra produced with these models, i.e. certain spectral features are shifted redward are blueward, but the overall spectral characteristics are similar.

From a more general perspective, we note that opacities are typically calculated from first principles, rather than measured. The line contribution depends on quantities such as transition energies, line strengths (quantum mechanical matrix elements) and atomic level populations. While it is beyond the scope of this article to provide a detailed discussion of these concepts, we mention that recent work[29,30] has been performed to compare calculated energies with benchmark values in the NIST Atomic Spectra Database[31] for a number of important, low-lying levels of the lanthanides. Also, most simulations employ the LTE approximation when calculating the level populations. This assumption is expected to be valid up to about one week post merger. But, as with many astrophysical transients, the LTE conditions become less and less valid as the expansion continues and the density becomes so low that the thermalization timescale from collisions becomes long compared to evolutionary timescales of the ejecta. A recent study[32] explores the possibility that non-thermal, β-decay electrons, produced from the radioactive decay of r-process nuclei, are primarily responsible for the heating and collisional ionization in the ejecta.

With the large number of atomic levels, the number of line features is enormous (in the 10s of millions). Implementing these opacities into a numerical calculation is intractable even from a computational memory standpoint. In addition, because of the high velocities in the ejecta, modeling radiation transport becomes even more difficult. For a single strong line, the Sobolev approximation can be used to determine the likelihood of a photon to both be absorbed as it expands out of a medium and its likelihood of escaping this line when re-emitted. Transient explosions exhibit homologous outflow conditions where the velocity of the ejecta is proportional to the radius. As a photon moves out through this ejecta, its energy spans a broad range with respect to the rest frame of the outflow. Even if the photon does not interact with a line feature at one radius, it may interact with this feature at a different radius.

This treatment includes the fact that the velocity of the ejecta spans a range such that, even if a photon does not interact with an absorption feature in the rest frame of the outflowing material at one position, it may, as it transports outward, interact with other material. Hence, a single line feature can affect a larger energy band of photons. On the other hand, if most of the re-emitted photons arise from a direct de-excitation of the absorption feature, the photons remain trapped in a line feature in material moving at a constant velocity. For the homologous outflow of astrophysical transients, the photon can escape more quickly, effectively reducing the opacity. Implementing the Sobolev approximation is already difficult, but in

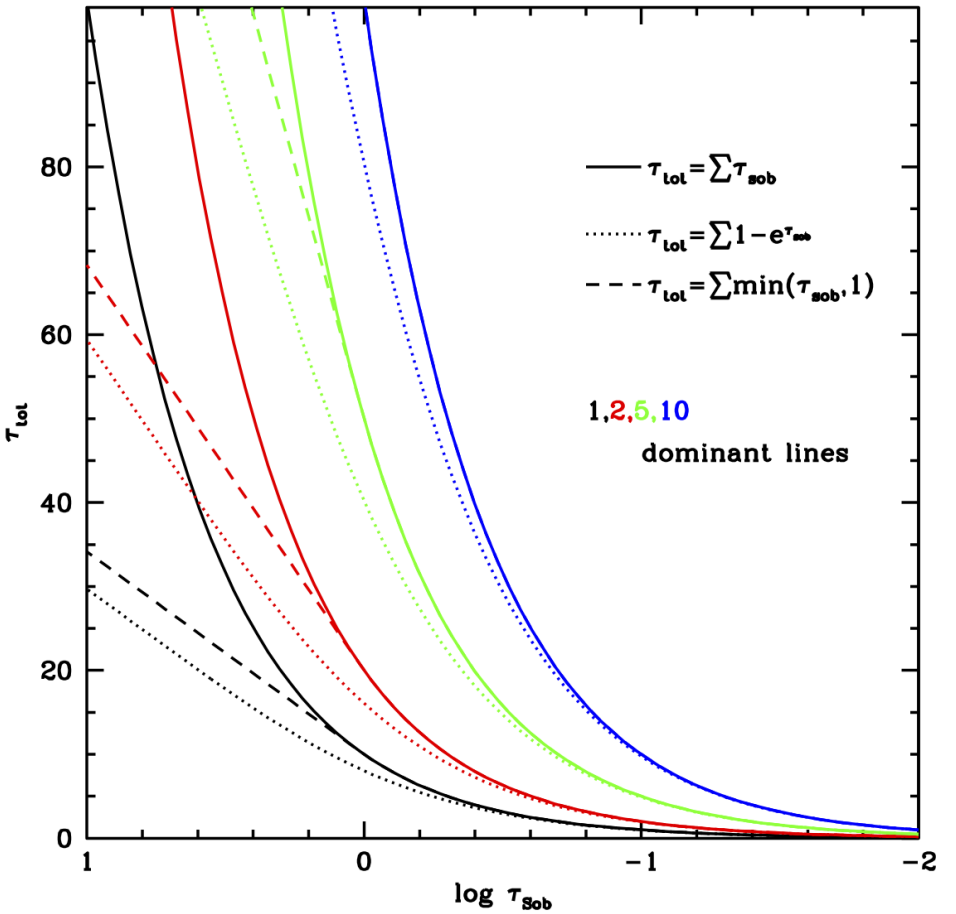

Fig. 4. A number of prescriptions have been proposed to model the expansion opacities. This figure shows the total optical depth using three different prescriptions for different numbers of dominant line features as a function of the optical depth of the line feature. There is some convergence with large number of lines, showing why a simple averaged opacity can work nearly as well as a more complicated expansion procedure.

a medium where a forest of lines exists, producing an accurate model for spectra becomes increasingly difficult. The deficiencies of the Pinto & Eastman expansion opacity[33] were outlined in its inception and a number of alternative approaches have been developed (for a review, see[34]). A number of methods have been developed to calculate the optical depth and these different models produce a range of results based on these prescriptions (Figure 4). For a simplified model with pure neodymium, Figure 5 compares the bolometric luminosity for different approaches: Sobolev, expansion opacity and a simple binned treatment. Compared to many of our other uncertainties, the opacity implementation errors seem low.

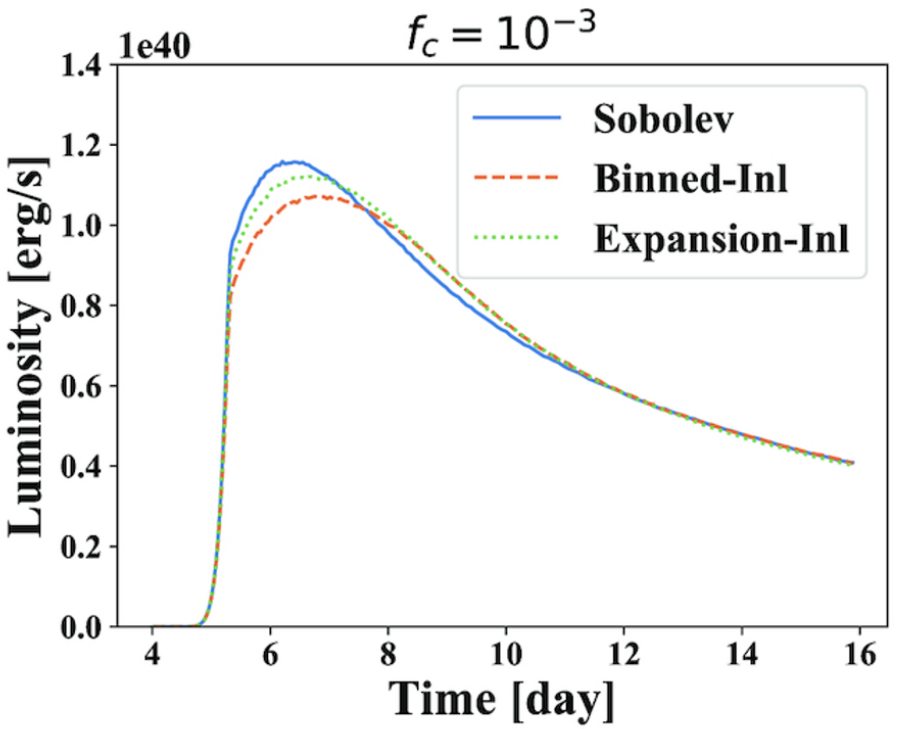

Fig. 5. Bolometric light curves using three different implementations of the opacity. The quantity $f_c = 10^{-3}$ indicates the cut off value for retaining oscillator strengths in the atomic physics model.

4. Alternative Energy Sources

Most calculations assume that the power source behind the kilonova emission arises solely from radioactive decay. But, just as with core-collapse supernovae, the light-curves and spectra can be powered by a variety of sources. For kilonovae, a number of additional power sources have been proposed to drive the observed emission: magnetar emission, shock heating in the ejecta, and fallback accretion. In this section, we will discuss each of these energy sources in turn, reviewing both their basic physics and expected features.

The black hole accretion disk engine paradigm argued that long-duration bursts are produced in stellar collapse, while short-duration GRBs are produced by the merger of compact remnants. Under this paradigm, scientists predicted that short-duration GRBs should be offset from their formation region due to the momentum imparted on compact binaries at birth.[35,36] Although other power sources do not differentiate between short- and long-duration bursts in this manner, magnetar engines for short-duration bursts have remained a competitive model for these bursts. The basic idea behind this engine is that the merged core of a NSM is expected to

be rapidly rotating. If strong, dipole magnetic fields are generated in this merged core, then the rotational energy in the core can power the GRB. Whether or not the magnetar drives the initial burst of gamma-rays, magnetars do provide a natural explanation for the roughly hall of all short-duration bursts that exhibit a long-lived ("plateau") phase in the X-ray that can last up to 10^5s.[37] The magnetar emission, if reprocessed by the expanding ejecta, can power the optical and even infra-red emission,[38,39] and can dominate the observed emission, altering the inferred r-process yield in the merger.

In supernovae, shock heating is believed to dominate the heating in type II supernovae, shock breakout events, and many superluminous supernovae. Shock heating may also play a role in kilonova emission. Shocks between the jet and the wind ejecta have been invoked to explain additional emission at early times (first day) in the kilonova emission.[40] At later times (beyond a day), material falls back onto the compact remnant, likely forming a disk and further outflows. The potential energy released in this fallback can be tapped to provide an additional power source. Depending upon the timing of the fallback, this accretion emission

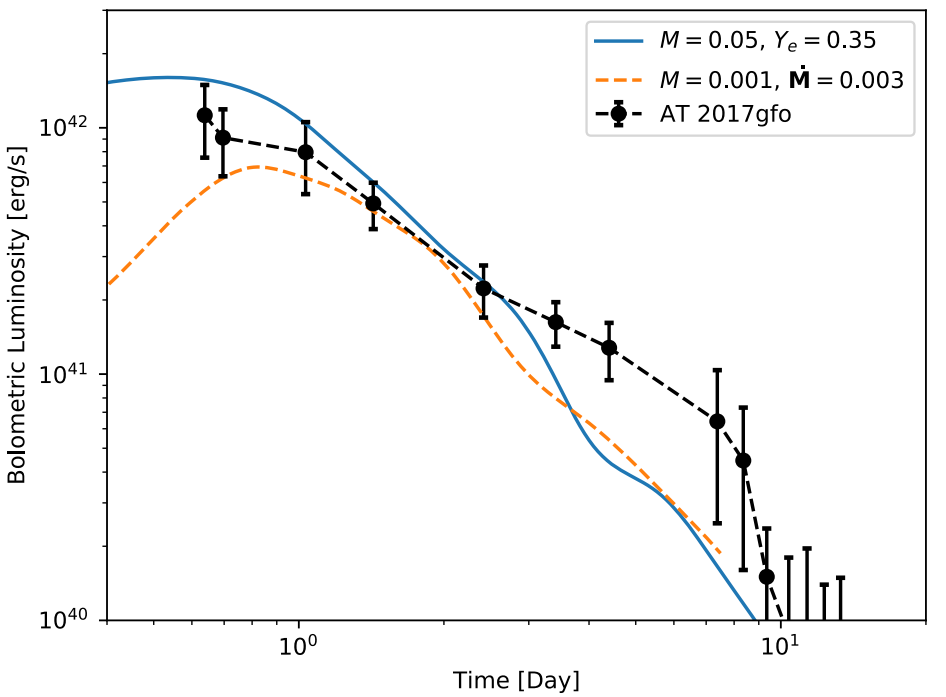

Fig. 6. Bolometric luminosity versus time for a 0.05 $M_\odot$ 1D spherical wind model (blue), a 0.001 $M_\odot$ 1D spherical model with a $\dot{M} = 0.003$ $M_\odot$/s central fallback luminosity source (dashed orange), and the EM counterpart of GW170817, AT 2017gfo (dashed black, with error bars).

can play a major role in the emission after the first day (Figure 6). The accretion luminosity is proportional to the potential energy released:

$$L_{\rm acc} \propto G M_{\rm core} \dot{M}_{\rm fallback} / r_{\rm ISCO} \quad (1)$$

where G is the gravitational constant, $M_{\rm core}$ is the mass of the merged core, $r_{\rm ISCO}$ is its innermost stable circular orbit if the core is a black hole or the neutron star radius if it is a neutron star, and $\dot{M}_{\rm fallback}$ is the fallback accretion rate. Whether the merged core is a black hole or a neutron star, the fallback material is likely to have sufficient angular momentum to initially be centrifugally supported in an accretion disk, providing a mechanism by which a fraction of the potential energy released in the infall can be converted to both energy and mass ejection.

5. Conclusions

In addition to being the primary mechanism behind short-duration gamma-ray bursts, NSMs have the potential to be the dominant source of r-process elements in the universe. To validate this claim, scientists must be able to accurately infer the mass and abundances from observations of the ejecta-driven transient from these mergers (a.k.a. kilonovae). In this paper, we reviewed a broad set of uncertainties affecting the modeling of kilonova light-curves and the current status of our efforts to characterize and, hopefully constrain, them. Much more work must be done to infer accurate r-process masses from these observations.

In this short paper, we focused mostly on broad-band light-curves. Spectra are key to constraining the different models and a number of studies have focused on trying to find line features in the kilonova observations e.g.[41]. Gamma-ray decay lines, particularly in the remnants of the NSM ejecta, also have the potential to probe detailed yields.[21,42] So despite the difficulties that face astronomers in understanding the yields from these mergers, the future is looking bright.

†E-mail: andrea.geralico@gmail.com

We review some recent results obtained at the sixth Post-Newtonian level of approximation for the Hamiltonian description of a two-body system, by using several methods whose combination has led to the so-called "Tutti-Frutti" approach.

Keywords: Two-body system; Post-Newtonian and Post-Minkowskian approximation; Scattering angle

1. Introduction

The two-body gravitational interaction is a fundamental physics problem whose descriptions necessitates a fully general relativistic treatment. The latter, in turn, is much difficult and over the years several approximation methods have been implemented for the mathematical treatment of this problem, ranging from weak-field and slow-motion (Post-Newtonian (PN) approximation[1]), weak-field but eventually relativistic motions (Post-Minkowskian (PM) approximation[2,3]), extreme-mass-ratio limit (i.e., the condition in which the mass of one of the two bodies is much larger of the other, discussed in the framework of perturbation theory and gravitational self-force (GSF)[4]), Effective Field Theory (EFT),[5] numerical relativity (NR).[6]

All these analytical (and semi-analytical) treatments have been used to build up a Hamiltonian description of the system. Since as soon as one raises the level of approximation considered the number of terms entering this Hamiltonian raises as well, in 1999 A. Buonanno and T. Damour[7,8] introduced the so-called Effective One-Body (EOB) approach aiming at a partial resummation of the Hamiltonian itself. Indeed, the EOB is especially useful since it condensates in a few gravitational potentials the essential characteristics of the interaction, and can be also continuously (and easily) updated as soon as new results become available in the literature by using whatever approximation scheme.

Let us recall also that 1) the gravitational interaction of two bodies is actually compatible with two basic scenarios: capture (the more massive of the two attracts and then swallows the other; the system in this case spirals undergoing ellipticlike motions) and scattering (the two bodies can be close enough but they have enough energy to resist the attraction; the system in this case undergoes hyperboliclike or paraboliclike motions). 2) Both cases are of particular importance in view of the

possibility to detect gravitational wave signals from Earth-based interferometers operating now (e.g., Ligo[9] and Virgo[10]) and also (more likely) by future, forthcoming satellite missions involving space-based interferometers (Lisa[11]). 3) The mathematical description of the dynamics by any available approximation method has strong limitations when the gravitational field becomes too strong, as for example in the case of the capture. In this condition one is only left with NR.

To add fuel to fire one should also take into account that new difficulties arise when taking into account the emission of gravitational radiation (energy, angular momentum and linear momentum) by the system as soon as a purely conservative scenario is no more possible. Indeed, starting from the 2.5PN level of approximation the problem is no more conservative, so that one has to deal with radiation-reaction effects. Furthermore, starting from the 4PN order the Hamiltonian of the system also includes a nonlocal part, which accounts for the past history of the system.

This picture clearly explains the difficulties which one encounters when trying to reach the 5PN (and beyond) level of accuracy in the model. Luckily, the various concomitant effects can be still computed separately so one can decide to limit to the study of the conservative and local part of the Hamiltonian, and later including nonlocal effects and radiation-reaction induced effects. This is the spirit of the recently developed "Tutti-Frutti" (TF) method, which combines several theoretical formalisms: PN, PM, multipolar-post-Minkowskian (MPM), EFT, GSF, EOB, and Delaunay averaging.[12–16]

2. EOB Hamiltonian

The EOB approach rewrites the (real, conservative) two-body Hamiltonian $H(r, p_r, p_\phi)$ in terms of an effective Hamiltonian $H_{\rm eff}(r, p_r, p_\phi)$ (ϕ is an ignorable coordinate in the conservative case)

$$H = M\sqrt{1 + 2\nu(\hat{H}_{\rm eff} - 1)}\,, \tag{1}$$

with

$$M = m_1 + m_2\,, \qquad \mu = \frac{m_1 m_2}{m_1 + m_2}\,, \qquad \nu = \frac{m_1 m_2}{(m_1 + m_2)^2} \tag{2}$$

the total mass of the system (M), the reduced mass (μ) and the symmetric mass ratio (ν). The effective Hamiltonian (per unit of reduced mass, μ) $\hat{H}_{\rm eff}$ written in the standard p_r-gauge or DJS gauge[17] involves several potentials: A, $\bar{D}$, $\hat{Q}$, etc.,

$$\hat{H}^2_{\rm eff} = A(u,\nu)[1 + p^2_\phi u^2 + A(u,\nu)\bar{D}(u,\nu)p^2_r + \hat{Q}(u,\nu;p_r)]\,, \tag{3}$$

where $u = GM/r$ and

$$\hat{Q}(u,\nu;p_r) = p^4_r q_4(u,\nu) + p^6_r q_6(u,\nu) + p^8_r q_8(u,\nu) + \dots\,. \tag{4}$$

The various potentials 1) have a polynomial structure in terms of the symmetric mass-ratio ν, e.g.,

$$\begin{aligned} A(u,\nu) &= 1 - 2u + \nu a^{\nu^1}(u) + \nu^2 a^{\nu^2}(u) + \nu^3 a^{\nu^3}(u) + \dots \,, \\ \bar{D}(u,\nu) &= 1 + \nu \bar{d}^{\nu^1}(u) + \nu^2 \bar{d}^{\nu^2}(u) + \nu^3 \bar{d}^{\nu^3}(u) + \dots \,, \\ q_4(u,\nu) &= 1 + \nu q_4^{\nu^1}(u) + \nu^2 q_4^{\nu^2}(u) + \nu^3 q_4^{\nu^3}(u) + \dots \,, \end{aligned} \tag{5}$$

etc., with the degree of the polynom increasing with PN approximation order; 2) have both a local part and a nonlocal part

$$\begin{aligned} A(u,\nu) &= A_{\rm loc}(u,\nu) + A_{\rm nl}(u,\nu) \,, \\ \bar{D}(u,\nu) &= \bar{D}_{\rm loc}(u,\nu) + \bar{D}_{\rm nl}(u,\nu) \,, \\ \hat{Q}(u,\nu;p_r) &= \hat{Q}_{\rm loc}(u,\nu;p_r) + \hat{Q}_{\rm nl}(u,\nu;p_r) \,, \end{aligned} \tag{6}$$

the nonlocal part starting at 4PN.

3. The Tutti-Frutti approach and the determination of the conservative dynamics at 6PN

The starting point of the TF approach is to consider the total two-body conservative action, which at the 6PN accuracy has both a local-in-time part and a nonlocal-in-time part (starting at 4PN)

$$S_{\rm tot}^{\leq 6{\rm PN}} = S_{\rm loc}^{\leq 6{\rm PN}} + S_{\rm nonloc}^{\leq 6{\rm PN}} \,. \tag{7}$$

The main steps are summarized below.

(1) Fix completely the nonlocal part of the Hamiltonian by using Delaunay averaging along ellipticlike orbits.
The nonlocal action is given by

$$S_{\rm nonloc}^{4+5+6{\rm PN}} = -\int dt\, H_{\rm nonloc}^{4+5+6{\rm PN}}(t) \,, \tag{8}$$

with

$$H_{\rm nonloc}^{4+5+6{\rm PN}}(t) = \frac{G\mathcal{M}}{c^3} {\rm Pf}_{2r_{12}/c} \int \frac{dt'}{|t-t'|} \mathcal{F}_{\rm 2PN}^{\rm split}(t,t') \,. \tag{9}$$

Here, $\mathcal{M}$ denotes the total ADM conserved mass-energy of the binary system, r_{12} entering the timescale of the the *partie finie* (Pf) operation is the harmonic-coordinate radial distance, and $\mathcal{F}_{\rm 2PN}^{\rm split}(t,t')$ is the time-split version of the fractionally 2PN-accurate gravitational-wave energy flux, i.e.,

$$\mathcal{F}_{\rm 2PN}^{\rm GW}(t) \propto I_{ab}^{(3)}(t) I_{ab}^{(3)}(t) + O(\eta^2) \quad \to \quad \mathcal{F}_{\rm 2PN}^{\rm split}(t,t') \propto I_{ab}^{(3)}(t) I_{ab}^{(3)}(t') + O(\eta^2) \,, \tag{10}$$

with $\eta \equiv \frac{1}{c}$, the superscript in parenthesis denoting repeated time-derivatives of the quadrupole moment I_{ab}. Taking then the (Delaunay) time average of the

harmonic-coordinates Hamiltonian (9) gives a gauge-invariant function of two orbital parameters

$$\langle \delta H^{4+5+6\mathrm{PN}}_{\mathrm{nonloc,h}} \rangle = \frac{1}{\oint dt_h} \oint \delta H^{4+5+6\mathrm{PN}}_{\mathrm{nonloc,h}}(t_h) dt_h \,. \tag{11}$$

Next, do the same computation in EOB coordinates. Comparison between the two results allows fixing the nonlocal parts of the EOB potentials.

(2) Use SF information about small-eccentricity ellipticlike motion to determine (part of) the local EOB Hamiltonian.
Compute the averaged redshift factor, z_1, i.e., a (first) gauge-invariant variable associated with the conservative dynamics of the two-body system, along ellipticlike orbits by using first-order SF techniques in a small-eccentricity expansion limit, including but high powers of the eccentricity (up to the eighth order). $z_1 \sim \langle \partial_{m_1} H \rangle$ incorporates both local and nonlocal contributions in the Hamiltonian, but it is limited from the fact that analytic computations are possible only at first-order in the symmetric mass-ratio ν. Combining this result with the information about the nonlocal part of the EOB Hamiltonian specified at the point 1 will allow one to determine all the linear-in-ν local EOB potentials. The remaining (i.e., higher order in ν) coefficients are still undetermined.

(3) Compute another gauge-invariant quantity, the scattering angle, χ, along hyperboliclike orbits to determine most of the remaining coefficients.
The total scattering angle $\chi^{\mathrm{tot}} = \chi^{\mathrm{loc}} + \chi^{\mathrm{nonloc}}$ can be expressed as a large-angular momentum (or equivalently large-eccentricity) expansion, with coefficients having a precise mass-structure (or ν-structure) as recently shown by Damour.[18] Therefore, one needs to separately compute both the local and the nonlocal contributions to the scattering angle. The latter is defined by

$$\chi^{\mathrm{nonloc}}(E, J, \nu) = \frac{\partial W^{\mathrm{nonloc}}(E, J, \nu)}{\partial J} \,, \tag{12}$$

where E and J are the total energy and angular momentum in the c.m. frame, respectively, and

$$W^{\mathrm{nonloc}}(E, J; \nu) \equiv \int_{-\infty}^{+\infty} dt \, H^{\mathrm{nonloc}}(t) \,, \tag{13}$$

is the integrated nonlocal action. In order to compute the local contribution χ^{loc}, instead, it is convenient to convert the local EOB Hamiltonian into the so-called energy-gauge.[19] Imposing then that χ^{tot} satisfies the prescribed ν-structure will fix most of the parametrizing coefficients of the EOB potentials.

All the above steps used jointly have lead to the determination of most of the coefficients entering the conservative Hamiltonian of the two-body system. More precisely at 5PN there remain only 2 quantities to be determined ($\bar{d}_5^{\nu^2}$ and $a_6^{\nu^2}$) and at 6PN there remain only 4 more quantities to be determined ($q_{45}^{\nu^2}$, $\bar{d}_6^{\nu^2}$, $a_7^{\nu^2}$, and $a_7^{\nu^3}$).

Within the EFT approach, the conservative scattering angle can be decomposed into a potential-graviton contribution, and a radiation-graviton one.[5] The $O(G^4)$ potential-graviton contribution to the radial action has been recently derived in Ref.,[20] whereas Ref.[21] has computed the potential-graviton contribution to the 5PN two-body Hamiltonian. Although the TF decomposition of the two-body dynamics into local-in-time and non-local-in-time parts is closely linked to the EFT decomposition, one cannot simply identify the TF time-symmetric local-in-time dynamics to the EFT time-symmetric potential-graviton dynamics. However, one can compare the total conservative scattering angle derived within the two approaches. This allows one to complete the result of Ref.[20] by providing the explicit expression (at the 6PN accuracy) of the complementary radiation-graviton contributions to the scattering angle, or equivalently, to the radial action. Furthermore, adding the radiation-graviton contributions to the 5PN Hamiltonian obtained in Ref.[22] yields explicit expressions for the two 5PN undetermined $O(G^5)$ and $O(G^6)$ TF parameters $\bar{d}_5^{\nu^2}$ and $a_6^{\nu^2}$, involving either π^2 terms and rational coefficients entering various (local-in-time) radiation-graviton contributions to the conservative effective 5PN action.[22] Our results are in agreement (for the π^2 contributions) with those of Ref.[21] A comparison with the results of Ref.[22] is currently under consideration.

4. Radiation-reaction effects

The presence of a radiation-reaction force implies a modification of Hamilton equations as

$$\dot{\mathbf{q}} = \frac{\partial H}{\partial \mathbf{p}}\,, \qquad \dot{\mathbf{p}} = -\frac{\partial H}{\partial \mathbf{q}} + \boldsymbol{\mathcal{F}}_{\rm rr}\,. \tag{14}$$

The work done by this force on the system implies energy, angular momentum and linear momentum losses by the system itself, as well as to the fact that the four-velocity of the center-of-mass is no more conserved, leading to recoil effects. For instance, the scattering angle will be modified as

$$\chi = \chi^{\rm cons} + \delta^{\rm rr}\chi\,, \tag{15}$$

where the radiation-reaction corrections to the conservative value can be written as

$$\delta^{\rm rr}\chi = -\frac{1}{2}\left[\frac{\partial \chi^{\rm cons}}{\partial E}E^{\rm rad} + \frac{\partial \chi^{\rm cons}}{\partial J}J^{\rm rad}\right]\,, \tag{16}$$

in terms of the energy and angular momentum losses $E^{\rm rad}$ and $J^{\rm rad}$. The latter include instantaneous and tail (i.e. hereditary) contributions, and admit a double PM and PN expansion. At the fractional 2PN order they read

$$\begin{aligned} E^{\rm rad}_{\rm 2PN} &= \nu^2\left(E_{\rm N} + \eta^2 E_{\rm 1PN} + \eta^3 E^{\rm tail}_{\rm 1.5PN} + \eta^4 E_{\rm 2PN}\right)\,,\\ J^{\rm rad}_{\rm 2PN} &= \nu^2\left(J_{\rm N} + \eta^2 J_{\rm 1PN} + \eta^3 J^{\rm tail}_{\rm 1.5PN} + \eta^4 J_{\rm 2PN}\right)\,, \end{aligned} \tag{17}$$

where tails start at the 1.5PN order. For example, the Newtonian values are given by

$$E_{\rm N} = \frac{37}{15}\pi\frac{p_\infty^4}{j^3} + \frac{1568}{45}\frac{p_\infty^3}{j^4} + \frac{122}{5}\pi\frac{p_\infty^2}{j^5} + O\left(\frac{1}{j^6}\right),$$
$$J_{\rm N} = \frac{16}{5}\frac{p_\infty^3}{j} + \frac{28}{5}\pi\frac{p_\infty^2}{j^2} + \frac{176}{5}\frac{p_\infty}{j^3} + O\left(\frac{1}{j^4}\right), \tag{18}$$

where $j \equiv cJ/(GM\mu)$ is a dimensionless angular momentum parameter, and the linear momentum at infinity, p_∞, is related to the binding energy by $\bar{E} \equiv (E - Mc^2)/(\mu c^2) = \frac{1}{2}p_\infty^2$, at the Newtonian level. At higher PN orders the coefficients of the above expansion become functions of ν: linear functions of ν at 1PN, quadratic at 2PN, etc., but the structure of the PM expansion is exactly the same.

We have computed in Ref.[23] the changes of 4-momentum during the scattering process (between the two asymptotic states of the two bodies labelled by $a = 1, 2$) which are linear order in radiation-reaction, i.e.,

$$\Delta p_{a\mu} \equiv p_{a\mu}^+ - p_{a\mu}^- = \Delta p_{a\mu}^{\rm cons} + \Delta p_{a\mu}^{\rm rr}, \tag{19}$$

where the radiation-reacted contribution $\Delta p_{a\mu}^{\rm rr}$ is the sum of a relative-motion term and a recoil one, which are linear in the radiative losses of energy, linear-momentum, and angular momentum. We have also shown how the polynomial dependence of $\Delta p_{a\mu}^{\rm rr}$ can be exploited to yield some identity relating the various radiative losses. Adding radiation-reaction effects at higher PN orders is an open issue for challenging future works.

Multi-channel astronomy is one of the most important and rapidly developing field of modern physics. The well known result of multi-channel observations is simultaneous detection of gravitational wave and gamma ray bursts associated with neutron star merger event. This observation open a new window to study the Universe, and actually triggered the broad scale study of astrophysical phenomena in hard X-Rays and gamma rays by orbital experiments together with ground based observations of gravitational waves, neutrino and ultra-high energy cosmic rays. From this perspective it appears that small satellites of CubeSat type are quite appropriate for multi-channel observations of astrophysical transients because it is the cheapest way to realize all-sky monitoring observations by orbital instruments. Presently at D.V. Skobeltsyn Institute of Nuclear Physics of the M.V. Lomonosov Moscow State University (SINP MSU) a new project named Universat–SOCRAT is under development which is intended for operational monitoring of near-Earth's radiation environment and monitoring of electromagnetic transients in the optical, UV, X-ray and gamma ranges. Here we discuss the first results of charged particles, gamma quanta fluxes and UV-emission measurements from the upper atmosphere in several CubeSat missions, which were successfully launched in 2019, 2020.

Keywords: Multimessenger astronomy; Universat-SOCRAT project.

1. Introduction

One of the most important and interesting fields of modern physics and astrophysics is the study of extreme processes and phenomena leading to the most powerful explosions, acceleration of particles to the maximum possible energies, generation of superstrong gravitational and electromagnetic fields. Such phenomena include cosmic gamma-ray bursts (GRBs) associated with the collapse of massive stars (hypernovae), merging of relativistic compact objects (neutron stars and black holes), leading to the generation of gravitational waves and short-term increases in gamma-ray fluxes, nonstationary processes in neutron stars with a superstrong magnetic field (magnetars), dynamic processes in the nuclei of active galaxies, pulsars and close binary systems, which can be associated with the acceleration of particles to high and extremely high energies and the generation of high and ultrahigh energy neutrinos.

Despite the fact that these extreme phenomena have been studied very intensively in recent years, there are still many unsolved problems. As for GRBs, this is, first of all, the definition of the mechanism of functioning of the "central engine", the formation of relativistic jets and the propagation of relativistic shock waves in them, the so-called shells. The related problems concern with the study of the possibility of particle acceleration on relativistic shock waves, and of the conditions for generation of polarized electromagnetic radiation. In this regard, especially important information can be obtained as a result of multi-wavelength observations of the so-called intrinsic emission of a GRB, especially in the optical and gamma ranges. Among the observational tasks, it should be noted that it is necessary to observe GRBs with the maximum possible temporal and spectral resolution, as well as at a high level of sensitivity, which will make it possible to expand the range of observed burst sources up to the most distant objects in the Universe ($z \sim 10-12$). The study of the fine temporal structure of GRB intrinsic emission, as well as of the so-called precursors, including their observations in the optical range, is very actual.

An important task is studying of the so-called short hard GRBs, includes the need to discover their intrinsic optical emission. It is known, that such bursts are associated with the processes of neutron stars merging in close binaries; therefore, their study is particularly relevant after recent discovery of gravitational-waves bursts generated during the merger of relativistic compact objects.

Considering the relevance of studying extreme astrophysical phenomena, it should be emphasized that for further progress in understanding their nature, multi-wave (at least simultaneous in the optical, X-ray and gamma ranges), multi-channel and multi-satellite observations are required. Multi-channel observations mean the simultaneous detection of events by space-based and ground-based facilities, including ground-based optical, radio and gamma telescopes, gravitational-wave antennas, and facilities designed to detect neutrinos and ultra-high energy cosmic rays. Multi-satellite observations are necessary to ensure the detection of each GRB on several spacecraft in order to localize the GRB source using the triangulation technique.

2. Advantages of CubeSat constellation for GRB observations

The main success of multi-channel astrophysical observations is connected with simultaneous detection of gravitation wave and gamma-ray burst in August 17, 2017 from neutron star merging.[1] It seems that one of the cheapest and very effective ways of multi-channel and multi-satellite observations of such events and GRBs in general is use of small satellites grouping, in particular the CubeSat constellations. Due to the relatively low cost and ease of manufacture, it is possible to carry out more, or less regular launches of CubeSat satellites as a by-pass mission. Thus, a constellation of nano-satellites can be created, which will significantly increase the efficiency of space radiation and electromagnetic transient monitoring.

The solution for the localization problem can be achieved by applying the triangulation method for observations of the selected area with different satellites. For this purpose the number of CubeSats should be launched for the joint observations of a given burst. To realize the triangulation technique in minimal variant 3-4 CubeSats are necessary (see Fig. 1). Optimally they should be launched as by-pass mission together with the main spacecraft of multi-satellite group, i.e. on the near circular solar-synchronous orbits with altitude about 400 – 600 km, inclination about 98° and longitude deviation of the ascending node $< 5°/year$. The error box of GRB source localization is defined by time delay of signals detected on each satellite. The longer delay the more accurate will be localization. Delay itself depends on distance between satellites, i.e. the larger distance corresponds to the longer delay. In the case of near-Earth orbits the distance between satellites is limited by about 10 000 – 15 000 km, because all satellites should be from one side of the Earth to avoid the screening of GRB source. By this the necessity of maintaining of given distance between satellites is a separate technical problem. It can be solved by the use of thrusters. Off cause CubeSat constellation can be used also for observations of transient events from the Earth atmosphere, including Terrestrial Gamma Ray Flashes (TGF) and monitoring of space radiation. However, there will be other requirements to the distance between satellites in the case of triangulation technique application for TGFs. In the last case the given area of Atmosphere should be observed by all satellites of grouping, thus the maximal distance should be no more than about 1000 km. For successive realization of multi-satellite mission for GRB observations certain conditions should be met:

- presence of satellite Internet (global star/iridium) plus high frequency transmitter;
- stabilization better than $1°/s$, satellite orientation on the "Zenith–Nadir" axis and velocity vector with accuracy $+/-10°$, information on satellite axes orientation with accuracy 0.1°;
- possibility of quasi-autonomous navigation, in particular with the use of millisecond pulsars as beacons;

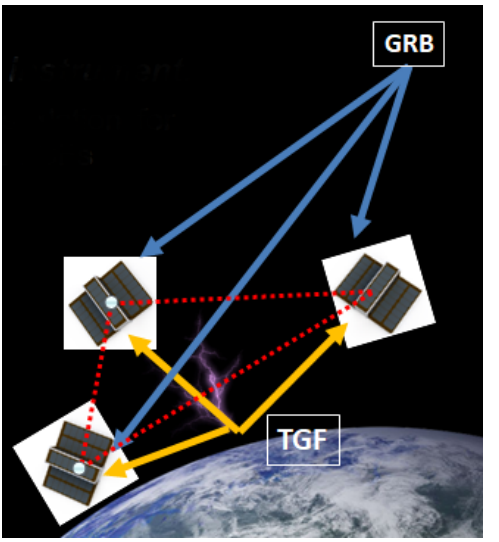

Fig. 1. The CubeSat constellation in minimal configuration.

- different data types, such as monitoring, event-by-event, telegrams about burst triggers (GCN);
- data daily volume no less 100 Mb;
- exact timing is needed;
- orientation accuracy $\sim 1^\circ$ is useful;
- fast telegrams are needed;
- necessity of charge particle variation control.

The last demand is particularly actually if the satellites are launched to the polar orbit because of the problem of false triggering by electron precipitation rises. It can be solved by monitoring of electron flux with the use of special electron detectors or instruments which are able to select true gamma-quantum flux rises on the background of electron precipitation. The last is illustrated by Figs 2, 3, on which the examples of GRB imitations by electron precipitation and the map with such imitation distributions from the BDRG/Lomonosov data[2] are presented.

For instruments, that can be used for GRB detection on-board CubeSats one of the main criteria is the detector area, that is sufficient for GRB registration, should be larger $\sim 50 cm^2$ in the energy range of photons from $\sim$ 20 keV up to several MeV. Such detector units can also be used to detect TGFs and X-ray and gamma ray emission of solar flares.

We note, that presently the space project of Moscow University Universat-SOCRAT is under realization. In the frame of this project the launches of a number of satellites including CubeSats, that can be used as the base of constellation for GRB study, is foreseen.

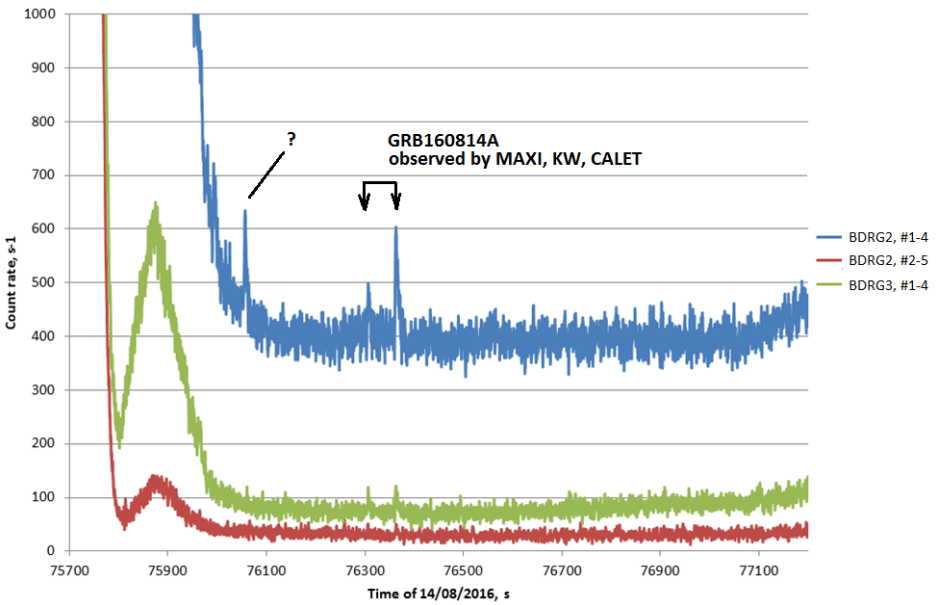

Fig. 2. Example of GRB and burst imitations by magnetosphere electron precipitation detected BDRG/Lomonosov near radiation belts.

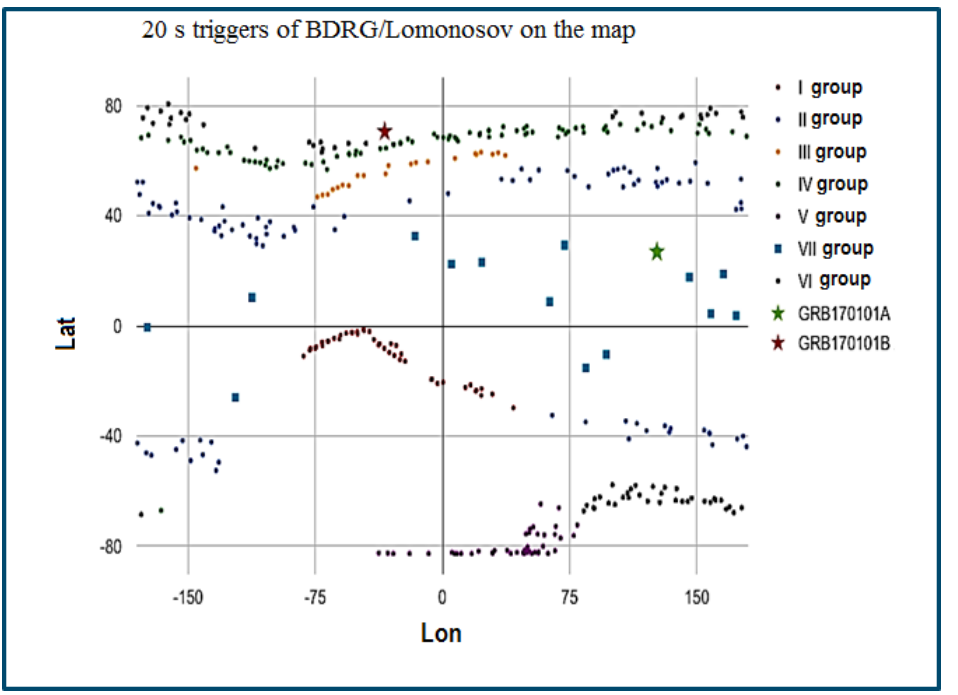

Fig. 3. Geographic distribution of different types of BDRG/Lomonosov triggers. By stars the real GRBs are marked.

2.1. *Universat–SOCRAT space project*

Under the Universat–SOCRAT project it is planned to create a grouping of small satellites for real time monitoring in the near-Earth space of potentially dangerous hazards, i.e. the radiation environment; dangerous objects of the natural (asteroids, meteors) and technogenic origin (space debris), as well as electromagnetic transients (cosmic gamma-ray bursts, optical, ultraviolet and gamma ray flashes from the Earth's atmosphere.[3, 4])

Within the framework of the Universat–SOCRAT project several small spacecraft should be launched on specially selected orbits. In the minimal version, the group of satellites should consist of three spacecraft. One spacecraft of medium mass (small satellite) should be launched on a low solar-synchronous orbit with a height of about 500–650 km and an inclination of 97–98°. Two other satellites of lower mass (micro satellites) should be launched on an orbit close to circular with a height of about 1500 km and an inclination of $\sim 80°$ and on an elliptical orbit with an apogee of about 8000 km, a perigee of 600–700 km, inclination 63.4° and argument of perigee $\sim 310°$.

The small satellite payload should include instruments for monitoring of space radiation, a set of instruments for optical monitoring of hazardous objects, a set of instruments for studying of atmospheric phenomena in the optical range, a set of instruments for monitoring in gamma- range, and special unit for data collection. The payload should also include three-component magnetometer. The payload of each micro satellite should include instruments for space radiation monitoring, a compact gamma spectrometer, a wide field of view optical camera, an ultraviolet detector and an electronics unit for data collection. Payload of all three satellites also should include the special electronic unit for data collection from detector units, its transmission to the board systems and feeding too the instruments power supply and commands.

The basic multi-satellite group can be supplemented with nano-satellites of the CubeSat type. Due to the relative cheapness and ease of manufacture, it is possible to carry out more or less regular launches of satellites as a by-pass mission. Thus, a constellation of nanosatellites can be created, which will significantly increase the efficiency of space radiation and electromagnetic transient monitoring.

The use of several nano-satellites of CubeSat type equipped with several multi-directional spectrometers of energetic protons and electrons will provide a solution of the problem of elaboration of a three-dimensional dynamic model of radiation in near-Earth space. For this, the satellites should be launched onto specially selected orbits and provide measurements that will allow us to calculate the current distribution of particle fluxes in a large volume of near-Earth space, i.e. from low orbits to geostationary, and, as a result, determine the current levels of radiation doses for a wide range spacecraft orbits, and also give a forecast of the radiation situation at low altitudes. Simultaneous measurements of particle fluxes on several spacecraft located at different points in near-Earth space will also allow sufficiently reliable

separation of temporal and spatial effects in detected variations of the instrument output readings.

The nano-satellite constellation also gives advantages for GRB and TGF study. As it was mentioned above, the crucial point from this view is necessity of good localization of the transient source. This can be achieved with the use of triangulation technique. In the case of GRB observations about 3–4 satellites will be enough. As for TGF study, optimally the spacecraft grouping should consist of 16 satellites pairwise launched in 8 double orbits, i.e. for each pair of orbits the angle between the planes of the orbits should be about For the all constellation spacecraft the main operational mode of the most instruments is on duty mode when the all instruments are switched-on and operate continuously. Instrument switching between the operational modes is carried out by commands from the Earth or by the internal programs. To optimize the payload energy consumption, the data exchange between instrument electronic and satellite board should be foreseen, including information on changing the parameters of the spacecraft power system and payload switching into energy-saving modes (changes in the instrument operating modes or their partial switching-off).

2.2. *Instruments for gamma transient monitoring*

Instruments for study of gamma transients in the Universat-SOCRAT project will include gamma-ray flash monitor (GFM), and a tracking gamma-ray spectrometer (TGS) of the high resolution and sensitivity, that will be sensitive also to neutrons with energies from about 1 MeV up to dozens of MeV.[5] The separate unit for data analysis and control of GFM and TGS should be also foreseen in the payload. This unit should contain digital electronics unit that will provide the record of data stream with a time resolution of $\sim 10\mu s$, and generate the triggers enabling the detection of different type events, including GRB/TGF flux increases. The data record must be referenced to the UTC time with an accuracy of $\sim 10\mu s$ to allow the positioning of the burst, if observed simultaneously by several space missions, using triangulation, and for the comparison with the data of ground based lightning nets.

To realize the triangulation technique sufficiently light X-ray and gamma-ray detectors aimed for the GRB/TGF detection only, without spectrometer capabilities, will be used on the CubeSats. The composition of each spacecraft of small satellite constellation of the cubesat type should include gamma-ray detectors in the amount of:

— Cubesat 1U – 1 instrument;
— Cubesat 3U – at least 1 instrument;
— Cubesat 6U – at least 3 instruments.

If one instrument is installed on the satellite, its axis should be directed along the nadir - zenith axis to nadir, and the field of view should not be obscured within $\pm 60^\circ$ from the axis of the instrument in the nadir direction. If two instruments are

installed on the spacecraft, their axes should be normal to each other, while the axis of one detector should be directed along the nadir—zenith axis to nadir, and the axis of the other detector should be directed along the spacecraft velocity vector in the case of the orbital orientation of the spacecraft (along the line "zenith - nadir" and the velocity vector), while the field of view should not be obscured within $\pm 60^\circ$ from the axis of the detector. If three instruments are installed on the spacecraft, their detector axes should be normal to each other, directed along mutually perpendicular edges of the cube, as if forming a Cartesian coordinate system, while the axis of one detector should be directed to the nadir, the other along the velocity vector, the axis of the third should complement the three-axial coordinate system to complete. Each gamma detector should be placed in a cubesat-type spacecraft in such a way that the surface of its input window coincides with the surface of one of the side faces of the satellite. The instrument should consist of detector assemblies and electronics boards. Various options for the use of detector units are considered. In the simplest version there are considered 4 detector units each from scintillation crystals with a size of $45 \times 45 \times 5$ mm, viewed by a photo-sensor. There are considered as possible scintillators CsI(Tl) crystals (a cheap option) or Ce:GAGG (an optimal option). For signal pickup, photodetectors such as tube photomultiplier tubes (PMTs) or silicon PMT arrays (Si-PM) can be used.

To provide identification of different types of space radiation (electrons, gamma-quanta), a variant with a fosphich detector can be used when a combination of a plastic scintillator/inorganic scintillator (CsI(Tl) or Ce:GAGG), viewed by a single photodetector, is used while the separation of signals from different scintillators is carried out by analyzing the time profiles of the PMT output signals.

A multi-pixel version of the detector can be also considered when it consists of individual crystals (pixels) of a relatively small size, each of which is viewed by its own photodetector. In this case, a variant can be considered both using standard arrays of silicon PMTs, and using original photodetectors and corresponding non-standard electronics.

2.3. *Instruments for electromagnetic transient monitoring in ultraviolet and optics*

Instruments for study transient luminous events (TLEs) in UV and optical bands should include position sensitive spectrometer, i.e. small lens telescope with high time resolution for spectral measurements of TLE and lightning and UV and infrared (IR) detector-photometer, which is similar to that used in Tatiana-2 and Vernov missions.[6] This instrument will be added by channels in far UV range. It allows comparison with data of previous experiments on study UV flashes in the Atmosphere. Spectral measurements are necessary to determine the type and altitude of TLE generation as well as to reveal lightning discharges by typical 777 nm line and by the absence of signal in the range of oxygen absorption lines about 762 nm. Axes of both instruments should be directed toward Nadir with open angles about 90°.

For the TLE observations on the CubeSats will be used compact UV detector with a wide field of view (AURA-2) or its improved version, i.e. telescope (AURA-2T).[7] These instruments are the development of the AURA (Atmospheric Ultraviolet Radiation) detector already launched on board the VDNH-80 satellite. In this instrument SiPM MicroFC-60035-SMT silicon photomultipliers with a sensitive area of 6×6 mm, spectral sensitivity from 300 to 800 nm, a maximum spectral sensitivity at 420 nm, and a quantum efficiency of about 41% at 420 nm are used as photodetectors. Silicon photomultiplier tubes, unlike traditional PMTs used for fast photometry, have a number of advantages that are significant for experiments on small spacecraft. It is compact (thickness about 1 mm), low voltage ($25 - 70$ V) and low weight. The main advantages of the new detector options are high temporal resolution ($1\mu s - 10ms$) and spatial resolution, higher sensitivity due to an increase in the area of the optical system.

The operation of the detectors in the monitoring mode under the condition of simultaneous operation on several spacecraft will make it possible to control transient activity in the Earth's atmosphere, both of thunderstorm and extra-thunderstorm nature with a large exposure. Cartography and monitoring of UV transients is an important task for understanding the interconnections of various energetic processes in the atmosphere. Also, the quasi-stationary UV glow of the atmosphere can be an additional indicator of the state of the geomagnetic situation and the effect of the solar wind on the atmosphere and magnetosphere of the Earth.

3. First results of Moscow University CubeSat missions

The first stage of the Universat–SOCRAT program began to be implemented on July 5, 2019 after a successful launch from the Vostochny cosmodrome of three nanosatellites of the cubesat type (SOCRAT, AmurSat, VDNH-80). These satellites are equipped with instruments DéCoR (Detector of Cosmic Radiation) for monitoring space radiation, as well as prototypes of instruments for observing transient phenomena in the Earth's atmosphere. In particular, scintillation fosphich detectors, which are prototype of the instrument intended for gamma transient observation on cubsats, are installed on two satellites (AmurSat, VDNH-80). These instruments detect charged particles and gamma rays in the energy release range of 0.1 - 2.0 MeV. The geometric factor of these instruments is $\sim 50 cm^2 sr$. One of the cubesats (VDNH-80) also contains an optical photometer AURA, consisting of four silicon photomultipliers, whose input windows are covered by different light filters. Thus, the instrument provides observations of the Earth's atmosphere in the range from ultraviolet to red. The satellites were launched into a sun-synchronous orbit with an altitude of ~ 800 km. This creates favorable conditions for monitoring space radiation in various areas of near-Earth space, including zones of captured radiation, areas of precipitation, etc. Such an orbit also allows observations of flash phenomena both in the near-equatorial atmosphere and at high latitudes.

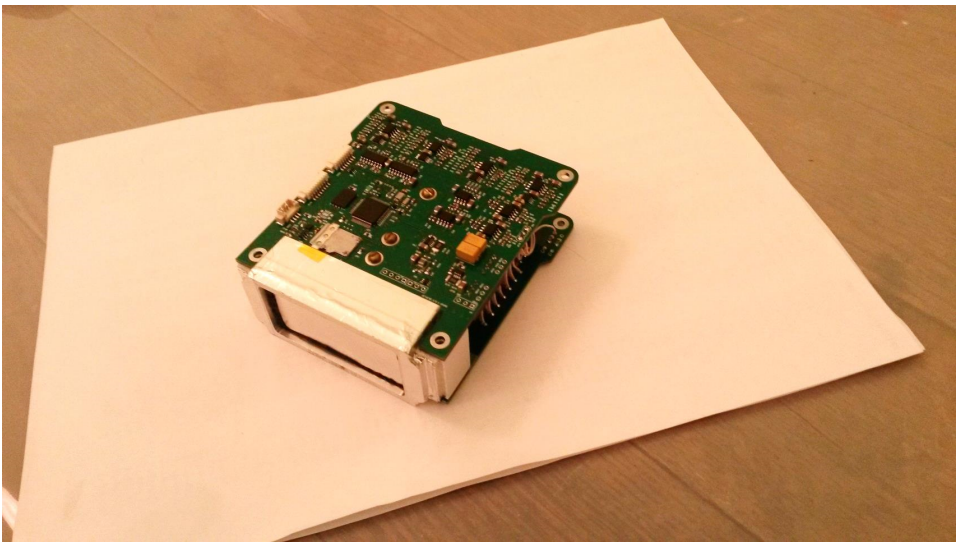
The implementation of the Universat-SOCRAT program was continued by the successful launch on 28 September 2020 of three more spacecraft of the cubesat type, on which DeCoR and AURA-2 instruments are installed. One of them, the DECART 6U satellite, contains three identical DeCoR instruments installed in such a way that their axes are mutually normal to each other, which makes it possible to estimate the angular distributions of the detected fluxes. DeCoR devices are also installed on the Norbi 6U satellite, developed jointly with the Novosibirsk State University, as well as on the Yarilo-2 spacecraft of the 1.5U format, developed jointly with the N.E. Bauman Moscow State Technical University. The AURA-2 instrument is operated on-board of DECART satellite.

3.1. *Parameters, structure and functioning principles of DeCoR payload*

The DéCoR payload is an instrument for measuring the fluxes and spectra of charged particles and gamma rays in the energy release range of 0.1 - 2 MeV. The main scientific goals are the study of fast variations of electron fluxes in the areas of precipitation and the slot between radiation belts, as well as the study of the dynamics of particle fluxes and gamma rays at low orbits in dependence on geomagnetic conditions. An important factor that allows more efficient scientific research is the installation of the instrument on two satellites, sequentially flying through the same region of near-Earth space. A photo of the instrument and sketch of detector unit are shown in Fig. 4.

The DeCoR instrument is adapted in order to be mounted in the cubesat satellite body. Its detector is a two-layer assembly of a plastic scintillator and a CsI (Tl) crystal (see Fig. 4b). The detector has a sensitive area of $\sim 18cm^2$. The assembly is viewed by two PMTs. Separate digitization of the initial and final parts of the PMT output pulse ("Fast component" and "Slow component") from each PMT allows determining the scintillator in which the interaction took place from the pulse shape analysis pulse and, thus allows separate measuring of electrons and gamma ray fluxes. Data and commands are exchanged with the satellite's on-board systems by the instrumentmicrocontroller of the device using the UART protocol. For the accumulation and storage of scientific data non-volatile memory with a capacity of 16 MB is foreseen in the instrument. For transmission to the Earth, the DeCoR instrument generates both monitoring data (particle counting rates 1 time per second) and detailed data about all interactions in the detector with a time resolution of $20\mu s$ (so call event by event mode), which are accumulated in the instrument's memory by a command that determines the moment of interesting time from the view of the researcher . The main way to conduct a scientific experiment is to regularly collect and transmit monitoring data to the Earth, as well as activate from time to time the detailed recording mode on pre-calculated sections of the satellite trajectory passing through the zones of possible variations of the trapped and quasi-trapped particle fluxes.

a



b

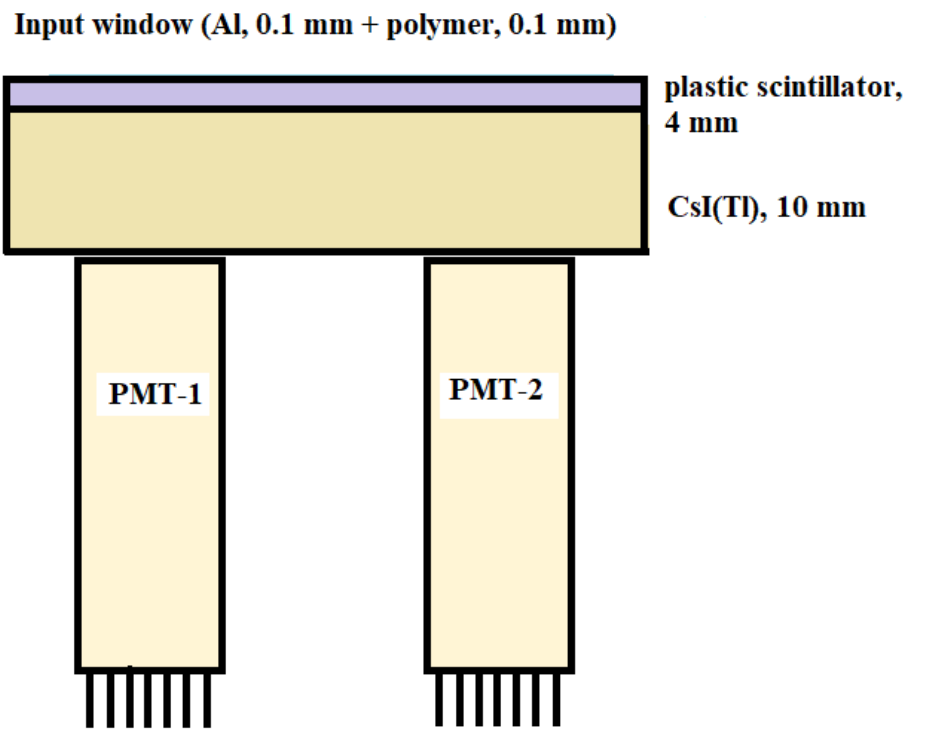


Fig. 4. The photo (a) and general view (b) of DeCoR instrument.

After viewing data of the "Monitoring" type, the researcher identifies the time points at which the flow variations of interest actually occurred. For these moments, detailed data is requested for transmission to Earth. The used data transfer rate allows you to transmit detailed data about an interesting phenomenon, for example, about the precipitation of magnetosphere electrons lasting several minutes, for A magnetometer is also installed in the DeCoR instrument, which makes it possible to measure the magnitude of the magnetic field along three mutually perpendicular axes. Using the outputs of this magnetometer allows taking into account spacecraft rotation in the study of trapped and precipitating electrons and even use it to estimate the pitch-angle distribution of particles. The magnetometer data are included directly in the monitoring information frames containing the parameters of the measured radiation.

3.2. *The results of observations with DeCoR instrument on-board AmurSat and VDNH-80 satellites*

Space missions with AmurSat and VDNH-80 satellites were the first Moscow University experience of monitor observations on cubesats. Due to technical problems, first of all connected with necessity of solar battery charging and limited transmitter capabilities, during both missions data were obtained from DeCoR instrument for about hundred and a half orbits. Taking into account that background conditions appropriate for GRB observations were on about a half of orbit, real instrument field of view about 1 sr and GRB detection threshold about $5 \cdot 10^{-7} erg/cm^2$, the expected number of detecting GRBs was no more than one. Really there were no detected any significant gamma-quantum flux increasing, which can be discussed as GRB candidates. Nevertheless sufficiently rich experience was obtained in view of radiation monitoring, especially of electron flux variation study by two spacecraft.

As noted above, an important advantage of multi-satellite experiments is the possibility of simultaneous measurements at different points in the near-Earth space on the one hand and measurements in the same regions with sequential passage of satellites through them on the other. Such measurements are illustrated in Fig. 5, 6, which show the orbital projections of the AmurSat and VDNKh-80 satellites and the outputs of two DeCoR instruments installed on these satellites, which were recorded on March 18, 2020. The difference in the positions of the satellites was about half of the orbit, so at the same time one spacecraft was taking measurements in the North Polar Region, and the other in the South.

Instruments on both satellites were switched on over Kaluga-city, when the satellites were moving in the direction of the northern polar region. At the moment of switching on the DeCoR instrument on the VDNH-80 satellite, the AmurSat cubesat was in the southern hemisphere, so the DeCoR instrument on it was switched on after ~ 45 minutes. At the same time, the AmurSat satellite continued to move along a similar trajectory with the VDNH-80 spacecraft.

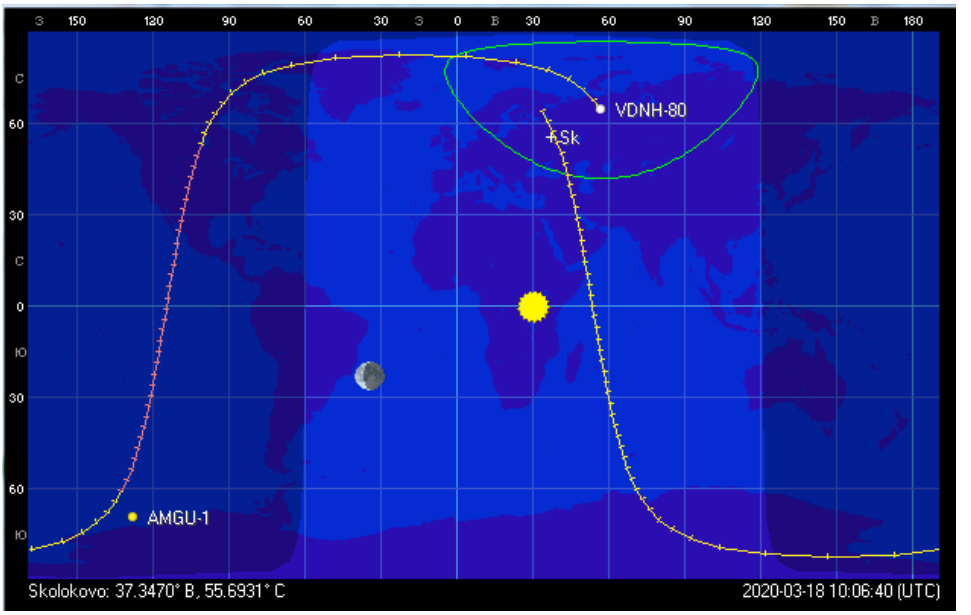

Fig. 5. Projection of VDNH-80 satellite orbit onto the Earth map when the DeCoR instrument was switched on March 18, 2020.

The orbital projection of the VDNH-80 satellite during the switching on of the DeCoR instrument on March 18, 2020 is shown in Fig. 5. It also shows the position of the AmurSat satellite at the moment when the DeKoR instrument was switched on the VDNH-80 satellite. The DeCoR instrument on the AmurSat satellite was switched on in $\sim$ 45 minutes above the communication point in Kaluga, thus, the data array transmitted from the AmurSat satellite corresponds to a trajectory close to that shown in the figure.

The time variation of the counting rate of electrons with energy $>$ 300 keV along the orbit of the VDNH-80 satellite, recorded in the monitor mode with a time resolution of 5 s are shown in Fig. 6a. The maxima are clearly visible at the moments when the satellite is in the outer radiation belt of the Earth, as well as some small increases in the polar region. Significant increases in the counting rate near the geomagnetic equator are also clearly visible.

The counting rates in a similar channel of the DeCoR instrument installed on the AmurSat satellite are shown in Fig. 6b. Noteworthy is the repeatability of the features visible when two satellites pass the same polar region with an interval of $\sim$ 45 minutes. During the flight of the geomagnetic equator, a smooth increase in the electron counting rate is also seen. The moving average line shows modulation with a period of $\sim$ 40 s associated with the rotation of the satellite. As noted above, the presence of such modulation indicates that the electron flux is non-isotropic in the near-equatorial regions.

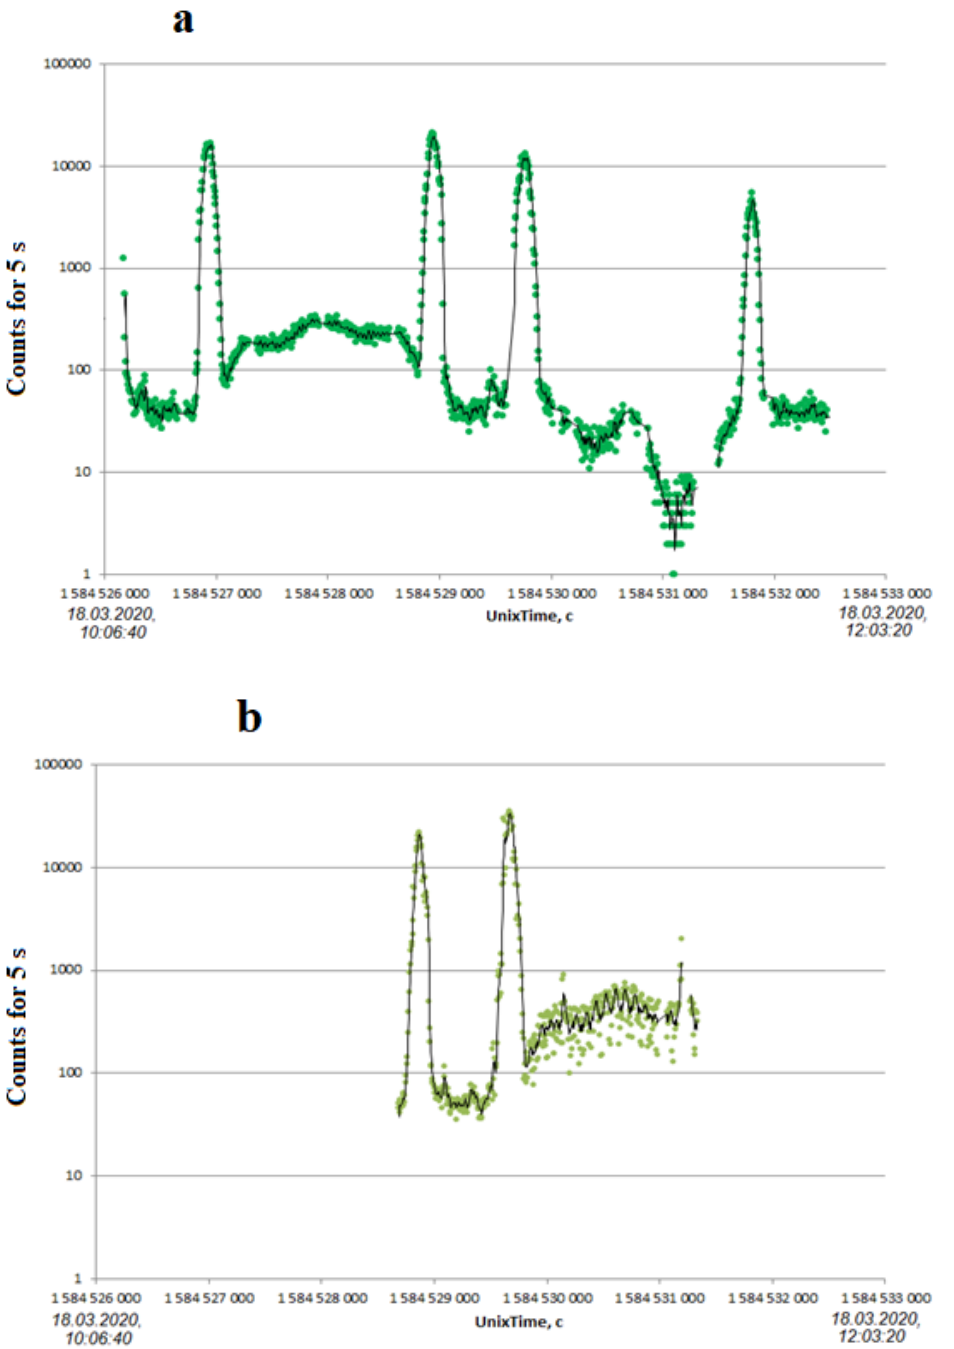

Fig. 6. Time variation of the count rate for electrons with energy > 300 keV, recorded in the monitor mode of the DeCoR instrument operated on-board VDNH-80 satellite on March 18, 2020 (a), similar readings of the DeCoR instrument on -board AmurSat satellite (b).

3.3. *The first experience of observations with DéCoR instruments on-board Norbi and DEKART satellites*

Just now the stage of flight tests of Norbi and DEKART missions was completed and regular observations were begun. The example of DeCoR instrument data obtained from Norbi CubeSat on July 14, 2021 is presented in Fig. 7. There it can be seen the monitor time dependent (with 5 s time resolution) count rates in plastic detector (mainly electrons) and CsI(Tl) (mainly gamma quanta) recorded for several consequent orbits. All typical variations caused by the near-Earth radiation flux distribution can be seen. There are seen peaks connected with the crossing of the outer belt regions and South–Atlantic Anomaly, as well, as in precipitation areas.

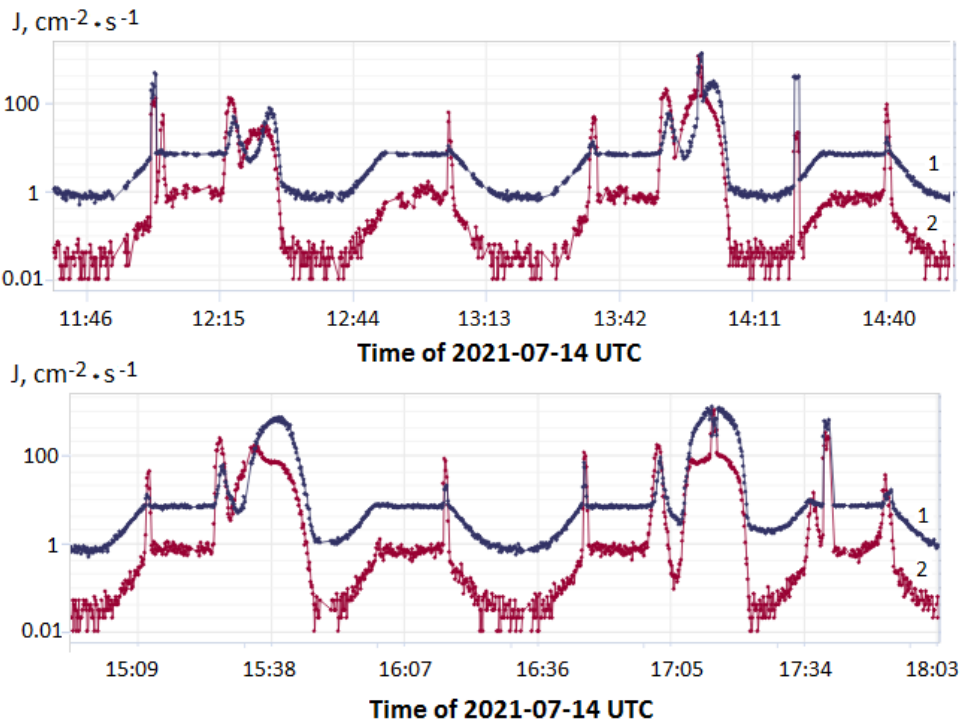

Fig. 7. Time variation of the count rate for electrons with energy > 300 keV (red curve) and for gamma-quanta (dark blue curve), recorded in the monitor mode of the DeCoR instrument operated on-board Norbi satellite on July 14, 2021.

It is necessary to note that gamma quantum count rate dependence along the orbit contains the intervals of quasi-constant background that correspond near-equatorial and polar cup regions. These intervals are quite appropriate for GRB detection. Nevertheless on these intervals flux increasing caused by electron precip-

itation can be observed. The example of such event detected on 04:49 September 28, 2021 is presented in Fig. 8.

The example of output data from one detector unit of DéCoR instrument on-board DEKART satellite is presented in Fig. 9. As it could be seen, time dependent gamma quantum and electron count rates, recorded with 0.5 s time resolution along the orbit, are quite similar to those obtained by Norbi satellite. Thus, it gives opportunity for multi-satellite measurements of time effects in near-Earth radiation fluxes and increase probability of GRB detection, including possibility of simultaneous GRB observation on two satellites.

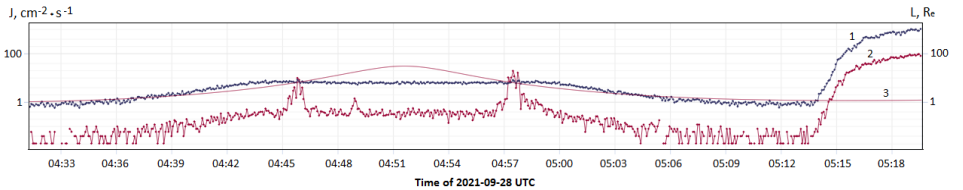

Fig. 8. Time variation of the count rate for electrons with energy > 300 keV (red curve), and gamma-quanta (dark blue curve), and L values (violet curve) recorded in the monitor mode of the DeCoR instrument operated on-board Norbi satellite on September 28, 2021.

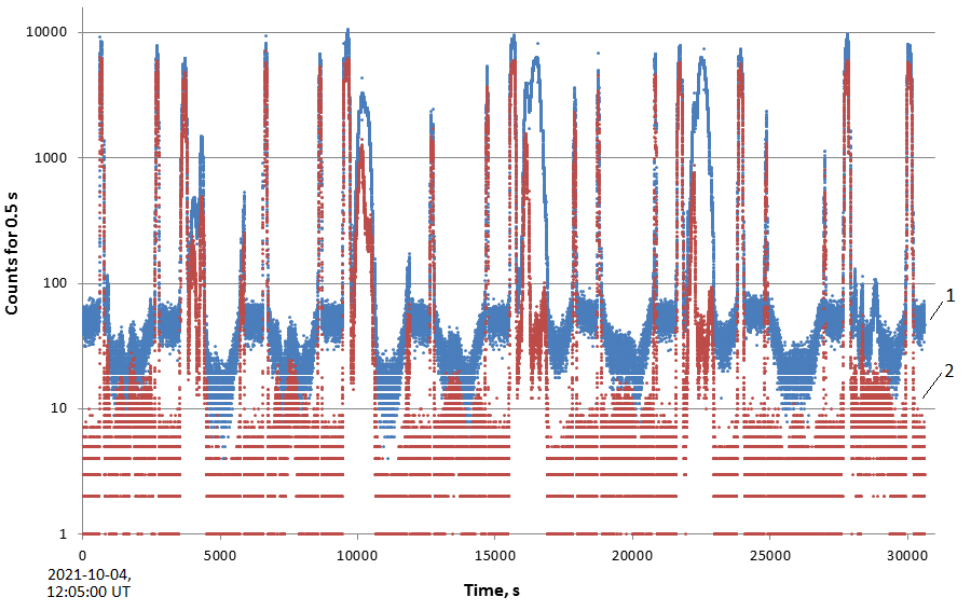

Fig. 9. Time variation of the count rate for electrons with energy > 300 keV (red curve) and for gamma-quanta (dark blue curve) recorded in the monitor mode of the DeCoR detector on-board DEKART satellite on October 4, 2021.

4. Conclusion

The successful realization of the CubeSat missions in frame of Universat–SOCRAT project make it possible for the first time to create a prototype of nano-satellite constellation a space system for monitoring of space radiation and electromagnetic transients including GRBs.

The first stage of this project was beginning from the launching of three CubeSats in July, 2019 and then three CubeSats in September, 2020. The prototypes of the instruments, which should be used in future Universat–SOCRAT missions were tested in these orbital experiments with CubeSats. Results of these tests confirmed that instruments operate well as in terms of command control as in terms of detector parameters. The particle flux measurements carried out during flight tests demonstrate the presence of variations corresponding to the expected changes in outputs at low polar orbit. During flight tests, both monitoring data with a time resolution of ~ 0.5, 1 and 5 s and event by event data with a time resolution of $\sim 20\mu s$ were successfully obtained from both DeCoR instruments installed on-board launched cubesats. Obtaining and processing of these data allows us to analyze both slow and fast particle flux variations. Thus, flight tests have confirmed the suitability of the instruments for the scientific research for which they were intended including principal possibility of GRB observation.

The detailed continuous fast optical photometry analysis obtained by MASTER Global Network for the GRB160625B optical counterpart MASTER OT J203423.51+065508.0 is presented. There are also hard X-ray and gamma-ray emission obtained by the Lomonosov and Konus-Wind spacecrafts detectors. We detected quasiperiodic emission components in the intrinsic optical emission of GRB160625B and propose a three-stage collapse scenario for this long and bright GRB. We associate quasiperiodic fluctuations with forced precession of a Spinar, i.e. self-gravitating rapidly rotating super dense body, whose evolution is determined by a powerful magnetic field. The spinar's mass lead it to collapse into a black hole at the end of an evolution.

Keywords: Gamma-ray burst

1. Introduction

Gamma-ray bursts (GRB) still remain a mysterious phenomenon. We proceed from the assumption believe that long gamma-ray burst occurs as a result of the collapse of the rapidly rotating core of a massive star. The fast rotation of the core slows down the collapse and extends time available to produce electromagnetic radiation. Two scenarios are possible here. In the first scenario (MacFadyen & Woosley, 2000),[1] a black hole first forms, and then the fallback of the supernova envelope, which has a supercritical torque, forms a heavy superdense disk. Due to the generation of magnetic fields by this disk, axial jets with a large gamma factor are generated, which we observe. In another scenario, a rapidly rotating magnetized object, a Spinar, is first formed, which is slowly compressed due to the dissipation of the rotational moment (Lipunov & Gorbovskoy, 2007).[2] In this case, a jet with a Poynting-Umov energy flow is formed along the rotation axis. The operating time of the central gamma-ray burst engine changes depending on the dissipation rate. In general, both scenarios require a fairly large torque in the collapsing stellar core. And here the authors are impressed by a binary scenario in which fast rotation occurs due to the tidal influence of the second component in a very close binary system (Tutukov & Cherepashchuk, 2016).[3] In this scenario, the centrifugal barrier is a consequence of the large torque acquired as a result of the natural evolution of the binary system. In the case of GRB160625B our attention was attracted by the quasiperiodic brightness fluctuations during the time of the central engine operation, and below we try to interpret them as a consequence of a Spinar Paradigm at work (Lipunova & Lipunov, 1997; Lipunov & Gorbovskoy, 2007;2008; Lipunova et al., 2009)[2,4–6]

In this paper, we present multiwavelength observations of GRB160625B, one of the brightest gamma-ray bursts in the history of their study. We have concentrated on the temporal behavior of itsintrinsic electromagnetic radiation. We present optical and gamma-ray data, recorded during the time of the operation of the central engine of GRB160625B. We made an attempt to find traces of the duality of the GRB system. We have suspected traces of the dual nature of long GRBs. Of course, we do not have one hundred percent proof of this scenario, but this study can serve as an example of searching for and finding the dual nature of long GRBs.

2. Observations

GRB160625B was observed by the large number of space and ground telescopes in a wide range of electromagnetic waves from gamma-ray to radio. For the first time in the GRB study history, the polarization of its own prompt optical emission synchronous with the gamma one was discovered (Troja et al., 2017a).[7] Now we present the details of synchronous observations in the optical (MASTER OT J203423.51+065508.0) and gamma-ray ranges.

GRB 160625B triggered Fermi observatory at 2016-06-25 22:40:16UT , firstly as a short pulse (Fermi-GBM trigger 488587220, Burns et al.2016),[8] then the

Fermi-LAT triggered (Dirirsa et al. 2016)[9] at 22:43:24.82UT, at 22:51:16.03 Fermi-GBM triggered again (trigger 488587880).The GBM light curve consists of multiple peaks over approximately 700 seconds, the first one being 1 second long soft peak. The main peak, corresponding to the LAT trigger, was very hard and about 25 seconds long. The peak that triggered GBM for the second time was soft and about 30 seconds long (Burns et al. 2016).[8] Swift has initiated a series of observations and discovered uncatalogued X-ray sources at R.A.,Dec.(2000)=20:34:23.25 +06:55:10.5 with an uncertainty of 3.8 arcsec (Melandri et al. 2016), publishied it at 2016-06-26 06:54:13UT.

This long, extremely bright GRB 160625B also triggered BDRG detectors on-board Lomonosov Space Observatory of Moscow State University (Sadovnichii et al. 2017)[10](Fig. 1) and Konus-Wind at 22:40:19.875UT (Svinkin et al. 2016)[11](Fig. 1) as well as the CALET Gamma-ray Burst Monitor (CGBM) at 22:40:15.49 (Nakahira et al. 2016).[12]

The optical counterpart was discovered by RATIR (Troja et al. 2017b)[14] starting 8.53h after LAT trigger. MASTER started observation in polarization filters (Lipunov 2010, 2019, Kornilov 2012)[17–19] 31 sec after GBM notice time (57 sec after GBM, i.e. 131 sec before LAT Trigger, Dirirsa et al.2016)[9] at 2016-06-25 22:41:13UT (Gorbovskoy et al. 2016),[20] but published the circular in GCN (Barthelmy et al. 1998ab)[21,22] at 16/06/28 14:05:38. The GCN publication was delayed by the installation of the new MASTER telescope in Argentina at this time (MASTER-OAFA). MASTER measurements probed the structure of the magnetic field at an early development stage of the jet, closer to a central black hole, and show that the prompt emission phase is produced via fast-cooling synchrotron radiation in a large-scale magnetic field that was advected from the black hole and distorted by dissipation processes within the jet (Troja et al. 2017a).[7] The optical data obtained by MASTER telescopes-robots (Lipunov et al. 2010,2019)[17,18] have the best temporal resolution with the minimum exposure time of 5 seconds. This resolution made it possible to suspect quasiperiodic variability in the optical range, which we try to associate with the dual nature of the long GRB.

The detection of a substantial (8.3 ± 0.8 per cent from our most conservative estimation) variable linear polarization of a prompt optical flash that accompanied the extremely energetic and long prompt γ-ray emission from GRB 160625B was discovered by MASTER (Gorbovskoy et al. 2016a, Lipunov et al. 2016a, Troja et al. 2017a).[7,15,16]

2.1. *MASTER*

MASTER Global Robotic Net of Lomonosov Moscow State University in 2016 consisted of orbital MASTER-Shok detectors on-board Lomonosov spacecraft and of 8 ground observatories with identical scientific equipment distributed all over the Earth: MASTER-Amur, -Tunka, -Ural, -Kislovodsk, -Tavrida in Russia, -SAAO (South African Astronomical Observatory), -IAC (Tenerife, Spain, Teide

observatory of Institute of Astrophysics of the Canary Islands), -OAFA (Argentina, San Juan National University Astronomical Observatory named by Felix Aguilar), see Lipunov 2010, 2019[17,18](Fig. 1). Identical equipment includes twin wide-field (MASTER-II, 4-8 square degrees up to 20m unfiltered limit at 180s exposition) and very wide field (MASTER-VWFC, 800 square degrees, up to 15m at summary image) optical channels (Kornilov et al. 2012)[19] which allows us to follow a target 24h per day in one photometric channel. MASTER-VWFC are the ground-based analogue of the MASTER-SHOCK cameras, that were installed on board the Lomonosov space observatory (Sadovnichy et al. 2017,2018, Lipunov et al. 2018, Svertilov et al.2018, Park et al. 2018).[10,23,25,37,38] Observations by MASTER-VWFC are unfiltered.

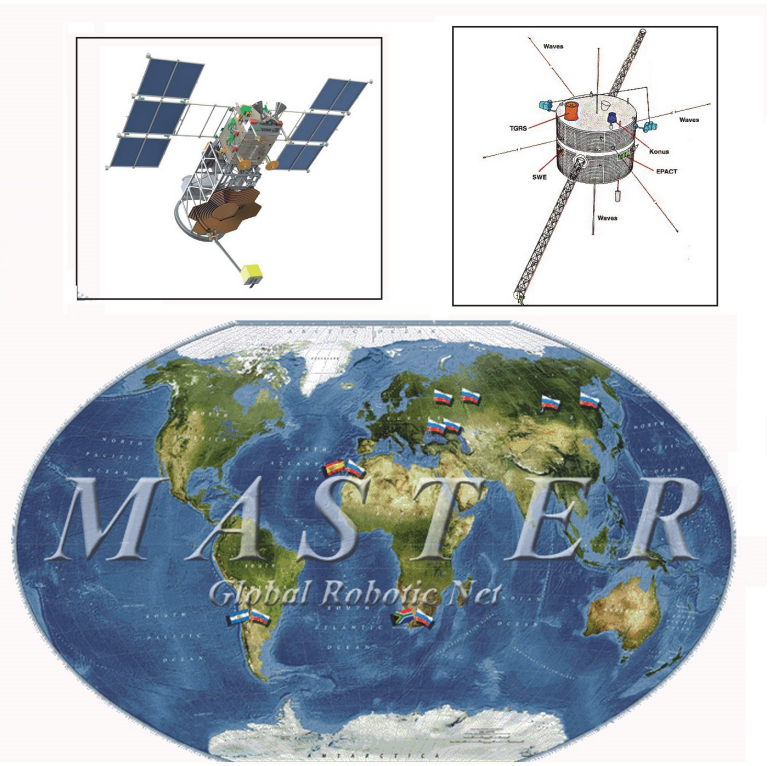

Fig. 1. MASTER Global Robotic Net. The upper left part shows Lomonosov satellite and the upper right part shows Konus-Wind. The flags indicate equipped sites of network stations.

MASTER own developed photometer can observe simultaneously in 2 orthogonally oriented polarization filters in both tubes of twin MASTER telescope

(Kornilov et al. 2012)[19] or in BVRI filters and unfiltered. Mount has fast positioning with the speed up to 30 deg/s.

MASTER key factors is own software for real-time reduction. It includes full robotization of all processes: hardware control, weather control, efemerides, central planner, automatic evening/morning calibration,and primary image reduction, astrometry and photometry, extraction of new optical sources and notification of the main station of them). Such features let us to discover significant and variable linear polarization during the prompt optical flash of GRB 160625B (Troja et al. 2017a),[7] to discover GRB optical counterparts (Lipunov et al. 2016, Gorbovskoy et al. 2016, Sadovnichy et al. 2018, Laskar et al. 2019),[20,24–27] to discover Smooth Optical Self-similar Emission of GRB subclass (Lipunov et al. 2017),[28] to make the most optical support to GW150914 event (Abbott et al. 2016ab, Lipunov et al. 2017,2018),[29–31] to independently discover Kilonova GW170817(Abbott et al. 2017, Lipunov et al. 2017),[32,33] to make the most optical support to the follow-up of a rare IceCube neutrino multiplet (Aartsen et al. 2017),[34] to discover V404Cygni polarization variability (Lipunov et al. 2017),[35] to make optical observationsthat revealed a strong evidence for a high-energy neutrino progenitor - blazar TXS 0506+056 for IC170922A (Lipunov et al. 2020)[36] , to discover more than 2000 optical transients of 10 different types and other.

2.2. *MASTER GRB160625B observation*

MASTER-IAC robotic telescope pointed to the GRB 160625B at 2016-06-25 22:41:13UT, and observed Swift X-ray error box (Melandri et al., 2016)[13] by MASTER-IAC wide field camera with a 5 second exposition time without filter and imaged several thousand frames.

MASTER-Tavrida started first frame exposition 12 seconds after LAT notice time (66s after trigger time) at 22:44:30UT.

MASTER-Tavrida and MASTER-IAC very wide field of view cameras (VWFC) observed GRB error-box when the Fermi-LAT detected the main impulse of GRB with a high coordinate accuracy of 0.5 degrees, 131 seconds after the first message.

MASTER OT J203423.51+065508.0 optical counterpart was detected at 22:43:30UT (+2.5 sec of exposition) UT with m_{OT}=8.60 and was getting brighter up to a maximum of 7.86m(see Fig. 2). The prompt optical emission strongly correlated with Konus-Wind gamma ray light curve (Svinkin et al., 2016).[11]

MASTER-IAC robotic telescope started observation of the error box 43 sec after LAT notice time or 95 sec after trigger time at 2016-06-25 22:44:59UTby main MASTER-II telescope in two polarizations. The OT was 8.6m at the moment.

As a result, MASTER not only registered the entire event of the GRB explosion in the optical range with the best time resolution (2.5 sec), but for the first time in the history of gamma-ray burst research, it detected the polarization of prompt optical emission from the gamma-ray burst while the flash was still going on (Troja et al. 2017a).[7]

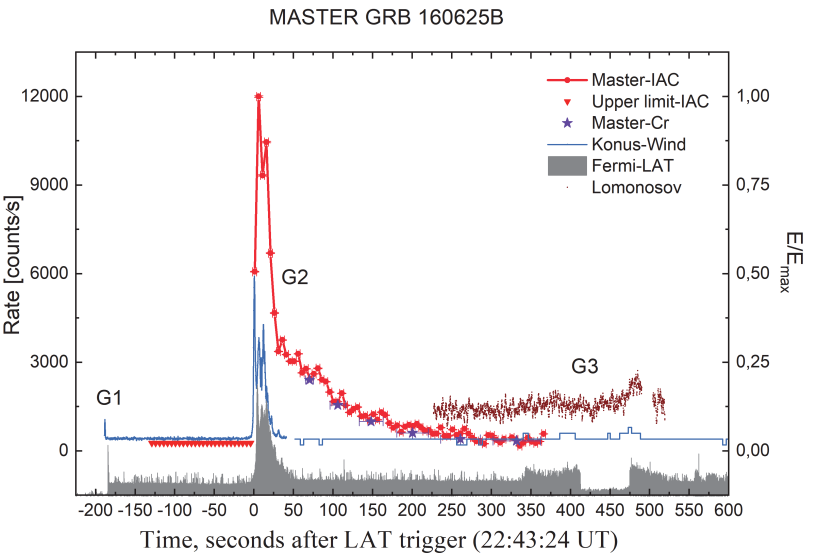

Fig. 2. Red curve - observations of the very wide-field MASTER-IAC cameras, reduced to the proper time of the system (compression of the burst time scale relative to the observed one). The purple dots corresponds to the MASTER-Tavrida measurements taken with a lower temporal resolution. The gray curve corresponds to the emission detected by Fermi-LAT (see Toja et al. 2017a.[7]

The gamma-ray burst GRB160625B turned out to be one of the most powerful cosmic explosions of this type, which appeared as a narrow jet of relativistic particles accelerated by the electromagnetic field of a rapidly rotating black hole at the other end of the Universe forming before our eyes.

An analysis of the MASTER's polarization observations made it possible for the first time to detect the polarization of GRB's intrinsic optical radiation and directly showed that the muzzle of the most powerful space gun was formed by an ordered powerful magnetic field of a forming black hole (Troja et al., 2017).[7]

This magnificent astrophysical experiment succeeded thanks to the interaction of scientists from several countries, who created unique robotic equipment to detect gamma rays, infrared radiation, and photons in the optical range born by the GRB event.

2.3. *LOMONOSOV Observations*

The GRB monitor (BDRG) aboard the Lomonosov (Sadovnichii et al. 2017)[10] observatory (hereafter BDRG/Lomonosov (Svertilov et al., 2018)[37] was built for the early detection of GRBs in the gammas of 0.01-3.0 MeV energy range and for generation of triggers for those events. The BDRG consisted of 3 identical detector units

connected to the electronic unit. The BDRG instrument detector units (blocks) were mounted on the spacecraft payload platform in such a way that their axes are oriented 90° to each other. Each detector has a cosine angular dependence for a sensitive area not shaded by satellite construction elements within $\sim 60°$ of its axis. The monitor's central axis, relative to which the detector axes are inclined, is directed toward to the local zenith. Thus, the total field of view for all three detectors is about 2π sr; and one quarter of this field, i.e. $\pi/2$ sr, is the value of a solid angle, within which limits the GRB position error can be estimated with sufficiently good accuracy through the comparison of all three detector outputs.

BDRG operates in two main observational modes: the monitor or continuous mode, and the burst mode. In the monitor mode all instrument outputs were recorded and stored continuously with time resolutions adjustable by commands from Earth. On the other hand, the burst mode was activated by on-board instrument triggers to record detailed information of each photon during the before-burst, burst, and after-burst time intervals. The BDRG trigger initiated the estimation of GRB positions and relayed the trigger not only to other GRB observation instruments onboard the Lomonosov spacecraft, i.e. SHOK optical cameras (Lipunov et al., 2018)[23] and Ultrafast Flash Observatory (Park et al., 2018),[38] but to the ground telescopes as well through the Gamma-ray Coordinates Network (GCN, Barthelmy et al. 1998ab)[21] viathe Global Star transmitter.

Each BDRG detector unit consisted of a thin layer (0.3 cm) of NaI(Tl) crystals optically coupled to a considerably thicker layer (1.7 cm) of CsI(Tl) crystals situated underneath. The diameter of the detectors is 13 cm, and both layers are read by a single photomultiplier tube (PMT). Thus, the overall detector area is about 130 cm2. The thickness of the NaI(Tl) layer is optimized for the soft part of energy range, and the working ranges of the units are 0.01-0.5 MeV for the NaI(Tl) layer and 0.05-3 MeV for CsI(Tl). As such, the NaI(Tl) layer serves as the main detector for hard X-ray timing, while the CsI(Tl) operates as an active shield against background gamma-rays. Additionally, the CsI(Tl) crystals can also detect gamma-rays with energies up to a few MeV. The difference in decay times for the NaI(Tl) ($\sim$0.25 ms) and CsI(Tl) ($\sim$2.0 ms) crystals permits the separation of light flashes in the scintillators through special electronic circuits that differentiate pulse shapes.

The information provided by the BDRG units consisted of a number of different categories for the data frames generated continuously (continuous mode) as well as irregularly by various triggers (burst mode). The continuous data stream included three types of frame corresponding to the instruments' monitoring, spectrum, and event. Monitoring frames provided count rates in 8 energy channels for the NaI(Tl) and CsI(Tl) scintillator crystals for each of the BDRG detector units, while spectrum frames contain 724 channel spectra for NaI(Tl) and CsI(Tl), separately. Event frames gave the primary values for energy release within the NaI(Tl) and CsI(Tl) crystals, combined with time data for a fixed number of detected gamma-quanta. Likewise, information about the main parameters for all GRB triggers was stored

and transferred in the form of "trigger logs". There are three trigger types categorized as "fast," "slow" and "super-slow," with characteristic times of 10 ms, 1 s, and 20 s, respectively. Corresponding to each trigger type, three data frame sequences for the monitoring, spectrum, and event were generated continuously in a manner similar to the continuous mode discussed above. A portion of data collected before the trigger was always included for all trigger types.

On 25 June 2016 near the GRB160625B trigger, the BDRG/Lomonosov operated in monitoring mode. The background environment at the time of event was very complicated. The Lomonosov satellite was flying through the radiation belts.

The count rate variations in the BDRG/Lomonosov gamma-quanta channels are illustrated by the curves in the upper panel of Fig. 3, in which count-rates of three BDRG-1 NaI detector channels 10 – 35, 35 – 170, 170 – 650 keV shown with the time resolution of 0.1 s are plotted. Full data is available on the link(http://master.sai.msu.ru/static/MG16MASTER/BDRG160625B.txt)

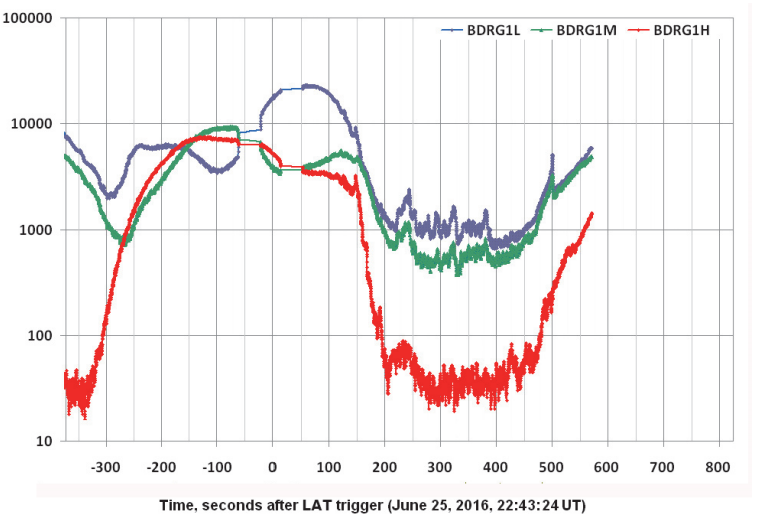

Fig. 3. GRB160626B γ-ray light curves.The BDRG-1(NaI detector) counts vs time in the 10-35keV (BDRG1L), 35-170 keV (BDRG1M), 170-650 keV (BDRG1H) ranges.

The clear count-rate increases in the time interval from about -150 to 350 seconds relative to the Swift trigger time (-300 to 200 seconds relative to the LAT trigger time) corresponds to the satellite crossing outskirts of the external radiation belt. After that the satellite flew into the region of the South polar cap, where the background is smaller, and after that it began to cross the outer belt again and the background began to increase. Thus, due to such background variations the main pulse (G2) as well as the precursor (G1) could not be observed on by the

Lomonosov satellite detectors. Only the "last tail" (G3) could be observed. However, during the corresponding time interval (from about 350 to 550 seconds from LAT trigger time) count variations in the BDRG/Lomonosov were in reality combination of GRB counts plus variations caused by unstable electron fluxes in the polar cap. The last component can give the significant input in gamma ray channels of the instrument due to electron bremsstrahlung. Thus, to obtain the real GRB light curve it is necessary to clean the detector outputs from electron background variations.

To realize this procedure we used the outputs from different BDRG detectors. Because of different BDRG detector orientation the given GRB source was observed by separate detectors at different angles. In the case of GRB160625B only BDRG1 detector unit was illuminated, the angle between the detector axis and direction toward the GRB source was about 56°, while for BDRG2 and BDGR3 these angles were about 136° and 116° respectively. It means that GRB source was out of field of view (FOV) of both latter detector units. On the other hand, since counting rate of the irregular variations observed in the polar cap regions are mainly due to the quasi-trapped electron fluxes having an anisotropic but rather wide pitch-angle distribution, they will exhibit similar temporal behavior in separate, although differently oriented detectors. It allows us to use regression analysis of detector unit count rates obtained for two detectors during time interval of GRB observation to estimate regression coefficients, which then can be used for rejection of the part of counting rate variations caused by electron fluxes. Because during the time of GRB160625B observation BDRG2 unit was switched-off, for regression analysis only the BDRG1 and BDRG3 unit outputs were used. To be exact, we selected time interval from 200 to 450 seconds after LAT trigger (22:43:24UTC) to estimate regression coefficients, which corresponds to the time between G2 and G3 events, when expected input to detectors counting rates from GRB160625B was negligible.

2.4. *Konus-Wind observations*

GRB 160625B triggered Konus-Wind GRB spectrometer (KW, Aptekar et al. 1995)[41] at T0= 81619.875 s UT (22:40:19.875; Svinkin et al., 2016).[11] The burst was detected by the S2 detector, which observes the Northern ecliptic hemisphere; the incident angle was 65.2 deg. The propagation delay from Earth to WIND is 3.356 s for this GRB; correcting for this factor, the KW trigger time corresponds to the Earth-crossing time 81616.519 s UT (22:40:16.519).

2.4.1. *Time history*

Count rates for Konus-Wind are recorded in three energy bands in the triggered mode: 17–70 keV (B1), 70–300 keV (B2), and 300–1170 keV (B3). The record starts at T0 - 0.512 s and continues to T0 + 229.376 s with an accumulation time varying from 2 to 256 ms. Waiting-mode count rate data are available up to T0 + 250 s

in the same energy bands with a coarse temporal resolution of 2.944 s. A source activity after time interval T0 + 250 s may be traced in the housekeeping mode with temporal resolution of 3.68s for the 70–300 keV energy range.

The prompt-emission light curve (Fig. 4) can be divided into three episodes. It starts, at ∼ T0 - 0.3 s, with a short, spectrally-soft initial pulse (precursor) which has duration of about 1 s. The precursor is followed, starting at ∼ T0 + 180s, by the main, extremely bright and spectrally-hard emission episode lasting for about 40 s. The final episode observed by KW in the housekeeping mode starts at ∼ T0 + 530 s and has duration of about 150 s. The total burst duration is about 680 s.

The first episode was localized only by Fermi (GBM) with a position uncertainty of about 2 deg (statistical only). The difference in the arrival time of the gamma-ray signals at Fermi-GBM and Konus-Wind provides additional significant constraints on the gamma-ray localization of the episode (Zhang et al., 2018).[42] The triangulation of the first episode is consistent with the source position determined by Swift-XRT in the main episode, supporting the association of the precursor and the burst.

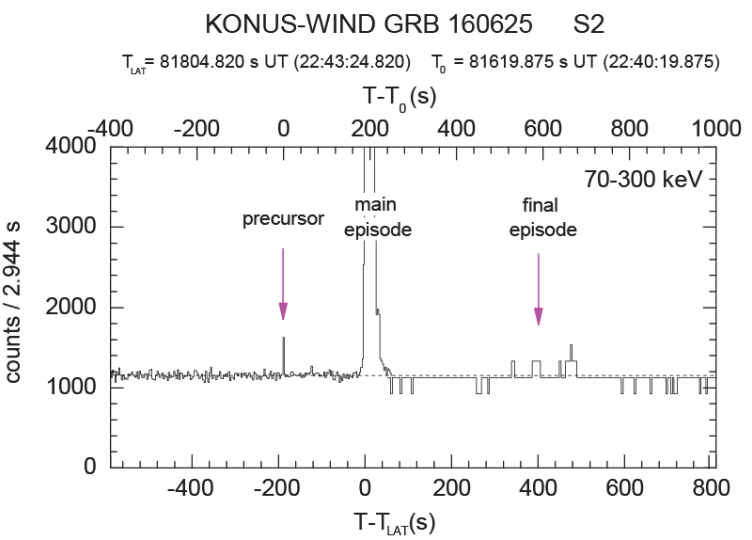

Fig. 4. GRB 160625B light curve recorded in the KW waiting and housekeeping modes in the 70-300 keV band (B2).

Let us discuss the time-resolved spectral analysis. In the triggered mode, Konus-WIND measures 64 energy spectra in 128 channels of two overlapping energy bands: 20–1170 keV (PHA1) and 244 keV–15 MeV (PHA2). The first four spectra have a fixed accumulation time of 64 ms; after that, the accumulation time varies over 0.256-8.192 s, depending on the current intensity of the burst. Five initial energy

spectra covered the precursor (T0 – T0+8.448 s) and 35 covered the main episode (T0+180.480 - T0 + 237.824 s).

The spectral analysis was performed with XSPEC version 12.9.0i (Arnaud 1996)[43] with the three model: Band GRB function (Band et al. 1993):[44] $f(E) \sim E^{\alpha} exp(-(2+\alpha)E/Epeak)$ for $E < Epeak(\alpha-\beta)/(2+\alpha)$, and $f(E) \sim E^{\beta}$ for $E > Epeak(\alpha-\beta)/(2+\alpha)$, where α is the power law photon index at low energies, Epeak is the peak energy in the EF(E) spectrum, and β is the high-energy photon index; a cutoff power law model (CPL): $f(E) \sim E^{\alpha} exp(-(2+\alpha)E/Epeak)$; and a simple power law. The spectral models were normalized to the energy flux in the 20 keV – 10 MeV range, a standard band for the KW GRB spectral analysis.

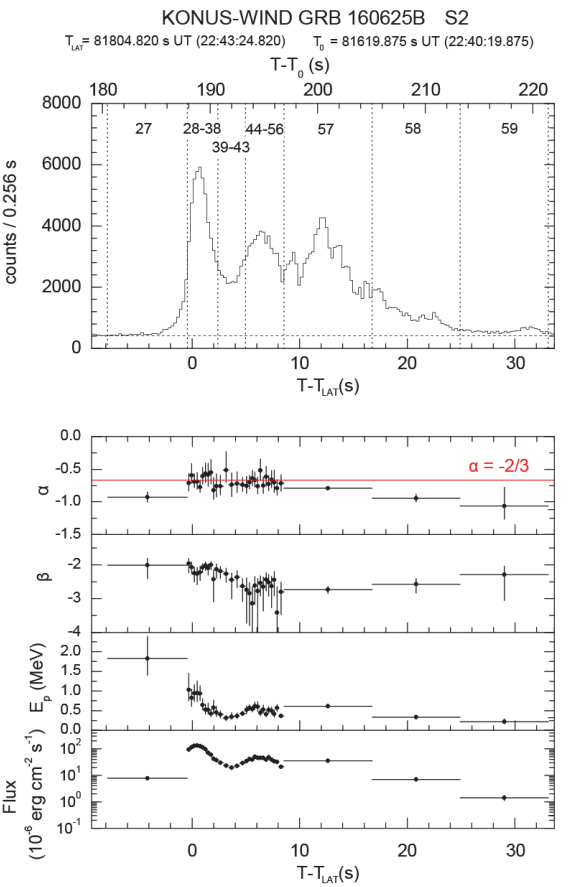

Fig. 5. Spectral evolution of the gamma-ray emission during the prompt phase of the burst main episode. The Konus-WIND light curve in the combined B1+B2+B3 energy band (17-1170 keV) is shown with 256 ms resolution, along with the temporal behavior of the Band spectral model parameters Epeak, α, and β obtained from the time-resolved fits.

Typically, the spectral channels are rebinned to have at least 10 counts per energy bin to ensure Gaussian-distributed errors and the correctness of the χ^2 statistic.

For the precursor, constrained spectral parameters of the CPL model are available only for the sum of the first four spectra, while for the main episode, a good count statistic is achieved for 35 individual spectra between T0+180.480 s and T0+237.824 s, the spectrum between T0+ 229.632 s and T0+237.824 s is well described by a simple power law. The good spectral coverage enables us to construct the temporal behavior of the model parameters (α, β, Epeak) and to trace in detail the evolution of the spectral composition of radiation over the course of the main episode (Fig. 5).

Spectrum 27 was measured at the onset of the very intense initial pulse of the main episode (Fig. 5). The emission at this moment is hard; Epeak reaches the highest value for the burst ($\sim$ 1.8 MeV). After the summit of the brightest pulse, Epeak starts to decrease gradually (spectra 28-38), down to $\sim$ 300 keV in spectra (39-43), and then grows up to $\sim$ 600 keV at the time of the second peak (spectra 44-56), staying at this level during the last peak (spectrum 57). Spectra 58-60 describe the decay of the main episode showing the typical decrease in Epeak. During the brightest part of the main episode the low-energy spectral index is approximately constant and is consistent with the synchrotron emission in the slow-cooling regime $\alpha = -2/3$ (Preece et al., 1998).[45] The high-energy index β shows no significant correlation with energy flux and is typical for long GRBs ($\beta \sim$ -2).

Spectrum 1-4 (time –averaged), corresponding to the peak of the initial pulse is well fitted with a CPL model with $\alpha \sim$ -0.4, and Epeak $\sim$ 70 keV (χ^2/dof = 16.5/29). The fit with a single blackbody (BB) component yields kT= 17.3 (-1.6, +1.6) keV, energy flux 1.92 (-0.19,+0.19) $10^{-6} erg/cm^2/s$, with $\chi^2/dof = 32.1/30$; the fit underestimates count rate at energies below $\sim$ 30 keV. Thus, despite the BB kT is consistent with the value found by Zhang et al., 2018,[42] we argue that BB model cannot be favoured for the spectrum.

3. Modeling

Looking at the optical light curve starting from 20 seconds relative to the main pulse and up to 200 - 250 seconds, one can suspect quasiperiodic brightness oscillations with an amplitude significantly exceeding the random brightness measurement error. Recall that a five-second exposure on ultra-wide field cameras is practically without delay. Such variability at times of the order of ($\tau \sim$ 10-20 seconds) is caused by internal physical processes in the operation of the central engine. However, it would be tempting to associate this phenomenon with the interaction of a relativistic jet with quasiperiodic inhomogeneous layers in the radial distribution of the progenitor's stellar wind. This type of inhomogeneity can be caused by the presence of a close second component in the collapsing star's binary system. Calculations carried out earlier (Lipunova et al. 2009)[6] show that in systems with an orbital period of less than 1 - 2 hours, tidal forces lead to a critical increase in the spin

moment of the collapsar. As a result, it is under these conditions that the formation of a massive accretion disk (Woosley 1993)[46] or a spinar (Lipunov & Gorbovskoy, 2007)[2] prolongs the magneto-rotational collapse, which leads to the phenomenon of a gamma-ray burst.

First of all, we will discuss the possible reasons for the quasiperiodic optical emission, which is an intrinsic emission at the stage of the central engine operation and must reflect some quasiperiodic oscillations of the central engine. This circumstance is supported by the fact that we detect oscillations after 30 seconds (in our own frame of reference) from the trigger, that is, at the same time when the optical and gamma spectra become one. Recently, Suvorov and Kokkotas (2021)[47] discussed quasiperiodic pulsations of X-rays from some short GRBs in the magnetar model. Actually, the only property of the magnetars used here is the one inherent to all radio transmitters they loose energy approximately according to the magnetic dipole law (Pacini, 1967)[48] and their total power changes over time $L \sim t^{-2}$. In connection with the gamma-ray bursts, this circumstance was expressed by Lipunova & Lipunov (1998).[4] The merit of the works of Suvorov and Kokkotas (2021)[47] is the attraction of the idea that the observed quasiperiodic oscillations are associated with the free precession of a neutron star with an anomalously strong magnetic field. In fact, the magnetar model is only a special case of a more general model of the magnetorotational collapse - Spinar Paradigm (Lipunov & Lipunov, 1998; Lipunov & Gorbovskoy, 2007, 2008; Lipunova et al., 2009).[2,4–6] In the framework of Spinar Paradigm, it is assumed that the initial rotational moment of the body is so great that centrifugal forces have a significant effect on the collapse process. In particular, this model successfully explains not only the plateau phenomenon, but also a sharp (by several orders of magnitude) cliff at the end of the plateau (Lipunov & Gorbovskoy, 2007).[2] In fact, an approximate non-stationary model of gravitational-rotational collapse (Lipunov & Gorbovskoy, 2008)[5] includes all relativistic effects plus the contribution of the nuclear forces of the neutron liquid. The collapse character depends on three main parameters: the core mass M of the collapsing star, the generalized Kerr parameter $a_0 = I\omega_0 c/GM^2$ and the ratio of magnetic and gravitational energy $\alpha_m = U_m/U_{gr} << 1$ which remains constant in the approximation of the conservation of the magnetic flux. A black hole or a neutron star can also be the end product of the collapse (Lipunova et al., 2009).[6] In the process of formation of both types of objects, an intermediate object is formed - a spinar - which can experience not only free, but also forced precession. In addition, if a neutron star can only slow down, decreasing the overall luminosity, the spinar can accelerate as it evolves, and this will even be accompanied at certain stages by an increase in luminosity. It is precisely by the spinar precession that we propose to explain the suspected oscillations of the intrinsic optical emission of the GRB160625B gamma burst. Remarkably, the magneto-rotational collapse model naturally explains the existence of the precursor, with which we begin.

In the spinar model, the precursor of the gamma-ray bursts occurs during the first abrupt stop of the collapse due to the increase in centrifugal force (Fig. 6).

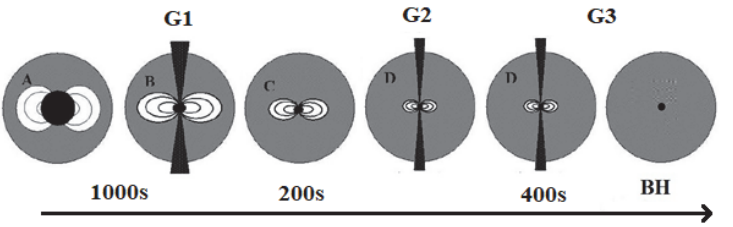

Fig. 6. Scheme of the three-stage magneto-rotational collapse in the Spinar Paradigm.

At this moment, half of the gravitational energy accumulated by the free-falling progenitor core is converted into heat. The second half of the work of gravitational forces turns into the energy of the spinar rotation. In other words, the centrifugal forces stop the collapse and a spinar is formed - which continues to slowly contract, losing its extreme moment and constantly increasing its radiation power (see Fig. 6). This is the formation of the precursor! Its maximum power $E_{precursor} \approx GM^2/2R_{sp}$ is determined by the radius of the formed spinar (Lipunov & Gorbovskoy, 2007)[2] $R_{sp} \approx a_0^2 R_g/2$, where R_g – Shwarcshild radius:

$$E_{precursor} \approx GM^2/2R_{sp} \approx (1/2a_0^2)Mc^2 \quad (1)$$

If the core torque is not too high $a_0 < 5-10m^{-1}(m = M/M_0)$, then this energy directed mainly along the spinar rotation axis will pierce the progenitor shell and we will see the precursor (Lipunov & Gorbovskoy, 2007).[2] However, immediately after the formation of the Spinar, the energy released by the spinar will already be determined by the magnitude of the magnetic energy $L_{sp} = U_m\omega \approx \alpha_m U_{gr}\omega$. Accordingly, the energy released by the spinar in one spin period and the corresponding pressure impulse on the shell will be reduced by a factor of $\alpha_m << 1$, hence the jet breakdown will happen. But if the torque is lost, the luminosity of the spinar will grow $L_{sp} = U_m\omega \approx \varepsilon_m U_{gr}\omega$ and finally break through the shell. This will be the time close to the beginning of the gamma-ray burst t_{GRB}. However, the time elapsed from the precursor to the start of the gamma-ray burst will be determined by the rate of loss of the spinar torque at the moment of its formation:$\Delta t \approx I\omega/U_m$. We can express the magnetic energy through the magnetic flux $\Phi = \pi BR^2 = \Phi_{28}10^{28}Gs\,cm^2$, thus normalizing the flux to the characteristic of magnetars the does not change during the collapse, according to our assumption. Then we get the precursor time:

$$\Delta t_1 \approx -800s\,\Phi_{28}^{-2}m_{10}^3a_0^3 \quad (2)$$

Kerr Black Hole released energy can reach 44% (Kip Thorne, 1974),[49] we get another important ratio of precursor fluence to gamma-ray burst fluence $E_{pre}/E_{GRB} \approx a_0^{-2}$. Usually there is a ratio $E_{pre}/E_{GRB} \approx 1-10\%$ (Troja, 2007),[50] corresponding

to the generic Kerr parameter $a_0 \sim$ 3-10 . For the masses of nuclei close to M $\sim$ M_{OV}, a larger Kerr parameter is required. However, in this case, it is necessary to include the contribution of nuclear forces (Lipunova et al., 2009).[6]

After the formation of the spinar, the direction of the magnetic flux of course does not have to coincide with its axis of rotation. We recall that we are considering the case of the conservation of the magnetic flux without an accompanying generation of the type of the dynamo mechanism. Therefore, a spinar can participate in a free precession, especially when it turns into a magnetar. However, a spinar is not a neutron star, whose surface is a hard boundary, beyond which there is a vacuum, or a highly discharged magnetosphere with a Julian-Goldreich density (Lipunov, 1992).[51] Spinar is an idealization of a superdense rotating body surrounded by a gas-dynamic plasma. Its evolution can be described by the equation:

$$dI\omega/dt = K_{\parallel} + K_{\perp} \tag{3}$$

On the right is the moment of forces, the parallel component of which leads to a change in the spinar's rotational moment in magnitude, and the perpendicular component leads to forced precession. It is clear that the spinar is not a rigid body, but the experience of studying the precession of accretion disks under the action of the magnetic moments of the seat shows that even thin disks successfully precess, though in a differential way (Lipunov & Shakura, 1980).[52] The maximum value of both moments of forces in equation 3 is determined as $|K| \approx U_m = \varepsilon_m U_{gr}$. The forced precession frequency turns out to be of the order of $\Omega = |K_{\perp}/I\omega| \approx \varepsilon_m \omega$. As the spinar radius approaches the event horizon $R \to R_g/2$ spinar frequency tends to the $\omega \to c/R_g$ as $R \to Rg$. So far as $U_m \to \varepsilon_m Mc^2$ we get an estimate of the precession period:

$$T = 2\pi/\Omega = (2\pi/\omega)\varepsilon_m^{-1} \approx 5000s\, \Phi_{28}^{-2} m_{10}^3 r^{3/2} \tag{4}$$

Here $r = R/Rg$.

For the precursor GRB160725B in its own frame of reference $\Delta t_{pre} \approx -70s$ (we took z = 1.406 (GCN circular №19600), and the characteristic time of variations is T $\approx$ 10 sec. From 2 and 4 we obtain the estimate $a \approx 10$ and $\Phi_{27}^{-2} m^3$. Accordingly, the magnetic flux turns out to be quite reasonable $\Phi_{27}^{-2} \approx 140 m^{3/2}$.

After the main pulse (G2), the luminosity of the spinar begins to decrease. This is a sure sign that the role of nuclear forces is becoming important. The role of nuclear forces can become important only if the mass of the collapsing nucleus does not greatly exceed the Oppenheimer-Volkov limit. Let us recall that the Oppenheimer-Volkov limit essentially depends on the contribution of centrifugal forces to the equilibrium of the neutron star. So if the fraction of the rotational energy in the virial theorem is 10-20%, the Openhemer Volkov limit can increase by 2-3 times, depending on the equation of state of the neutron star (Lipunov, 1992).[51] With a mass of 4-5 solar masses, the spinar will be supported by nuclear forces until it freezes. This will happen during the after

$$\Delta t_3 \approx I\omega/U_m \approx 6I\omega R/\Phi^2 \approx 10s\, m^2 \Phi_{27}^{-2} r^2$$

So far as $r \to 1/2$ relativistic effects should be taken into account immediately.

Next, we applied a dynamic model of gravimagnetic collapse, which allows us to describe the evolution of a collapsing spinar from the moment of the loss of stability to the collapse into a black hole (Lipunov & Gorbovskoy, 2008; Lipunova et al., 2009).[5,6] In this formulation, a simple non-stationary three-parameter model of collapse is obtained with the decisive role of the rotation and the magnetic field. The input parameters of the theory are the mass, angular momentum and magnetic field of the collapsar. The approximate model includes: centrifugal force, relativistic effects of the Kerr metric, pressure of nuclear matter, dissipation of angular momentum under the influence of a spinar magnetic field, decrease in the dipole magnetic moment as a result of compression and the effects of general relativity (a black hole has no hair), neutrino cooling, time dilation due to gravitational redshift.

In Fig. 7 the results of calculating our approximate model are shown, the parameters of which are given in Fig. 1. Obviously, the main time intervals between the events of the gamma-ray burst G1, G2, G3 are in good agreement with observations. Of course, we do not pretend to describe a detailed light curve within the framework of our approximate model. We can only compare with observations the total energy release of the central engine at times G1, G2 and G3.

Table 1. Core collapse with the mass $M = 3.52M_\odot, M_{OV} = 2.5M_\odot$, effective Kerr parameter $a_0 = 4.9$ and magnetic parameter $a_m = 10^{-4}$.

Stage	Time(obs),s	E(obs)/E90	Time,s	E/E90	R/Rg	B,Gs	a_0
G1	-180	0.02	-75	0.03	37	10^{13}	4.9
G2	0	0.88	0.93	2	3	$2 * 10^{14}$	2.4
G3	$\sim$450	190	0.04	0.04	3	$1.2 * 10^{15}$	1

We associate a slight increase in the gamma flux in G3 with an increase in the power of the central engine at the moment when the spinar loses its stability and collapses into a black hole. Note that such a three-stage collapse occurs only when the mass of the collapsing nucleus exceeds but is comparable with the Oppenheimer – Volkov limit.

4. Discussion

We presented multi-wavelength observations of GRB160625B, one of the brightest gamma-ray bursts in the history of their study. The authors of the article have already published a paper, concerning the first in the history discovery of variable polarization of the intrinsic emission of gamma-ray bursts (Troja et al., 2017).[7] Here we have concentrated on the temporal behavior of itsintrinsic electromagnetic radiation and presented optical and gamma-ray data, recorded during the time of the operation of the central engine of GRB160625B. We made an attempt to find

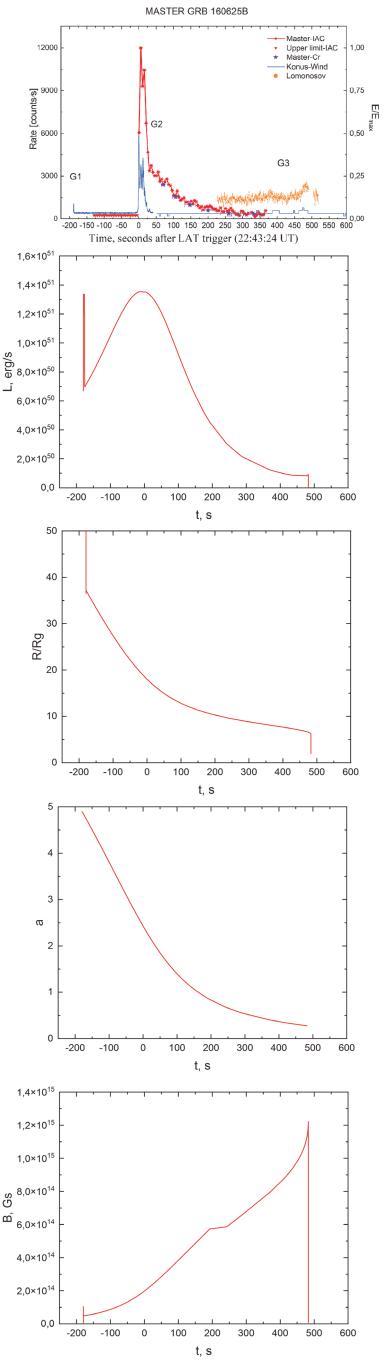

Fig. 7. In the diagram of the GRB160625B event in the observer's frame of reference is shown. In the top diagram, we have shown three principal G1 events - the position of the precursor (Δt = −200 s), the main peak of the G2 pulse (t = 0) and finally the last episode of increased G3 activity (Δt = 400–500 s).

traces of the duality of the GRB system, suspected traces of the dual nature of long GRBs. This study can serve as an example of searching for and finding the dual nature of long GRBs.

Long bright GRB160625B is rare, but not unique. GRB 080319B (Racusin et al., 2008)[53] also had a significant gap between the optical flux and the flux obtained by extrapolating the standard spectrum to the low frequency range. For GRB 080319B Kumar and Narayan (Kumar, Narayan 2009)[54] (see also Lazar et al 2009)[55] proposed a relativistic turbulence model to explain the fine structure of the light curve observed in the gamma range. It is assumed that the matter of the dropped shell is divided into two phases: the turbulent cells and everything in between. In this case, gamma emission is generated in both phases (reverse Compton), and synchrotron radiation of electrons in the inter-cell space is responsible for the radiation flux in the optics.

This explains a number of observed properties of gamma-ray bursts and, what is important in the context of this work, the huge excess of the flux in the optical range over what is dictated by the Band function. However, the natural consequence of this theory is a diminishing of the polarization over time, since the assumed turbulence entangles the magnetic field, leading to depolarization. In fact, the MASTER polarization observations (see Troja et al., 2017)[7] show an increase in polarization. Thus, in the case of GBR 160625B, the relativistic turbulence model does not work.

We interpret the features of the GRB160625B radiation within the framework of the model of a three-stage magnetorotational collapse of the core of a massive star whose mass exceeds but is comparable to the Oppenheimer-Volkov limit. In this model, the first G1 event in Spinar Paradigm will be explained by an abrupt stop of the nucleus collapse at the centrifugal barrier and the formation of a spinar. In this case, half of the accumulated gravitational energy is converted into rotational energy, and the second can be converted into jet energy along the spinar's axis of rotation. Further, as the rotational moment is lost, the spinar is compressing, gradually increasing its rotational energy, mainly emitted along the axis of rotation with a power of the proportional to the Umov-Poynting vector electromagnetic energy flow $E_{G1} = U_m\omega$. Of course, the observer will not see a smooth curve, since the jet must accumulate enough energy to pierce the progenitor shell (Lipunov & Gorbovskoy, 2007).[2] Naturally, in a model based on the conservation laws with an approximate description of the torque dissipation, one should not rely on the exact repetition of the light curve at the moment of the mainpulse G2. Therefore, we only achieved the coincidence of the moment of the maximum energy release with observations and the interval preceding the collapse of a heavy spinar with a powerful magnetic field and a mass exceeding the Oppenheimer-Volkov limit for a non-rotating neutron star.

Gamma-ray bursts (GRBs) are bright extragalactic flashes of gamma-ray radiation and briefly the most energetic explosions in the Universe. Their catastrophic origin —the merger of compact objects or the collapse of massive stars— drives the formation of a newborn compact remnant (black hole or magnetar) that powers two highly relativistic jets. As these jets continue to travel outwards, they collide with the external material surrounding the dying star, producing a long-lasting afterglow that can be seen across the entire electromagnetic spectrum, from the most energetic gamma-ray emission to radio wavelengths. But how can such material be accelerated and focused into narrow beams? The internal shock model proposes that repeated collisions between material blasted out during the explosion can produce the gamma-ray flash. The competing magnetic model credits primordial large-scale ordered magnetic fields that collimate and accelerate the relativistic outflows. To distinguish between these models and ultimately determine the power source for these energetic explosions, our team studies the polarization of the light during the first minutes after the explosion (using novel instruments on fully autonomous telescopes around the globe) to directly probe the magnetic field properties in these extragalactic jets. This technology allowed the detection of highly polarized optical light in GRB 120308A[1] and confirmed the presence of mildly magnetized jets with large-scale primordial magnetic fields in a reduced sample of GRBs (e.g. GRB 090102,[2] GRB 110205A,[3] GRB 101112A,[3] GRB 160625B[4]). Here we discuss the observations of the most energetic and first GRB detected at very high TeV energies, GRB 190114C,[5] which opens a new frontier in GRB magnetic field studies suggesting that some jets can be launched highly magnetized and that the collapse and destruction of these magnetic fields at very early times may have powered the explosion itself.

Additionally, our most recent polarimetric observations of the jet of GRB 141220A[6] indicate that, when the jetted ejected material is decelerated by the surrounding environment, the magnetic field amplification mechanisms at the front shock —needed to generate the observed synchrotron emission— produce small magnetic domains. These measurements validate theoretical expectations and contrast with previous observations that suggest large magnetic domains in collisionless shocks (i.e. GRB 091208B[7]).

Gamma-ray bursts (GRBs) are briefly the most intense sources of gamma-ray photons in the Universe to the extent that they outshine any other kind of gamma-ray emitter present in the sky map. The amount of energy released in a matter of milliseconds to hundreds of seconds provides a unique opportunity to study physics in extreme environments (e.g., GRB central engines, jet composition, energy dissipation, acceleration, collimation, shock physics) and test the physical models regarding the nature of their progenitors.[8,9] Additionally, their brightness and cosmological distances make them useful for probing the composition of the early Universe.[10,11]

GRBs with long duration (typically $> 2\,$s; see Ref. 12) are related to the death of massive stars as single collapsars[13,14] or in binary systems,[15] and short GRBs ($< 2\,$s) to mergers from an old population of degenerate compact stars. Possible merger candidates include neutron star binaries[16,17] or binaries containing a stellar black hole and a neutron star companion.[18–20] Due to their inspiral and coalescence, they are emitters of gravitational waves[21] and they are also promising candidate sources of high-energy neutrinos.[22]

GRBs are produced when the central engine (a black hole or magnetar) drives out two bipolar relativistic jets that burrow through the stellar ejecta and emit the characteristic prompt gamma-ray emission via internal dissipation mechanisms[23] —i.e. internal shocks[24] or reconnection.[25] Later on, the relativistic ejecta are decelerated by the circumburst medium by a pair of external shocks:[26,27] a short-lived reverse shock[28,29] and a forward shock (see Fig. 1). This lagging emission called the afterglow radiates via synchrotron emission and can be detected seconds to years after the burst at wavelengths across the electromagnetic spectrum.[30,31] In this context, a variety of afterglow light curves are expected depending on the relative contributions of the reverse and forward shock.

1. Magnetic fields in GRBs

Magnetic fields play an important role in the physics of GRBs by affecting how the jet is launched (formation, acceleration, collimation and composition of the jet) and in shaping the afterglow emission (particle acceleration by the shock). Depending on the driving mechanism of the relativistic outflow —if dominated by kinetic or magnetic energy— GRBs jets can be launched as baryonic (also named hydrodynamical jets[32]) or magnetized jets (i.e., Poynting-flux jets[33,34]). The degree

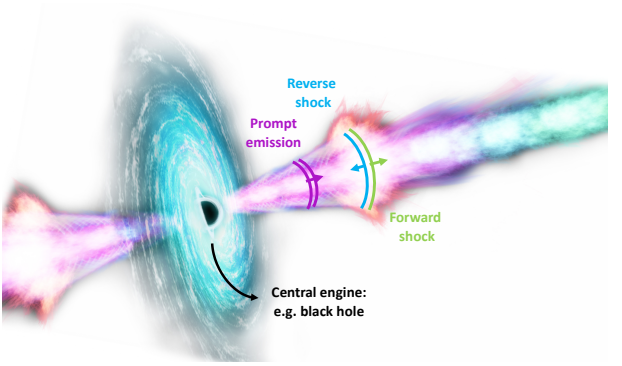

Fig. 1. Schematic representation of a GRB outflow. The steps for the formation of a GRB are: (1) an extragalactic massive star collapses or two compact objects merge, (2) there is accretion onto a newborn black hole, and (3) the ejecta are collimated and accelerated to relativistic speeds along the narrow beam of a jet. Note that the emission we detect (prompt gamma-ray emission and afterglow) comes from sites at different distances from the central engine. Additionally, the afterglow (reverse and forward shock) is formed at the contact discontinuity between the outflow and the circumburst medium.

of magnetization of an outflow is usually characterized by the parameter σ, which is defined as the ratio of magnetic to kinetic energy flux.[35]

In a baryonic jet ($\sigma \ll 1$), neutrino annihilation at the polar region of a hyper-accreting system would launch a thermally-driven fireball that accelerates the material.[13,36] In this model, tangled magnetic fields are locally generated in shocks.[37]

In a magnetized jet ($\sigma \gg 1$), large-scale magnetic fields extract rotational energy from the black hole, accretion disk or magnetar (in a magnetohydrodynamic extraction[33,38,39]), which accelerates the material. The magnetization parameter σ influences the dynamics of the jet and it is thought to decrease with increasing distance from the central engine.[40] In this scenario, the magnetic field configuration is likely toroidal far from the black hole.[41] The detection or non-detection of this large-scale magnetic field remnant is crucial to support or discard the magnetic jet model. Furthermore, a plausible scenario is that GRB outflows are launched with a combination of both hot-baryonic and cold-magnetic components, leading to a broad range of magnetization degrees σ with consequences in the prompt and afterglow emission phase.[34,35,42]

2. The polarization of GRBs

GRBs are extragalactic collimated sources that are not possible to spatially resolve. Polarization offers a tool to study the magnetic field properties and the jet geometry on length scales orders of magnitude smaller than what imaging can probe. Additionally, it can give an extra dimension of information on the jet physics and underlying emission processes and provide complementary information that can

break degeneracies in the temporal and spectral evolution of the emission. Overall, the expected polarization signals in GRBs depend on the magnetic field topology (i.e. ordered or random depending on the jet model), the jet angular geometry,[43,44] and the emission mechanisms. While the emission mechanisms for the prompt emission are still under debate,[45] the afterglow emission is widely assumed to be synchrotron.[46] In the lab frame, synchrotron-emitted photons are linearly polarized,[47] with $P \approx 70\%$. However, the intrinsic polarization from synchrotron emission can be averaged out if the magnetic field topology is random.

During the afterglow stage, the forward shock emission is produced by shocked ambient medium, with tangled magnetic fields locally produced and amplified by e.g., a two-stream magnetic instability (Weibel instability[37,48]). Consequently, the forward shock emission is insensitive to the magnetic field structure of the original ejecta and it is expected to be unpolarized (see Section 2.2). In contrast, the prompt and reverse shock emission is still sensitive to the properties of the central engine ejecta and measuring the polarization allows discriminating between competing jet models (see Section 2.1).

2.1. *The polarization of baryonic and magnetized jets*

Distinct polarization signatures are predicted for magnetized and baryonic jet models. We expect unpolarized emission if the jet is baryonic[37] and polarized emission in a magnetized jet[49] from large-scale ordered magnetic fields advected from the central engine (see Fig. 2). Even if the magnetic fields become slightly distorted during the internal shocks, a mildly magnetized jet is still expected to produce large polarization levels, as only a small area of the jet is observed due to the relativistic beaming. However, note that the maximum synchrotron polarization is reduced to $P \approx 50\%$ due to relativistic aberration effects —i.e., the rotation of the polarization vectors.[50] In the case of a highly magnetized jet (see Fig. 2), reconnection mechanisms are thought to power the prompt emission,[25,51] which would in principle distort the order in the magnetic fields.

2.1.1. *Prompt gamma-ray emission*

Polarization studies of the prompt gamma-ray emission offer great prospects for the study of jet models.[52] However, current studies have yielded a wide range of polarization results,[52–59] i.e. $P = 0\% - 100\%$, with the discrepancy usually related to data with low signal-to-noise, instrumental bias or selection effects in the data analysis.[52,54] Furthermore, time-resolved analyses suggest that the polarization degree in time-integrated studies has been averaged out given that the polarization angle evolves through single pulses (see Refs. 60–62). More importantly, the interpretation of these results is complex given that the underlying physics of the prompt emission remain unknown.[45]

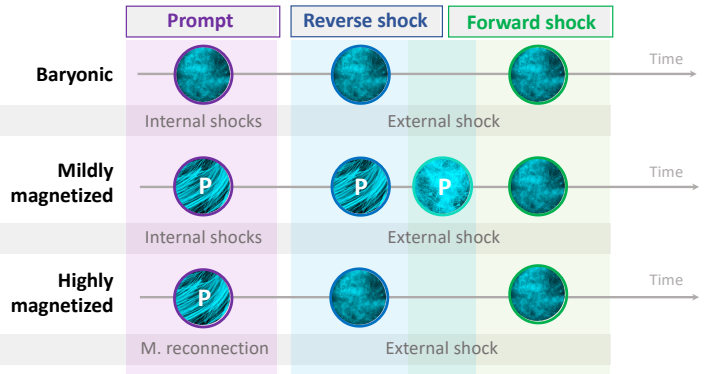

Fig. 2. Summary of the magnetic field structures expected in each jet model (baryonic and magnetized) for the different shocks (internal and external) and assuming synchrotron as the emitting mechanism. The white **P** letter denotes those magnetic field structures that would give rise to significant polarization (large-scale ordered or locally tangled magnetic fields). Note that emission from different origins can be blended into the overall received; e.g. in a mildly magnetized jet, the polarization can be reduced from the maximum expected given a mix of reverse and unpolarized forward shock emission.

2.1.2. *The early optical afterglow*

At optical bands, the polarization measurements from the early afterglow are the domain of robotic telescopes with rapid follow-up capabilities[69–72] (see Fig. 3). The first robust evidence of large-scale ordered magnetic fields in the fireball was the detection of $P = 10\% \pm 1\%$ polarization during the steep decay of GRB 090102 bright reverse shock.[2] This result suggested that primordial magnetic fields do play a role in GRBs outflows and that they can persist at great distances from the central source —up to the external shock radius. The GRB 120308A measurements further proved this idea with a time-resolved polarimetric light curve during a reverse-forward shock interplay[1] (see Fig 4); the polarization decayed steadily from $P = 28\% \pm 4\%$ to $P = 16^{+5}_{-4}\%$ with constant polarization angle due to the increase of unpolarized forward shock photons. Additionally, polarization degrees of $P = 13^{+13}_{-9}\%$ and $P \approx 6\%$ were also detected in GRB 110205A and GRB 101112A.[3]

Overall, current observations of polarized reverse shocks and the modelling of the early GRB afterglow suggest mildly magnetized jets at the deceleration radius,[35,73] with magnetization degrees $\sigma = 0.1 - 1$. These intermediate values of magnetization allow the existence of bright reverse shocks and are also consistent with the measurements of polarized reverse shocks (see Fig. 2). However, we note that some observations suggest higher magnetization at different stages of the jet. The $P < 8\%$ constraint during the fireball deceleration of GRB 060418[74] implies that the reverse shock could have been suppressed due to high magnetization in the fireball at the external shock radius, with $\sigma \geq 1$. Additionally, the optical emission

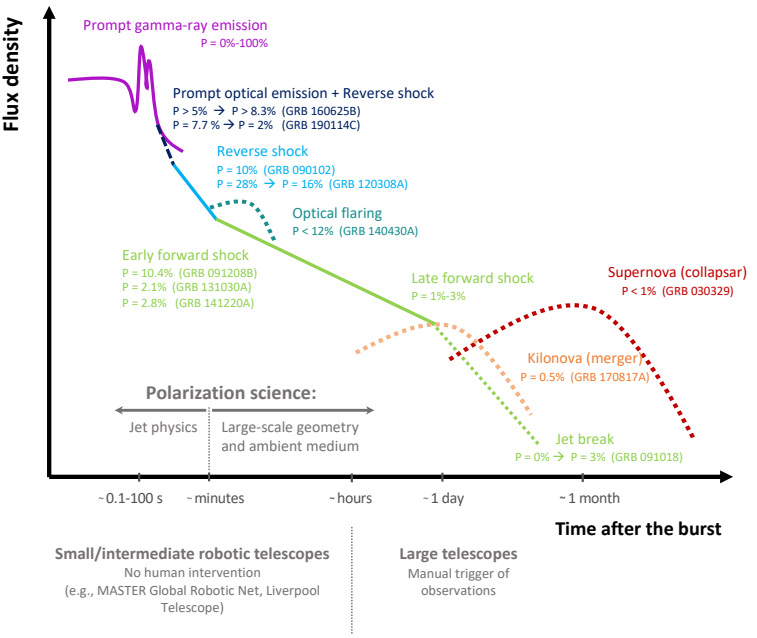

Fig. 3. Schematic representation of the different types of GRB emission and relevant polarization measurements. Note that, with the exception of the prompt gamma-ray emission, the represented "canonical" light curve refers to optical wavelengths. *References:* GRB 030329[63] GRB 090102,[2] GRB 091018,[64] GRB 091208B,[7] GRB 120308A,[1] GRB 131030A,[65] GRB 140430A,[66] GRB 141220A[6] GRB 160625B,[4] GRB 170817A,[67] GRB 190114C,[5] late-time forward shocks[68] and the AstroSat CZT/POLAR gamma-ray polarization catalogues.[52,59]

in between gamma-ray pulses of GRB 160625B[4] was interpreted as reverse shock and presented a significant increase from $P > 5.2\% \pm 0.6\%$ to $P > 8.3\% \pm 0.5\%$ simultaneous to a gamma-ray pulse —implying that polarized prompt emission photons contributed at optical wavelengths. The polarization lower limits were quite low through observations, which led to speculations regarding distorting mechanisms during the prompt gamma-ray emission, such as reconnection.[25,51]

2.1.3. *The highly magnetized jet of GRB 190114C*

Both MASTER II from the Master Global robotic net and RINGO3 instrument from the Liverpool Telescope observed GRB 190114C, the first GRB detected at very high energies (in the TeV domain[76]). Interestingly, the afterglow emission decay rate presented a steep to shallow transition, which suggested reverse shock contribution.[5] Our observations report remarkably low polarization just after the end of the gamma-ray flash ($P = 7.7\%$), a sharp drop of polarization one minute later ($P = 2\%$) and constant levels during the following half an hour. In Ref. 5, we suggest that the $P \approx 2\%$ constant polarization is due to differential dust absorption

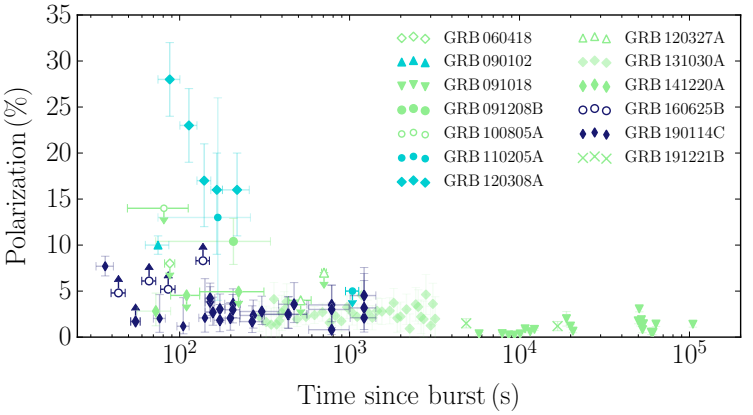

Fig. 4. Rest-frame polarization measurements of GRBs at optical bands —adapted from Ref. 1. Overall, the polarization dependency with time indicates that the regime in which we can infer the jet physics corresponds to observations before ~ 5 min postburst. In contrast, the polarization at later times gives information about the jet geometry and dust. *References:* GRB 060418,[74] GRB 090102,[2] GRB 091018,[64] GRB 091208B,[7] GRB 110205A,[3] GRB 100805A,[3] GRB 120308A,[1] GRB 120327A,[3] GRB 131030A,[65] GRB 141220A,[6] GRB 160625B,[4] GRB 190114C,[5] and GRB 191221B.[75]

in the line of sight —mainly due to the highly obscured environment in which the GRB was formed— which means that the intrinsic polarization of the jet is very small for reverse shock emission. Our low optical polarization measurements are also consistent with $P = 0.87\% \pm 0.13\%$ measured 2.2 h later at millimetre frequencies, during the reverse shock emission.[77]

The temporal and spectral modelling of GRB 190114C emission indicates a clear interplay between the reverse and forward shock and more magnetization in the reverse shock, which suggests the existence of a primordial large-scale magnetic field ejected from the rotating black hole. However, GRB 190114C polarimetric observations reveal that the magnetic field in the ejecta was mostly random oriented in space, which does not agree with what we expect from previous measurements of reverse shocks[1,2] (see Fig. 4).

In Ref. 5, we propose that the polarization was low because the large-scale magnetic field catastrophically collapsed during the first tens of seconds of the gamma-ray flash via magnetic reconnection mechanisms and that the $P = 7.7\%$ measurement is a relic from this emission.[25,51] As opposed to previous polarization measurements,[1,2] these findings suggest that at least some energetic GRBs can be launched highly magnetized and that magnetic dissipation mechanisms can power a bright gamma-ray prompt. Additionally, it opens a debate about the nature of the bright early-time steep emission, which could be a reconnection tail instead of a reverse shock. That is because the reverse shock emission could have been suppressed if, at the deceleration radius, the outflow was still in the highly magnetized regime.[42]

These results pin down timescales and distances for which large-scale magnetic fields survive in astrophysical jets and challenge the current models for the production of GRBs.

2.2. *The polarization from collisionless shocks*

Polarimetric studies of the late afterglow have measured low degrees of polarization at optical wavelengths during the decay of the long-lived forward shock[68] and have provided information on the angular structure of jets[43] and the dust properties of GRB host galaxies[78] (see Fig. 4). Additionally, these polarization levels agree with theoretical predictions and suggest that forward shocks are intrinsically unpolarized due to tangled magnetic fields locally generated in shocks.[37]

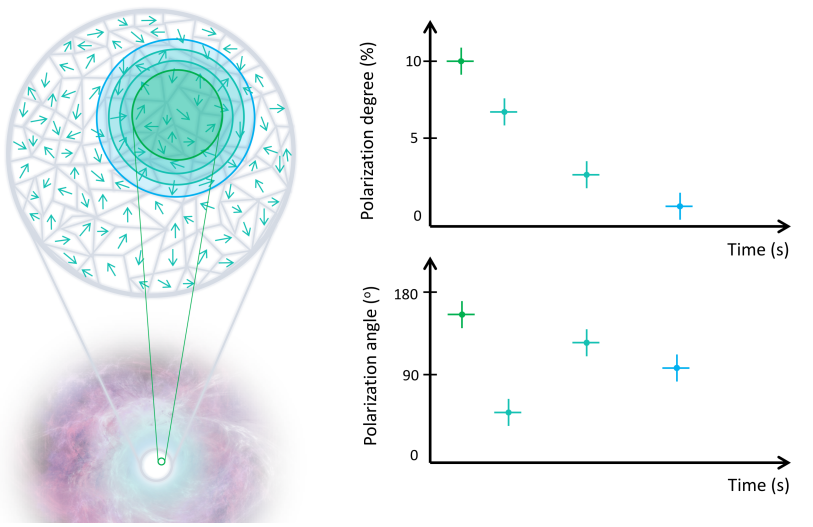

Fig. 5. Schematic representation of the evolution of the polarization degree and angle in the patches model.[79]

However, Ref. 7 observations set a debate on the intrinsic polarization of forward shocks at early times given the detection of significant polarization in the GRB 091208B forward shock ($P = 10.4\% \pm 2.5\%$), which favoured the patches model.[79] Phenomenologically, the patches model implies that as the outflow decelerates and the visible emitting region increases, more patches with coherent magnetic fields (i.e., highly polarized; $P \approx 50\%$) are visible. As the orientation of the magnetic field is random from one domain to another, the overall observed polarization decreases with time (see Fig. 5). Consequently, GRB 091208B measurement still agrees with the $P \approx 1\% - 3\%$ polarization found in late-time forward shocks. Physically, the patches model proposes that the amplification mechanism of the magnetic field at the shock front —needed to increase the magnetic energy density from interstellar

to the observed levels— leads to the formation of large magnetic domains (i.e. large coherent length scales for the magnetic field).

The GRB 091208B measurement gives rise to new possible mechanisms for magnetic field amplification, as well as adding a problematic degeneracy in early-time polarimetric studies. Note that the GRB 091208B polarization level is comparable to that measured in the reverse shock of GRB 090102.[2] If forward shocks are polarized at early times, it becomes difficult to disentangle the possible polarized components that probe the jet physics from the contribution of the shocked ambient material. Consequently, a good understanding of the typical polarization levels of early-time forward shocks is crucial.

2.2.1. *The polarization of the early-time classical forward shock of GRB 141220A*

In Ref. 6, we report the early-time observations of GRB 141220A forward shock. Interestingly, this afterglow presented temporal and spectral properties typical of late-time forward shocks but starting as soon as 1.4 min postburst. Furthermore, our polarimetric observations at 2.2-3.4 min postburst are earlier than GRB 091208B measurement (2.5-11.8 min), which allow us to probe smaller emitting regions. If the length scale of the magnetic field was the same as in GRB 091208B, we would expect $P = 20\%$ polarization for GRB 141220A at the time of observations (as predicted by the patches model; see Fig 5). Instead, we measure $P = 2.8^{+2.0}_{-1.6}\,\%$ in GRB 141220A, which we find is compatible with that induced by dust in the GRB environment and agrees with theoretical predictions of unpolarized forward shocks,[37,80] i.e. $P_{\rm th} = 0\% - 2\%$ (but see Refs. 81, 82).

The GRB 141220A and current early-time forward shock polarization measurements suggest that GRB 091208B is an outlier (see Fig. 4). We speculate that GRB 091208B scenario could be similar to the reverse-forward shock interplay in GRB 120308A.[1] As the polarization measurement was integrated over a large time window, we suggest the presence of a more stable underlying polarized component and ordered large-scale magnetic fields in the fireball.

3. Outlook

After 15 years of progress in early-time polarization studies of GRBs afterglows, we can confidently confirm the presence of large-scale ordered magnetic fields in a subset of bright afterglows, suggesting that the magnetic field ejected from the central source does play a role in the jet launching. In general, we have not measured the maximum polarization allowed by theory in reverse shocks ($P = 50\%$) and polarization observations indicate that highly polarized emission at $P = 28\%$ level is not that common (GRB 120308A;[1] see Fig. 4). Therefore, mechanisms that can change the magnetic field topology might play an important role at the early stages of GRB jets.

Observations of reverse shocks remain rare,[73] and a way to overcome the lack of reverse shocks in the optical is to look at millimetre and radio wavelengths. The predictions are that, if the forward shock peaks at optical bands, the reverse shock will peak at $1 - 100\,\mathrm{GHz}$ bands and $\sim 0.01 - 0.1\,\mathrm{days}$ postburst with fluxes of $0.01 - 0.1\,\mathrm{mJy}$.[83] However, if the magnetization is high at the external shock radius, the reverse shock would be suppressed.[42] The lack of reverse shocks at optical and radio wavelengths would indirectly imply that jets are still highly magnetized at large distances from the central source. Consequently, the rate and the polarization of reverse shocks at optical[1–5] and lower frequencies[77] can greatly constrain the magnetization of GRB jets and further test the mildly and highly magnetized jet regimes.

Great advancement will be made on constraining GRB jet models with a faster target acquisition and the increase of the polarimeters' sensitivity.[84] This will allow gathering a large polarimetric dataset of measurements at early times, sampling most of the GRB population at lower luminosities. Furthermore, other TeV GRBs have been discovered[85–88] —something we did not expect before the Cherenkov Telescope Array (CTA). With the start of the CTA era, we will be able to track the earliest stages of the magnetic field and its evolution in the most energetic systems. Consequently, we will need new polarization technology to optimize CTA follow-up as well as other multimessenger triggers from gravitational waves and possibly neutrinos.

We present MASTER Global Robotic Net (Lipunov et al. 2010) earliest optical alert observations of IceCube-170922A error box. We discovered fast variability of blazar TXS 0506+056 27 sec after notice time (73s after the trigger time) at 2017-09-22 20:55:43 UT by MASTER-Tavrida robotic telescope. MASTER found the blazar TXS 0506+056 to be in the off-state after one minute and then switched to the on-state no later than two hours after the event. The effect is observed at a 50-sigma significance level. We also analysed own unique 16-years light curve of blazar TXS 0506+056 (518 data set).

Keywords: Gamma-ray burst

1. Introduction

High energy cosmic neutrinos sources are still mysterious. MASTER Global Robotic Net (Lipunov et al. 2010)[19] starts Ice Cube alert and follow up observations a few

years ago. On 22 September 2017 the robotic telescope of the MASTER global network automatically imaged the error box of the high-energy neutrino event IceCube-170922A (Kopper et al. 2017). Observations were carried out 27 seconds after receiving the alert, i.e., 73 seconds after the IceCube-170922A neutrino event was detected by the IceCube observatory at the South Pole (Lipunov et al. 2018a).[23] Observations started at 84 degree zenith distance (MASTER has fully opened roof as alert telescope).

We calibrated these images using the Gaia (Brown et al. 2018) catalog as the source of reference stars, and found the BL Lacertae type blazar TXS 0506+056 (IceCube et al. 2017) to be in the off-state after one minute and then switched to the on-state no later than two hours after the event. The effect is observed at *delta* m =0.790+-0.016 (a 50-*sigma* significance level).[27]

IceCube registered events with error regions, whose sizes are currently comparable to one square degree. Therefore finding a blazar within the error box of a VHE neutrino event cannot be considered sufficient to prove that blazars are actually progenitors of these particles. Detecting some non-standard event from the supposed source at a time close to the neutrino event is required. For example, a blazar emitting gamma and cosmic rays and showing a sharp flux variation near the neutrino detection time would provide compelling evidence of the association of the neutrino event with a known astrophysical object. The first candidate object for an astrophysical neutrino event was the blazar TXS 0506+056 (IceCube et al. 2017)[14,15] found inside the error box of the IceCube-170922A neutrino event. This blazar turned out to be located at a distance of $\tilde{3}$.7 billion light years (its redshift is z = 0.3365+/- 0.0010) (Paiano et al. 2018).[29]

TXS 0506+056 blazar was registered in the gamma-ray active state several months before the neutrino event. Detection of high-energy particles (175Gev) began one week after, and the optical, x-ray, and gamma-ray emission was observed with low temporal resolution and showed no appreciable variations near the detection time . Therefore although when combining the available data suggested that TXS 0506+056 was a very promising high energy neutrino source optical candidate, the temporal resolution of multi-messenger data did not provide conclusive evidence at the time and the object remained just a likely, but still debatable, candidate. In this letter we report conclusive detection of light variation of the blazar TXS 0506+056 just several minutes after the neutrino event, which ended no later than after two hours. For comparison, nearest ASAS-SN, Kiso/KWFC and Kanata/HONIR optical observations do not show the same decrease in optical brightness (because they started 18 hours after MASTER observations when effect disappeared. Although the blazar was in the gamma-ray active state, this state started several months before the neutrino event. Detection of high-energy particles (175Gev) began one week after, and the optical, x-ray, and gamma-ray emission was observed with low temporal resolution and showed no appreciable variations near the detection time. Therefore although when combining the available data suggested that TXS 0506+056 was a

very promising high energy neutrino source optical candidate, the temporal resolution of multi-messenger data did not provide conclusive evidence at the time and the object remained just a likely, but still debatable, candidate . In this letter we report conclusive detection of light variation of the blazar TXS 0506+056 just several minutes after the neutrino event, which ended no later than after two hours. For comparison, nearest ASAS-SN, Kiso/KWFC and Kanata/HONIR optical observations do not show the same decrease in optical brightness (because they started 18 hours after MASTER observations when effect disappeared.

2. MASTER alert optical observations of IceCube-170922A error box

MASTER Global Robotic Net, as the leader of early gamma-ray burst observations (Troja et al. 2017; Ershova et al. 2020, Lipunov et al. 2016, Lipunov et al. 2017, Gorbvoskoy et al. 2016)[10, 11, 18, 20, 21, 32] has an almost 20-year long experience with real-time rapid pointings to GRB alerts within the first minute of the alert . In 2015 MASTER started actively participation in the program of fast optical support of major physical and astrophysical experiments, such as detection of very high energy neutrinos (ANTARES (Dornic et al. 2015;[9] Gress et al. 2019[12]), IceCube (Aartsen et al. 2017)[1] , Baksan (Lipunov et al. 2019a),[25] gravitational waves (LIGO/VIRGO collaboration (Abbott et al. 2016),[2] and Fast Radio Bursts (FRB (Lipunov et al. 2018b)[24]). The favorable arrangement of MASTER sites makes it possible to inspect all gravitational-wave error boxes. MASTER made the crucial contribution to the optical support of the first gravitational-wave event GW 150914 by inspecting the most part of the error box (Abbott et al. 2016, Lipunov et al. 2017).[3, 21] On 17 August 2017 MASTER, together with 5 other telescopes, performed the first ever optical localization of a gravitational-wave source independently discovered Kilonova from GW 170817 (Abbot et al. 2017, Lipunov et al. 2017).[3, 22]

At the 22nd of September, 2017, MASTER received an alert from IceCube event and MASTER-Tavrida telescope acquired the first three images, starting from 2017-09-22 20:55:43UT 27 sec after notice time (i.e.73s after the trigger time). The field of view of the MASTER telescope has a size of four square degrees (Lipunov et al. 2010)[19] and fully covers the final field of view of IceCube (Lipunov et al. 2020[27]).

MASTER limiting magnitude was 19.0m at 180-second frames, despite the large zenith distance (84 degrees). Hence the TXS 0506+056 blazar at the time of the alert was a 15.12 +- 0.01 magnitude object in all three frames acquired over $\tilde{1}5$ minutes (the light curve is shown in Fig. 2). There was the faintest blazar brightness over the full period of this alert. After 2 hours, at 2017-09-22 23:11:36 UT, the flux from the blazar increased in brightness by a factor of two and reached 14.33m+-0.01m. We emphasize that here in the text we give the averaged values for the triples of frames in the first minutes and after two hours (compare[27]). Hence our observations show at an extremely high confidence level of 50 sigma that within several minutes of the neutrino event, the blazar was in an anomalously extinguished state. This conclusion

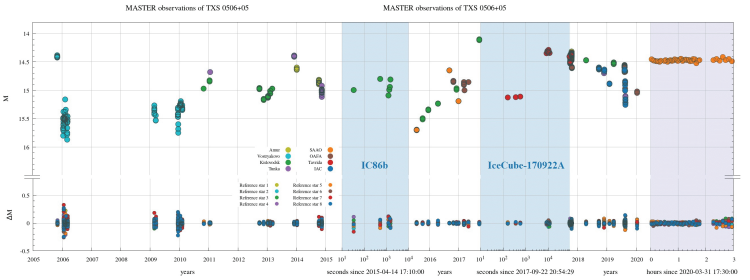

Fig. 1. MASTER light curve of the TXS 0506+056 blazar for the 16 years. Archive light curve of the TXS 0506+056 blazar based on observations made by MASTER Global Net robotic telescope of from 2005 until now (red point). Below we see the photometry of 8 reference stars, to the pink and blue panels represent three very narrow episodes in time. The first of these is April 2015 when IceCube IC86b saw a 3.5 sigma excess of the neutrino flux over the background (IceCube 2017) . The second is the 22 September 2017 event (IceCube 2017). Logarithmic time is shown in seconds from the neutrino trigger. It is easy to easily see the rapid change in the luminosity of the blazar in $\widetilde{2}$ times. Finally, the third episode is a uniform blazar monitoring timeline in the first quarter of 2020. With these new observations, the total number of observations submitted reached 518 (See the photometry table)[27]

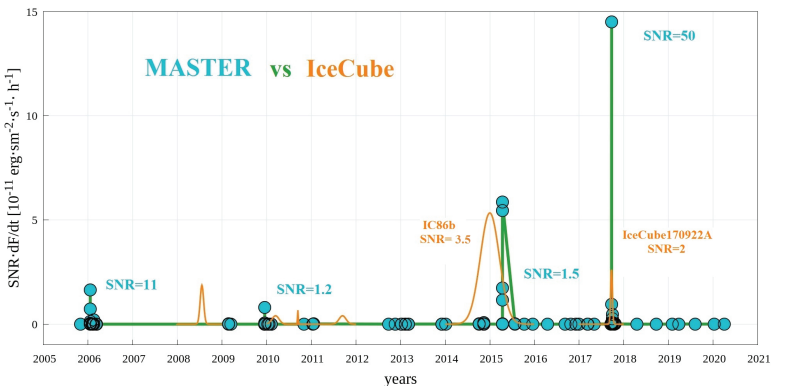

Fig. 2. MASTER optical variability rate history for blazar TXS0506+056. Flux deriviation the multiplied by the signal-to-noise ratio (blue). The orange curves schematically show the Gaussian analysis of the archive data of IceCube.[27]

was fully confirmed during the two days after the alert, when the MASTER-SAAO robotic telescope joined the blazar observation campaign (Lipunov et al. 2018)[23, 24]

To undestand, was it a unique event for the TXS 0506+056 blazar or no, we analysed 518 2x2 square-degrees images in MASTER Global Robotic Net database, starting from 2005, when we had only one MASTER I telescope located near Moscow (Lipunov et al. 2010,[19] MASTERVostryakovo).[27] All MASTER telescopes has identical equipment, that gives us possibility to make photometry in one system (Lipunov et al. 2010, 2019b).[19, 26]

Fig. 1 shows our photometry of the blazar over the last 16 years. We chose 8 Gaia catalog stars, having the brightness and color similar to those of the blazar, as photometric reference stars, and estimated the errors of individual photometric measurements from the scatter of the magnitudes of these reference stars. We also checked these stars for rapid and long-term variability and found them to be quite stable. We found three times when the brightness of the blazar varied $\tilde{0}$.5m more than 1-3 significance level. The first such time was in 2006, when IceCube neutrino observatory was not yet operating. The second time was in April 2015 (substantial increase of neutrino signal IC86b). The MASTER observation date is in April but statistically close to Gaussian IceCube half year window 9/2014 to 3/2015. And the third time was in September 2017, when the IceCube-170922 (IC86C) event occurred.[27]

The event of September 22, 2017 has outstanding characteristics in terms of flux derivation and signalto- noise ratio. Recently, we conducted detailed blazar monitoring over several nights at the right end of Fig. 2. As we see in the usual state, the blazar is stable at times of several hours and even days with an accuracy of $\tilde{0}$.02 mag. This means that the instability we discovered on 22 September 2017, a few minutes after the neutrino alert, has a reliability of 50 sigma by this criterion(Fig. 2). This result shows the power of fast alert observations of sources of ultrahigh energy particles.

The event of September 22, 2017 has outstanding characteristics in terms of flux derivation and signal-to- noise ratio. Recently, we conducted detailed blazar monitoring over several nights. In the usual state, the blazar is stable at times of several hours and even days with an accuracy of $\tilde{0}$.02 mag. This means that the instability we discovered on 22 September 2017, a few minutes after the neutrino alert, has a reliability of about 40 sigma, and by this criterion. This result shows the power of fast alert observations of sources of ultrahigh energy particles.

3. Discussion

We find for the adopted set of Hubble cosmological parameters (Planck Collaboration et al. 2016)[4] H0 = 67.8 km/s/Mpc (the Hubble constant), $Omega_m = 0.308$, $\Omega_\Lambda = 0.692$ (the matter and vacuum density) that several minutes after the neutrino event the optical isotropic luminosity of the blazar was L_{opt} $4.3{*}10^{45}$ erg/s and after two hours it returned to the typical level within several weeks of the neutrino event, $9.7 * 10^{45}$ erg/s (we include galactic absorbtion AB=0.4 (Schlegel et al. 1998)[31]). The generally accepted picture (Schlegel et al. 1998)[31] is that blazar radiation arises from relativistic jet directed toward us. The boosted jet gamma factor is moderate Γ 10. In the shock wave at the front of the jet there is an acceleration of protons to ultrahigh energies, which in turn collide with target photons and generate pion production. The decay of pions, in turn, gives rise to a muon neutrino which registers an IceCube detection and high gamma photons detected by the Fermi gamma-ray observatory.

During the period within $\tilde{2}$ weeks around the neutrino event detection time the 0.1 – 100 Gev gamma-ray luminosity was $1.3 * 10^{47}$ erg/s (IceCube et al 2017). Note that the neutrino luminosity of the quasar was equal to about $4 * 10^{47}$ erg/s, which is appreciably higher and, evidently, closer to the gamma-ray luminosity. However, this is not surprising because neutrinos and gamma-ray emission have the same source of energy — that of high-energy protons accelerated by the central supermassive black hole.

The event that we discovered, namely the decrease of the brightness of the TXS 0506+056 blazar near the neutrino detection time, provides complementary and very compelling evidence for the link between the blazar and the IceCube-170922 neutrino event. We analyzed archival data (MASTER unique 518 photometry data for 16 years), which we found to be consistent with this fact. We also propose a hypothesis explaining the anti correlation of the optical and neutrino flux. An increase in neutrino flux means that up to half of the protons disappear. If we assume that these protons produce synchrotron optical radiation, then any increase in neutrino luminosity will lead to a decrease in the optical brightness of the blazar.

MASTER and Lomonosov Space Observatory are supported by Lomonosov Moscow State University Development program (equipment). VL, PB are supported by RFBR grant 19-29-11011. NB is supported by FZZE-2020-0017).

In this proceedings contribution we summarize a series of results on nonlinear perturbation theory for modified gravity models, in which a scalar field changes the gravitational dynamics at cosmic scales. We discuss its effects on large scale structure, focusing on screenings and the power spectrum of matter fields and tracers. We also discuss a redshift space distortions model for modified gravity and the departures from the LCDM model.

Keywords: Perturbation theory; modified gravity.

1. Introduction

In recent years we have witnessed important developments on the understanding of large scale structure (LSS) formation. The experimental confirmation of baryon acoustic oscillation (BAO) feature and measurements of redshift space distortions (RSD) have boosted the search for an increasing accuracy in the determination of the cosmological parameters from the LSS side, apart from those of the cosmic microwave background (CMB) measurements, and other probes.

On the other hand, there is a growing interest to test gravity at cosmological scales. One the one hand, because we do not really know the origin of dark energy (being this a constant or a field), so it can be due to some modified gravity (MG). On the other hand, because the level of understanding of the LSS phenomena mentioned in the previous paragraph opens the possibility to test gravity at cosmic scales at high precision. Due to these facts, a natural interest arose to develop perturbation theory (PT) for MG models. At the same time, MG simulations have been carried out, see for example Cautun et al.[1] Both PT theory and simulations allow us to understand the role that gravity plays to form structure.

Nonlinear PT for LSS in MG models have been developed in the last decade or so, beginning with approach proposed by Koyama et al[2] for standard perturbation theory (SPT) to one-loop. Later, we and other collaborators developed the
